Warm poultices and hot fomentations should now be prescribed to the end of exciting local action; the diet improved by increasing the quantity of the food, even to the allowance of a moderate quantity of wine or porter; even exercise may be permitted. The surface becomes soft; careful pressure of the finger will determine the first formation of matter by fluctuation; and the day and almost the hour is to be fixed as the crisis of the abscess, which should then be opened with a moderately free incision, not merely that of a puncture, but something more. It is very important to select this critical period, where time is an object: and all I can tell you on the subject is that the abscess should be tumid, and of a bright red colour over the whole of the projecting surface.

In this condition an abscess will often exhaust its own powers without bursting; the bright red colour will be gradually converted into the purple of venous congestion, and the cuticle will desquamate. In this neglected condition of the abscess, the surface next the skin will be too greatly reduced by ulcerative absorption, and too far disorganized by the protracted inflammation, ever to regain its natural structure, and it will either slough or ulcerate. In either case new substance must be formed, and hence loss of time to the patient. If the lancet be plunged into the mass too early, before the inflammation of the skin marks the crisis of the suppurative action, matter will be discharged undoubtedly, but not in quantity proportionate to that action. The action itself is not exhausted, and the wound will heal; or if not, the sac will continue to discharge for many days or weeks; and hence again loss of time*. These observations will apply to all forms of phlegmonous abscess, whether acute or chronic. If the medium time be selected, the abscess will heal in the course of a few days; if the early date, probably a fortnight or more may be required; if the late, the abscess will degenerate into an ulcer, for the healing of which a month or six weeks may not suffice.

These chronic forms of ulcer in the groin are most generally met with in hospital patients of low unhealthy circulation, from depraved habits. We find a flap of morbid integuments overlapping the ulcer, discoloured by long inflammation, and

* As I have said elsewhere, the only excuse for opening an abscess before it is *ripe*, is to diminish pain and its effects on the constitution, in promoting irritative fever.

forming a cavity in which the secretion of the surface gravitates; a form of ulcer that would without surgical aid probably remain for many weeks without making the slightest approach towards cicatrization. This morbid integument must be immediately removed or destroyed with caustic; and for the same reason in opening a phlegmonous abscess such as I have before mentioned, which becomes chronic before it bursts, the incision should be made in a direction to divide the largest number of its vessels, and if circular a crucial incision is preferable.

When the integuments are removed whether by nature or art, the sore may be filled with the flue of dry lint, and changed each morning, or night and morning according to the quantity of the secretion; and at the same time half a grain to a grain of opium may be given internally night and morning; under which treatment the sore will heal with a degree of rapidity, not a little astonishing to those who are unaware of the remarkable influence of opium in rousing healthy actions; and to the value of which suggestions I have received too high and too general testimony from my fellow-practitioners, to warrant any hesitation in strongly recommending it for your adoption.

Opium, says Mr. Hunter, "is a medicine capable not only of relieving pain, but of altering diseased actions, and producing healthy ones; for the future it will be given with another view than that it has commonly been, not merely to allay pain, but to cure diseases."

OBSERVATIONS

ON

COMPLICATED SURGICAL INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with the Auxiliary Forces in Portugal and Spain.

(As delivered in his Lectures at Sydenham College School of Medicine.)

[Continued from p. 369.]

II.—INJURIES OF THE HEAD.—ON THE ELEMENTARY FORMS OF INJURY AND THE CLASSIFICATION OF THEIR EFFECTS.

Various kinds of Injury.—Cause of the complicated nature of their signs.—True mode of studying the pathology of the Brain.—Necessity of carefully avoiding the deduction of general laws from inadequate data.—Classifi-

cation of Injuries of the Brain: 1. Concussion; 2. Compression; 3. Lesion; 4. Ramollissement.—Necessity of determining their symptoms singly, and then in various combinations.—System of investigation in such cases.—Analysis of the causes of stertorous breathing—not a sign of any particular form of injury or compression.—Progress of the case.—Post-mortem.—Important points for observation.—Difficulty of establishing general diagnostic laws in these injuries.—Observations on the various kinds of morbid impressions on the brain.—Arrangement of cerebral organs and structure.—Remarks on general effects of cerebral injuries.

SOME observations have already been made in a preceding lecture on fractures of the head, considered merely as a form of injury to the bones of the skull, with contusion or laceration of the external soft parts. I have now to call your attention to their most important feature—the accompanying or consequent injury on the parts contained, and first of the brain.

Observing this dense shell or case of triple layers, the skull, it is evident that no fracture can take place without considerable violence. And, if in addition to its texture we consider its vaulted form presenting an arch in every direction, we shall obtain the strongest conviction that no fracture can take place without certain effects on the organ it envelopes—among the chief of which is *Concussion*; and, further, that the brain must be liable to this effect, even to a violent degree, from blows which do not fracture the skull—from falls upon the other extremity of the spine whence would be communicated a vibratory shock or jar of the most injurious character.

But a blow on the head, with or without fracture of the bones, is capable of producing other effects on the brain and membranes than concussion—lesion of the medullary matter, rupture of blood-vessels, effusion of blood in the substance of the brain, or between the organ and its membranes, softening degeneration of the fibre—and in considering these injuries it is of some importance to be able to distinguish the nature and extent of these effects by certain symptoms or diagnostic signs.

To concussion—to compression by extravasation of fluid, another injury or complication may be superadded—the lodgement of a foreign body, as a musket-ball, within the skull; or the

bones themselves may be bent down with violence so as to project inwards on the brain, producing either lesion or violent compression, or both.

All or any of these injuries are capable of inducing inflammation in the brain or its membranes, going through all the stages from increased action to sloughing—another form, another consequence of injury.

The brain, as the organ by which the powers of the mind are manifested, as the grand organ and centre of volition and sensation, cannot be injured without some degree of disturbance of its various and complex functions. By an influence more or less direct follows lesion of the functions of all the important organs of the body: hence of all the accidents to which the human frame is liable, none are of more serious import to the life and intelligence of the patient, none offer such complicated signs or symptoms of the injury inflicted. Anatomists, physiologists, surgeons, have all since the revival of letters, anxiously sought to trace each symptom to its cause, and make it the indication of a particular and specific effect; and all have signally failed in thus establishing the diagnostic signs of the various forms of injury inflicted on the brain and its membranes.

The manifestations of intellect disturbed by violence offer the most confused and uncertain guides, indicating, in truth, little beyond the existence of disturbance of which information may be obtained from other and physical signs. The sympathetic disturbance in all the important functions of the body—in respiration, the circulation of the blood, deglutition, the action of the liver and bowels—unless most carefully studied and classed, present the most variable and uncertain indication of the exact nature of the action or extent of the injury at any moment existing within the cavity of the skull.

The little certain knowledge, the few distinct guides to a correct diagnosis, which past labours have discovered, I propose to bring before you. And in detailing the result of my own observation on these injuries, I will endeavour, as far as possible, to unravel the complication of symptoms and effects which strike the observer while studying the nature and treatment of such cases at the bed-side. To attempt this with any fair prospect

of success, I must beg your attention for a short time while I endeavour to define clearly the elementary forms of injury, the best mode of studying them, and the chief objects to be kept steadily in view.

The true mode of studying the pathology of the brain, it seemed to me when I first began my observations on its diseases and injuries, was first carefully to define all the elementary forms; then the complications superadded; and lastly, to note the symptoms of a number of parallel cases, and, in the event of death, minutely examine the alterations in structure, and so attach to the effects already observed the physical causes, whenever the links of the chain could be traced. Imperfect as even this must seem, it offered to my mind better prospects of a positive advance in our knowledge of causes and effects, as regarded injuries of the head, than any other means; for disease far more perfectly and beautifully illustrates the physiology and anatomy of organs than any experiments, however well devised. In a long continued series of observations, conducted with a view to improve our diagnostic powers and means of treatment, having the complete control and direction of large hospitals for several years, where injuries of the head were frequently admitted—sometimes fifteen or twenty on the same day—all apparently similar injuries, were placed side by side in parallel beds. Every succeeding day the opportunity was thus afforded of comparing at a glance the symptoms and appearances of each. From a careful record of a large number of these cases, I have endeavoured to draw some useful conclusions.

Keeping in view the complicated nature of the subject, I determined that many parallel cases would be necessary in order to form any safe conclusion. I therefore carefully avoided drawing deductions, thus to leave my mind unbiassed for the observation of facts, until notes had been made of a sufficient number. I did not begin to form any of the conclusions of which some account will shortly be given, until I had carefully observed and noted fifty cases of severe injuries to head and spine, giving rise to marked effects and symptoms. I thus felt entire confidence in the unbiassed accuracy of my facts, and felt entitled implicitly to rely upon

them, whatever the inferences to which they might give rise. I mention this, that the facts at least may be as implicitly relied upon by others, however the conclusions may be esteemed, which may or may not be strictly logical and warranted deductions. They have been made from a careful consideration of the large group of injuries and symptoms which a great number of cases furnish. In support of each conclusion I will select one or more of a set of parallel cases as the ground upon which it is established.

To pursue any inquiry with the best guarantees for a successful result, order and method in the steps taken, and a defined object, are essential. I was thus early led to form, for my own guidance, the following classification of injuries, by which an abstract was obtained of the chief objects to be kept in view, and the true end to be attained. As it is now given, some modification, and I think improvements, have been carried into it. Originally more complicated, it is now reduced to four elementary forms, the first of which is the giant power occasionally giving birth to all the others.

By thus classifying and carefully defining all the objects of the inquiry, the attention and powers of the mind are concentrated and directed in a single channel, by which men are always better enabled to avoid diffuseness and a desultory mode of investigation, that can lead to no great or useful result.

Injuries of Brain—Elementary Forms.

1. *Concussion*.—(Any vibratory shock or jar, whether produced by direct violence to the head, or indirectly through any other part of the frame.) These lesions are various, and give rise to numerous and very different effects. There may be loss of consciousness, volition, sensation, and motion—disturbance of the organic system and functions—destruction of one or many functions without perceptible change of structure in cerebral fibre—softening—disorganization—lesion—extravasation—effusion—inflammation of brain or its membranes—ulceration—partial gangrene—compression on weakened fibre by fluid *within* the vessels—permanent irritability or weakness of cerebral fibre.

2. *Compression* arises from many and

very different causes; whatever the causes, certain effects may be classed as its consequences—viz. disturbed consciousness, sensation, and motion—disturbance of organic and excito-motory systems and their functions. Inflammation of the brain or its membranes—ulceration—gangrene.

3. *Lesion* of cerebral structure can never be simple, but must be complicated either by some disease producing that effect by extravasation, ulceration, &c. or by *concussion*, or the passage of a foreign body, and is co-existent with all these forms.

4. *Ramollissement* may either arise spontaneously, without other perceptible action or disease, or it may follow violence to the head, as the sole perceptible effect. It may also be a result of concussion, inflammation, &c.

Three of these elementary forms may exist separately, or all four may be variously combined as the consequences of each other; very frequently the three latter are observed as effects and products of the first. The great object of the surgical pathologist is to determine which of these forms of injury exist; whether simple or complicated by some combination, and in what that complication consists. To gain such power of diagnosis, it is necessary to determine what are the symptoms of concussion solely, beginning with its mildest form and ending with the gravest.

To determine, in like manner, the symptoms of each of the other elementary forms of injury, and the usual character and order of their effects, forms a next and equally necessary step. Then, and not until then, can we hope to investigate with any good result—what modification of appearances, effects, and symptoms, the supervention of one elementary form on the other produces—what the signs are indicating the various degrees of complication or combination of the elementary forms.

This investigation I soon found could only be productive of any satisfactory or useful fruit by following a well-devised system, which should ensure, in all cases, accurate and pointed observation on every feature of the injuries and their consequences. In order to obtain power of correct diagnosis, you will find it essential to do so.

In all notes of such cases let me recommend the following form or skeleton frame for observations and inquiries:—

INJURIES OF THE HEAD.

No.

NAME. Age. Temperament.

PREVIOUS HEALTH. Occupation.

PRESENT STATE. Mode of Accident.

Nature, site, and degree of Injury.

(These points should be defined with the utmost possible precision and accuracy.)

ANIMAL LIFE OR CEREBRAL SYSTEM.

Consciousness ; Perception ; Volition.

(The degree and kind of disturbance, if any.)

Sensation. (Cerebral sensation is evinced by volition—by voluntary motion ; but as there is motion from impressions or sensations conveyed to the spine as a centre or axis, it is necessary to distinguish these two sources of motion, and not confound them, inasmuch as there may be total abolition of cerebral sensation, with a perfect development of the functions of the spine, or true spinal system, as it has been termed. Our modes of judging of cerebral sensation may be referred, 1st, to the iris, which, by its contractility, may imply unimpaired sensation, or, by its immovable dilation, the reverse ; 2dly, the sensibility of the skin, the manifestations of pain. If there be consciousness of this, there may be impaired cerebral sensation, but not abolition of it. As far as possible, the kind, degree, and locality of its evidences, should be defined.)

Volition and Motion. (Separated from spinal impressions and reflex motions, which may take place without the intervention of the cerebrum. The degree remaining, and the different parts affected or paralysed, should be defined. Temperature of those parts compared and noted. Voluntary motion is frequently spontaneous ; thus we may often decide whether any which takes place is to be referred to the excito-motory or the cerebral system.)

ORGANIC LIFE.—GANGLIONIC OR NUTRIENT AND SECRETORY SYSTEM, AND THE EXCITO-MOTORY OR TRUE SPINAL SYSTEM.

Respiration. (Character and number of inspirations. Respiration, it must be remembered, is a mixed function. Sir C. Bell considered the medulla

oblongata the source and *primum mobile* of the respiratory actions. It seems, indeed, to be the nervous centre ; but the true source of the movements which, combined in the medulla, form the act of respiration, as Dr. Hall has pointed out, are certain excitor nerves, consisting chiefly of the pneumo-gastric, also of the fifth and spinal nerves. But there is still another point of great importance, viz. that the characters of the respiration, and the sounds by which we sometimes classify it, as “stertorous breathing,” &c. depend upon the apparatus of the air-tube, and the muscles, &c. at the entrance. Hence paralysis, more or less complete, of these nerves entirely alters the character, and these, in a great measure, are independent of the cerebrum. Thus, if the superior laryngeal nerves be divided in a rabbit, great distress of breathing succeeds, the aperture of the glottis is no longer held open ; and this you see, without any lesion or injury to the brain whatever. To this I must recur hereafter ; for some very erroneous conclusions have been founded upon respiratory signs in head injuries.)

Circulation. (Character and number of pulsations per minute. The action of the heart, to a certain extent independent both of the cerebral and sympathetic system, receives, nevertheless, strong impressions and influences from both. Into this question it is impossible now to enter ; but in all these cases the pulse should be frequently and carefully noted.)

Secretions. (The ganglionic is the nutrient or secretory nervous system, for the most part independent of other systems, although intimately united to the brain and spine, and not beyond the possibility of even very strong impressions from either the one or the other. It may or may not be affected by severe injuries to the brain or spine. The degree and order in which its functions are affected, afford important indications, hitherto, it has seemed to me, not well classified or understood. The secretions of the liver, bowels, and skin, are those most readily and ordinarily affected, and in that order. The state of the sphincters throughout the body are amongst the most important indications in severe injuries of the head. In a normal state the

reflex function or system presides over the orifices of the body; the nerves which convey the sensations to the medulla oblongata or spine are distributed chiefly about the larynx and pharynx; these referring to the medulla oblongata, and about the sphincters of the bladder and anus, in connection with the lower part of the spinal marrow. In fact, to this division of the nervous system is specially entrusted the regulation of the orifices and exits of the human frame. It governs the acts of ingestion, deglutition, and respiration, of excretion of the fæces, urine, and semen. The difficulty in respiration and deglutition, or the relaxed state of the sphincters at the lower part of the body, may imply the last and worst degree of cerebral injury: they may exist without any injury whatever to that organ, or that which is more likely to mislead, with an injury *which is not the source of the impaired power*. You will now see, that the stertorous breathing, and the involuntary discharge of fæces, which, in all works, you will find descriptive of the worst form of injury to brain—by some referred to lesion, by others to compression, concussion, &c.—is, in effect, the result of a relaxed state of the sphincters which regulate the orifices, producing, above, stertorous breathing, from the aperture of the glottis being no longer held open—below, involuntary discharge of fæces. You now know, also, that while, on the one hand, these actions of the true spinal system are capable of being affected or annihilated by lesion of the cerebral functions, yet they may be long unimpaired during the total abolition of the true cerebral: and without this knowledge, it is impossible that you should draw true diagnostic signs from these effects. In the same manner, paralysis of a lower limb may take place without impaired action of the sphincters. What does this indicate? That it is a cerebral paralysis, a loss of all voluntary motion—a loss, in truth, of power of volition, not of motion; but the two conjoined indicate the implication of the excito-motory system. There may be a total paralysis, either from the spine alone, preventing the communication of cerebral volition, which may exist unimpaired; or both sys-

tems may be engaged, producing the most complete form of paralysis. It is only when the excito-motory system is affected by the influence of the cerebrum upon the spine, that we have the worst features and most fatal indications. You see what different indications, as regards injury to cerebral function and structure this one effect of paralysis affords, when truly understood; and, otherwise considered, to what serious errors it might give rise in diagnosis and treatment.)

PROGRESS OF THE CASE. (The points referred to under the above heads having all been ascertained, and accurately stated. It is necessary each day, in the same order, to note the indications offered in every class, and thrice a day, if the patient's condition varies frequently. This must be continued until the death or final recovery of the patient.

It is well to underline any change or deviation from the previous report, the more certainly to fix the attention. The treatment each day, and any apparent action of the remedies employed, must of course, be recorded.

Pains should be taken in defining the injury to the functions of animal life, to ascertain, as far as possible, and record which of the intellectual faculties are affected, and to what degree. If dismissed from treatment, a careful note of his state at the period of dismissal should close the case; if death is the result, then an accurate and detailed account of the—

SECTIO CADAVERIS. (Commencing with the head, from the scalp to the surface of the brain, any appearances at the site of the wound, if one exist, and throughout the brain, either continued from above downwards, or from the base, according to circumstances, should be observed—especially deviations from healthy structure—and carefully recorded at the moment, not made up from recollection at a subsequent period; otherwise, like miscalled sketches from nature, done from memory, they may look very perfect, but are worse than useless—they are mischievous, and likely to lead to false deductions.

The chief points for observation in such a post-mortem examination are the following:—

The state of the scalp and skull, internally and externally; then of the membranes—any change from their normal appearances, injection or change of colour in dura and pia mater, opacity in arachnoid, effusion of fluid, serous, purulent, or sanious, between them.

The texture, colour, and consistence of the medullary and cortical parts of cerebrum and cerebellum, any injection or marks of inflammation, softening and disorganization, and if so, as far as possible, the degree and boundaries should be defined.

The state of the ventricles, particularly as to fluid, quantity, and character; also at the base. The tracts from whence the cerebral nerves proceed, or into which they enter, should be examined, and their examination specified. Blanks are always negatives of a very doubtful character. State of the veins and venous system generally.

The head thus scrutinized, the thoracic, abdominal, and pelvic viscera should be successively examined, and their state recorded, and any deviations from health accurately and carefully described.)

By such means alone can the study of the injuries of the head be properly conducted, and by observations thus pointedly directed alone can their pathology be more accurately known, their diagnosis improved, and redeemed from the vague and uncertain state in which it has hitherto been, or the principles of the most successful treatment fixed on a sure basis.

I shall now endeavour to deduce from the present state of our knowledge of the physiology and pathology of the brain and nervous system, with such facts and observations as I myself have gleaned, certain general laws; and, especially from these facts and observations, to trace the links connecting structures and functions, diseases or injuries, and their symptoms, and to determine how far these admit of beneficial and practical application in the more severe and complicated forms of injuries of the head.

The difficulties of such a labour are great, and peculiar to the organ in question. The nervous system is the last link in animal nature, uniting us to other and higher forms. Strictly

material and animal, on the one hand, both by its dependence on blood for nutrient matter, and by its important functions regulating the whole animal economy—distinctly immaterial (as we understand matter), and linked to a higher and more subtle form by its powers of thought and creation—by its connection with the influences of a world beyond it.

There can be little doubt that it is from the blood oxygenated that the brain as an apparatus secretes its vital and *quasi* electrical properties. We find increased circulation increases the energy or amount of nervous power; the want of circulation, or carbonated blood, prevents its generation. This leads to a strictly practical conclusion. If blood be the nutrient matter of vital or nervous energy, then must the quality and quantity of that fluid exercise a most important influence. Any injury of the brain implicating, directly or indirectly, that portion of the nervous system on which respiration depends, and impeding that action, must necessarily diminish oxygenation, and tend to produce the comatose state—to gorge the lungs; and thus, by a mutual reaction on each other, the nervous energy is diminished; on which the due performance of respiration depends, and the oxygenation of blood is less and less perfectly performed, on which the vitality of the brain and nervous power rests.

Hence, in all such cases, the necessity of promptly relieving lungs and brain of blood. It has been too frequently inculcated, that in coma from concussion you should wait for reaction. To wait for reaction in many such cases is to consign the patient to certain death, for a free reaction becomes each moment more impossible.

That there is a strictly reactive power between the blood and nervous system cannot be disputed. Let us not forget, however, that the latter draws some of its most powerful stimuli from other sources than the blood. The senses in communication with the external world, and thoughts which link us with another creation and higher and more subtle forms, carry the nervous system and its great centre, the brain, in a manner different from all other organs and parts, out of the mere boundaries of animal matter, or the human body. It has a double and intimate connection with what to us seems an immaterial world,

and its hidden influences—with the external world and its grosser impressions and impulses—with the animal frame, of which it is itself the highest form and most important part, strictly fettered to it by the necessity in which it exists for nutriment from the blood; while it is not less certainly acted upon, invigorated, diseased, or destroyed, by other and far more subtle influences and agents, some of which corrode like a slow poison, gradually diminishing its life and energies—while others sweep through the nervous centres with the blighting power and rapidity of lightning.

From these considerations naturally arises the question, what are the nature of the impressions of which the brain is susceptible? and in the endeavour to define its nature and injuries none more frequently recurs than this:—Is the fibre of the brain gifted with, or is it susceptible of, irritability? If so, may this be excited by stimulus, both mental and physical—by passion or a blow equally?

If the fibre which forms the substance of the brain, considered as a material organ, is susceptible of irritability, the question naturally suggests itself—why may not the stimulus of an injury, of thought, or of passion, each and all produce a disorganizing or decomposing action, which shall give softening and other effects as a result—not of inflammation, but of an action, *sui generis*?

Irritability is not inflammation; but it is action of a particular kind, and it may be in excess. Excessive action in all structures leads, first, to exaltation; secondly, to diminution or depression of power. Its ultimate result is weakness, disorganization, and destruction. Excessive actions all over the body meet in the death of the part. Thus, ramollissement, or softening—one of the most common effects of diseased action observed in the brain—may be accounted for, when, as is often the case, no trace of inflammation, of injury, or other disease, can be discovered. It forms, I think, an original type, and so I have classed it.

These remarks, although they all tend to some practical end or inference, carry us, however, too far into one of the widest and most interesting fields of pathological inquiry; but, as I have shown you, one too complicated in character to be entered into with advantage

in the very limited space of a lecture. The best mode of investigating the changes of structure, in connection with the diagnostic signs of the diseases and injuries to which the brain and spinal cord are liable, is a subject better calculated for a course of lectures, which, assuredly, would be inferior in interest to none within the province of medicine or surgery.

The enunciation of principles of direct application to the nature and treatment of disease, which principles are, in truth, numerous conclusions compressed into the most concentrated form, together with a few of the more obvious facts on which they are founded, is generally all that can be attempted with advantage in lectures, particularly on such a subject as this.

We will commence our consideration of the injuries of the head by *Concussion*, one of the most frequent attendants on every kind of injury to which the head is exposed, and which I have defined as the first great elementary form. But before an attempt is made to describe the particular effects, and establish the true diagnostic signs, let us inquire briefly what are the great classes of effects, generally, which result from injuries to the brain. What is the brain?

This organ, as it lies within its soft envelopes, and its bony case—the skull, you know to be composed of parts, having various offices and functions, more or less accurately known. The spinal column is formed of the motory and sensory tracts, and, between the two, of the respiratory, and is the axis or centre of the excito-motory system. The anterior of each lateral division is for motion, and proceeds in the brain from the corpus striatum. The posterior is for sensation, and forms the thalamus nervi optici. The respiratory or middle tract, being independent of the brain, ends in the medulla oblongata.

The thalamus, in which terminates the posterior sensory column of the spinal cord, forms a nucleus, round which the corpus striatum, from whence proceeds the motory anterior tract, bends; and when their layers expand in rays beyond these modulated bodies, to form the great fan into the hemispheres of the cerebrum, these rays mingle together, or interlace rather. Sir Charles Bell has happily explained this, by a familiar illustration. He says, if the wrists are placed together parallel, and closing one

hand, it is embraced by the other, the two portions of one crus are represented; thus the closed fist is the thalamus, and the overlapping hand is the corpus striatum. If, now, I extend the fingers, and interlace their points, the final distribution of the portions of the nervous matter which are devoted to sensation and volition, are represented. From the outer side of the ganglion the medullary fibres issue forth, spreading in a star or fan-like mode, until they meet the cineritious neurine or matter of the hemispherical ganglia, where their course is terminated; the cortical matter of the convolutions on the surface completing the contour of the brain. The medullary fibres throughout all present their extremities to the cineritious substance. These motory and sensory tracts, to their ultimate expansion and contact with the cineritious matter of the convolutions, are held in constant intercommunication by commissures; and not only every part of each hemisphere is thus intimately connected, but each, with the cerebellum—a kind of second and somewhat similar brain, composed alike of cortical and medullary matter—derived from the same sources; and so complete and perfect is the communication, that no one part is so isolated that its injury may not in some degree implicate the most remote: there are six transverse, two longitudinal, and one oblique commissures; all so many media of communication between each and every part of cerebrum and cerebellum, and the medullary and cortical structure of both; thus blending the whole contents of the skull into one organ, every fibre of which communicates with, and responds more or less directly to, the other.

This glance at the relative position of the ganglia, the commissures connecting them, and their relation to the ganglia and columns of the spinal cord, must lead you to the conclusion that the distinct office, the power and the function of each individual part, even were they far more accurately known than can be asserted at present, where all are provided with such complete provisions for intercommunication and mutual dependence, could never enable us to decide that thus far and no farther had injury extended, and such a point must be its exact site. Mischiefs in one may create disturbance in another, or in all. How little, indeed, we can depend upon

distinct indications pointing to the site of injury within the brain, I had a remarkable case under my care in 1834. An aide-de-camp of Marshal Saldanha was struck in the forehead by a musket-shot; the ball was divided as it passed through the skull, and a shaving passed along one hemisphere, abrading the corpus striatum of one side, and lodging upon it, producing considerable disorganization. He lived from ten to fourteen days, retaining consciousness, and without any impaired motion of either side. Yet the corpus striatum is one of the parts of the brain, of the functions of which we speak the most confidently.

The most, therefore, I have been led to hope as capable of attainment, after repeated and carefully compared observations in many cases, is to define the *kind of injury*, its *degree* to some extent, and particularly the violence or intensity of the action ensuing in the structure of the brain, and consequently the probable result, and the nature of the treatment best calculated to avert death or permanent injury to functions. But this is much more than has been hitherto attained.

The effects which ensue from injuries of the head are of several kinds, as well as degrees, and require classification before they can afford unerring indications. This I have in a great measure already shewn, when describing the best mode of taking notes: they refer to the three systems:—

1. The *cerebral*, extending also down the spine, directly influencing *motion* and *sensation*, furnishing the particular senses—the seat of judgment and perception—the source of all *voluntary motion*.

2. The *spinal* or *excito-motory*.—Its axis is the medulla oblongata and spine, intimately connected with the involuntary motions of the viscera, with the muscles guarding the orifices of the body.

3. The *ganglionic*,—the sympathetic. The secretory and nutritive system, contributing largely to bind the other two together, and both to it, by interlacement of sensitive, motory, and secretory filaments, uniting to a certain extent the functions of both brain and spine.

The whole of these actions are often and variously combined; and occasionally, to arrive at a true diagnosis of cerebral injury, it is essential that they should be distinguished from each other; often acting in a manner singularly in-

dependent of each other, yet, undoubtedly, the integrity of all is essential to the continued well being of any one. The cerebral functions, however distinct, are necessary to the continuance of either the ganglionic or excito-motory system. An animal from which all cerebral influence is cut off by division of the spine near the occiput, will gradually die; the powers of the sympathetic and excito-motory become exhausted, and cease. I have never seen the true spinal functions deranged, or the powers of that system impaired, in injuries of the head, without impaired cerebral functions.

Having thus pointed out the intimate connexion between the different nervous systems, I may observe that the first may be impaired, almost annihilated, without any very serious disturbance, for a considerable period, of the second; of which the following case of concussion is a remarkable instance.

A patient was brought to me in a state of insensibility, after fighting some twenty rounds with one of his comrades. The pulse was much slower than usual—from 50 to 60; pupils a little dilated; breathing somewhat stertorous.

In the course of a few days he partially recovered so far as to eat and drink whatever was carried to his lips, but without moving, or seeming to be aware of the calls of nature. When the evacuation of the contents of the bowels and bladder took place, he seemed perfectly heedless—indeed, unconscious; he paid not the slightest attention, nor seemed to hear any question, and moved no muscle when pinched.

About the middle of the second week a second stage came on: he was able to move; he recovered in some degree sensation and motion; answered "Yes" to every question, aware, apparently, that he was questioned, but altogether unconscious and incapable of understanding the purport; felt hungry, which, however, was only evinced by his seizing any food that came in his way.

In this state, with no other evidence of disease, he remained for some weeks, his consciousness of what was passing around very slowly improving; a slight stutter had supervened in his speech; and his memory was exceedingly impaired.

I repeat the case from recollection, the notes having been mislaid; but I remember all the circumstances dis-

tinctly, and they are essentially correct, as I have stated them.

Another remarkable example of destruction of one cerebral function, without detriment to any other—more common than the one I have described, yet still worthy of note—I remember seeing in a lunatic asylum at Newcastle. A young farmer, a robust and athletic man, was thrown when riding, the consequence of which was an aberration of intellect, with a sluggish and impaired consciousness. Thus we see here the effects confined to the functions of animal life, and to only one, and that the highest form of it—the intellect.

Generally speaking, in injuries of the head, when the excito-motory or ganglionic system is affected, their impaired function is dependent upon the degree and site of injury in the brain; and therefore do they form such fatal signs. Although the cerebrum may be so injured as to produce death in a few days, and yet not affect either of the two systems mentioned, or not until the last hours of exhaustion of all nervous power, yet the degree or kind of injury capable of affecting through the cerebrum the other systems, is not the less of a fatal, although, as I shall hereafter shew, of a different character.

An injury of the head which affects the functions of the cerebral system only, *ceteris paribus*, is of a less dangerous and fatal character than one which involves the others, although, by destroying all cerebral functions, death may ultimately result from the first form; but death comes then as *the mere result of exhausted cerebral power* necessary in man to the continued action of all other systems.

Hence you understand, *that when the injury is in the brain*—and through it the other nervous systems are affected—the cerebral mischief is great, the functions of the brain are always seriously disturbed: intellect, consciousness, sensation, and voluntary motion, either deeply impaired, or abolished for a time entirely. I have witnessed no exception to this.

These are some of the leading features of the general effects: we may now proceed to the nature and treatment of particular injuries.

ON THE
INDUCTION OF PREMATURE
LABOUR.

To the Editor of the Medical Gazette.

SIR,

IN the last number of the GAZETTE (June 1st) you have inserted a letter from Dr. Paterson, of Glasgow, on the Induction of Premature Labour; and I take the liberty of noticing it, among other reasons, because it contains the following sentence:—"The mode I adopted for accomplishing this purpose, so far as I can ascertain, differed from that of any preceding obstetrician, inasmuch as it was effected by the administration of the *secale cornutum*, to the exclusion of every other means."

I am happy to corroborate Dr. Paterson's statement in regard to the power of the ergot for this particular object. It is not, indeed, quite new to the profession; for some years ago I was induced to try its effect in bringing on labour prematurely; and in my lecture on that subject (one of the series published in your periodical) I have detailed at length six cases, selected from a considerable number, in which the uterus was excited to action, *ab initio*, by the agency of this specific drug. Since that publication I have received communications from many professional friends, notifying its successful exhibition for the same end. I would refer any of your readers, who may be curious on this point, to the GAZETTE for June 28th, 1834. They will there find it recorded, as my opinion, that the effects produced were as much attributable to the medicine employed as purging would be to jalap, or vomiting to ipecacuanha.

The intention I had in view in substituting the *secale* for the artificial puncture of the membranes, was twofold; partly to diminish the sufferings of the mother, by preserving the membranes whole, until the labour was nearly completed, but principally to preserve the child. For it is reasonable to suppose that, when the liquor amnii has drained away before the commencement of efficient pains, the pressure exerted by the contracting uterus upon the fœtal body, or the placenta, or more

probably on the *funis umbilicalis*, would often, by impeding the circulation, destroy the life of the infant before its expulsion; and I considered myself borne out in this reasoning by the result of Dr. Hamilton's practice in Edinburgh. When I had the advantage of attending his instructions he used to recommend that the membranes should not be punctured, but separated by the finger from the mouth and neck of the womb to the extent of an inch all round; and he stated, that by acting in this way he had saved 24 children out of 28 successive cases. When I contrasted this very favourable result with my own cases, in which labour was induced by puncturing the membranes, more than one-third of the children being born still, I thought myself bound to adopt the plan so strongly advocated by Dr. Hamilton. I followed it implicitly on five or six occasions; but being disappointed in my expectations, I determined to give a trial to the ergot; and the success that followed fully justified me in the experiment, as far as the mothers were concerned; for in very few instances was the medicine exhibited without effect. I was, however, in time, most distressed to find that, under my hands, in comparison to the number of cases, more children were still-born after the exhibition of the medicine than when the membranes had been punctured; and though formerly most unwilling to concede it, I can now no longer withhold my assent to the doctrine that this drug, when taken in large quantity, exerts a poisonous influence on the child's body through the mother's system. I have been strengthened in this conviction by the fact, that in four instances where the labour was induced by the ergot, under my own superintendence, the children died in convulsions within a few hours after their birth. Now, sir, when we take into consideration the very few infants who perish from convulsive attacks speedily after birth in this climate--when we consider, also, that one of the first symptoms of the disease known by the name of *ergotisme* (in those countries where it is prevalent), is a convulsive seizure—I think we may fairly refer these deaths to the medicine; and if so, it must possess a deleterious property, capable of being transferred to the infant within the mother's uterus,

although she herself may escape uninjured.

I have been at the pains of looking over with attention the notes of all the cases in which I have induced premature labour since I commenced practice; and I subjoin the following summary, that your readers may have before them the means of appreciating the value of the ergot in promoting that end, deduced from a considerable number of trials.

I find that the cases in which it has been thought necessary to have recourse to this expedient, from the patient's possessing too narrow a pelvis to admit a mature fœtus to pass alive, amount to 62: of these—

In 36 cases the membranes were punctured.

21 children were born alive.

16 ————— still.

Of those which were born still—

1 was a twin case, both children still.

3 were breech or footling cases.

2 were transverse presentations, requiring turning.

Of those born alive—

1 was a breech case; the child never breathed freely, and soon died.

1 was a footling case.

Four patients took the ergot with little or no effect:—

1 took 10 drachms infused.

1 — 20 drachms infused.

1 — 24 drachms infused. The child died in 48 hours, not in convulsions.

1 — 30 drachms infused.

The other 19 children lived for a considerable period; many are alive at this time to my knowledge.

In 26 cases the ergot induced labour without any other means being used.

Of these—

12 children were born alive.

14 „ „ still.

Of those born alive—

1 was a shoulder presentation; the child was turned, and the respiratory function was never perfectly instituted.

3 died within the hour—not in convulsions.

4 died of convulsions.

Of these—

1 died in 6 hours.

1 „ 10 „

1 „ 15 „

1 about 36 „

So that, of the 12 born alive, 4 only survived for any length of time.

Of the 14 born still—

1 was a breech presentation.

In 2 craniotomy was performed, the women being farther advanced than they had calculated on, and the children being too large to pass. One of these children was still before the operation; the other was alive at the time.

The quantity each of these patients took varied from 2 to 12 drachms, and they all had it given to them in the same form. Half a drachm of the powdered grain was infused for half an hour in an ounce and half of boiling water; the *strained* infusion was exhibited, and the dose repeated every four hours.

It is right I should add, that in no one case did the women suffer any bad consequences from the medicine, nor was any perceptible effect produced on the general system, except nausea and vomiting in a small number.

From the foregoing analysis, I think we may conclude that, although the ergot may bring on labour without having recourse to any operation, yet that it does not present us a more likely, nor, indeed, so probable a means of saving the infant as the older method of puncturing the membrane, though I hoped such would be the case when the lecture I have referred to was given to the public. It would seem, also, that however much the woman may have taken, unless it exerted a decided influence over the uterus, the child suffers no detriment.

It may, perhaps, be advantageous, when it is necessary to anticipate the proper period of parturition, to administer three or four doses of this drug before the liquor amnii is let off, in the hope that it may dispose the uterus to act, and tend to soften and prepare the passages for the child's exit; it being presumed that so small a quantity would do no injury to the infant.

I cannot help expressing my fears that the ergot, from its powers being now so well known, is not unfrequently had recourse to, in ordinary cases of labour, both unnecessarily and injuriously; and

I feel it my duty to join Dr. Paterson in impressing a strong caution on our younger brethren, with regard to its indiscriminate employment. I have myself witnessed very sad effects follow its exhibition, and I think reasonably attributable to its agency.

There is another part of Dr. Paterson's letter that calls for remark. He thinks "this medicine can by no means be regarded as an abortive;" and he quotes some distinguished names in confirmation of that view; but that "in proportion as the period of natural parturition draws near, *ceteris paribus*, so will the action of the secale be manifested on the system." "For," he states in a sentence closely following the last quoted, "it is rational to believe, that as the full period of gestation draws near, the natural predisposition of the uterus to expel its contents will be greater;" "though he is not as yet prepared to draw a line of demarcation, as to the exact period when it may be said to act, as it were, specifically on the gravid uterus."

I hold a different opinion. I cannot grant that the uterus has a greater disposition to expel its contents prematurely in the latter than in the earlier stages of gestation; because, in this city at least, abortions before quickening has taken place are much more frequent than premature labours at the seventh or eighth months. Neither can I refuse credence to the notion that this medicine has a specific influence over the uterus even at an early period of pregnancy; because I have seen its stimulating effects on that organ in very numerous cases of dangerous hæmorrhage in the early months, when it was desirable to procure the complete evacuation of the uterus, and where no manual or instrumental means could be put in practice. Besides, it is neither philosophical, nor in accordance with our knowledge of the action of other drugs, to deny its influence over the gravid womb at one period of pregnancy, while we concede to it such an almost incredible power at another. But this is a subject which should be lightly touched upon in a publication such as this, for reasons that I need not more deeply enter into.—I am, sir,

Your obedient servant,

FRANCIS H. RAMSBOTHAM.

June 8, 1839.

ANALYSES AND NOTICES OF BOOKS.

—
"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

—
Researches on the Development, Structure, and Diseases of the Teeth. By ALEXANDER NASMYTH, F.L.S., F.G.S. Member of the Royal College of Surgeons, London; Fellow of the Royal Medical and Chirurgical Society.—Churchill.

CIRCUMSTANCES and events apparently fortuitous seem to exercise an influence over the destinies of mental energy as well as of every thing else; and thus the introduction of improved microscopes in our own more immediate æra, appears likely to revolutionize the anatomy and physiology of almost every tissue which makes up the animal frame.

In some, indeed, it has opened up entirely new fields of investigation; and of these a prominent one is the subject of the work before us—namely, the minute structure of the teeth. The beautiful displays of arrangement, and peculiar adaptations of these organs, to the circumstances of different animals, which have been brought to light, form one of the most striking proofs of the utility of this instrument in the province of minute anatomy with which we are acquainted. The author tells us in the preface, that the interest excited by the views of Professor Retzius, of Stockholm, in 1837, induced him to resume a course of investigations on all points connected with the structure of the teeth. It is, however, not the structure only of these organs which is considered by Mr. Nasmyth, but his work is, in fact, intended to form an entirely new system of odontology. The particular views now alluded to not only demonstrate that such a work was required, but the unsettled state of every point connected with the subject seems to demand it.

The general arrangement of the subject seems to betoken novelty in all its parts, and it admits of great amplification. The portion now before us consists chiefly of a digest of the labours of others up to the present day: it is illustrated by a set of beautifully executed engravings, and so contrived as to infuse a great degree of interest into the

discussion. The labours of Purkinje, Müller, Raschkow, Retzius, and others, who have of late done so much in this branch of science, are described, and many curious and interesting facts adduced. The labours of the physiologists above named have tended to prove the existence of a system of tubes, which ramify and unite with one another in the body of the tooth, and in which tubes the fluids of the teeth percolate. The researches of these anatomists are given fully, and with very ample details; but the reader who wishes to follow up the subject must consult the work itself, as our limits will not admit of our entering upon it fully: at the same time, we quite agree with Mr. Nasmyth in his concluding observations on the subject:—

“The labours of Retzius and his contemporaries must be considered as a most splendid contribution to minute anatomy; but I still think that the evidence in favour of the existence of a *system of ramifying tubes* in dental bone or ivory, requires much further examination and corroboration, before we can be justified in adopting a theory tending to overthrow many received opinions, results of ordinary experience. The difficulty in arriving at just views of this subject is partly owing, I think, to the circumstance that writers have comprehended very different structures under the same term. All the diversified textures entering into the composition of the *bodies* of different teeth have been described as dental bone or ivory; and it is unfortunate that the advocates of a tubular system have not been much more precise than their predecessors in defining the specific nature of the various dental structures, in which they state that they have traced hollow fibres.

“Like all newly propounded doctrines, the theory of a tubular system, as laid down in the preceding pages, will be found to present some internal contradictions. ‘It can scarcely be doubted,’ says Retzius, ‘that the minute tubes in dental bone, in the cortical substance, in common bone, and in the horns of deer, as well as the cells with which they are in connexion, are a peculiar kind of vessels containing a nourishing and supporting fluid.’ In another part of his work, however, he says, ‘with respect to the contents of the canals, I, as well as Professor

Müller, have found that they consist of an inorganic or earthy substance, which appears white when viewed on a dark ground, but which disappears when the preparation is placed in diluted muriatic acid. When the light falls into these canals, this matter is seen to be composed apparently of infinitely fine particles, adhering together in lumps. The greater or less number and distinctness of these lumps seem to depend on the degree in which the preparation has been penetrated by water, oil, or turpentine.’ ‘That the small osseous tubes and cells,’ he afterwards adds, ‘contain osseous earth, is seen from their whiteness.’ And one of his followers states, that ‘these tubes are chiefly rendered visible by means of their contents.’ How a tube can be filled with osseous matter, and at the same time allow of the circulation of a ‘nourishing and supporting fluid,’ I cannot understand. It must not be forgotten, too, that Retzius allows ‘that, in the tooth, no renovation of the material appears to take place.’

“Nor is it with respect to the more direct inductions drawn from the tubular system alone, that I must avow myself in some respects at issue with the ingenious and industrious Professor of Stockholm. ‘When the milk-teeth,’ he says, ‘are examined just before they are about to be shed, they are found to present an appearance as if, from pressure of their permanent successors, they had wasted or been absorbed at their roots. The crown of the advancing tooth appears to have pressed itself into the extremity of the deciduous one. I have carefully examined how this appearance is produced, and have come to the *decided conviction* that neither *tabescence*, *absorption*, nor *erosion*, has any thing to do with it.’ This is a statement which may be so easily refuted by the simplest observation, that I need not here waste the time of the reader by entering into a formal demonstration of its fallacy.

“With a candour which cannot be too highly praised, Retzius allows that he is ignorant of the specific functions of the tubes in the dental bone of the adult tooth. His ideas on this subject, as might be expected at this early stage of the inquiry, are far from definite. ‘In common bone, *probably*,’ says he, ‘the peculiar vessels in question take a part in the continual, or apparently con-

tinual, exchange of substance: this cannot in the same degree be the case in dental bone, inasmuch as in this no such exchange appears to take place. What end, then, is served by this beautiful organization of dental bone? We have many examples that nature organizes structures which have a close affinity to each other according to one and the same plan, and hence we have, in different parts or organisms, formations which in some are of the greatest importance, whilst in others they are of much less functional significance, or of *none whatever*. If we hence assume, what is highly *probable*, that in bone the peculiar vessels in question give passage to fluids during the entire life of the animal (or a great part of it), which fluids contain the solid as well as the liquid materials of the osseous substance; it does not necessarily follow that the same process must be carried on in the teeth during the whole of life. On the contrary, I am inclined to believe that these vessels in dental bone are at their height during the first period of the formation of the tooth, and exercise then their more perfect action. At the same time, the existence of a continual vital process in the tooth, as well as in the crystalline lens, cannot be denied, which, however, appears to be carried on without any constant exchange of solid matter, and must hence consist in a renovating circulation.' I have quoted this sentence again, because it characterises, more justly than any objections I could make, the imperfect state of the inquiry.

"The theory of the tubular system, assumed to be true, has been with considerable ingenuity employed by a very eminent naturalist, to explain that which takes place when teeth are stopped: it has been said that the mouths of the vessels which have been cut across in this operation deposit a layer of calcareous matter under the *stopping*; but I believe that no facts bearing out this assertion have yet been observed; and I cannot but think that the general character of the tooth, and the nature of the functions which it has to perform, are altogether incompatible with the existence of a system of open-mouthed vessels ready to pour out fluid of any kind to a greater or less extent. It is well known that even the least increment, or change of the material of the tooth under the stopping, renders that operation quite ineffectual, either by

displacing the stopping or by admitting the fluids of the mouth, and thus promoting decomposition beneath it."

We shall look with interest for the development of the views of our author on this subject, as we are led to infer, from the care which he seems to have bestowed upon it, that something precise and valuable may be expected.

Minute practical knowledge is obviously requisite for conducting an inquiry such as this into minute structure. We do not know who the naturalist is to whom allusion is made in the last paragraph of the above quotation, but it demonstrates that no advantage can be expected from a distribution of labour so unlikely to be followed by practical results; the merest tyro in the management of the organs in question, knows the absurdity of the opinion which is therein stated.

It is proper to observe, that the present portion of the work does not enter fully into the details of the researches and views of the author himself, but enough is done to shew that he has paid much attention to the subject, and that he has arrived at various new results. The system which has obtained the appellation of tubular, was discovered 160 years ago; nothing positively new has been noticed. The *rediscovery* of these appearances by our German contemporaries may claim something of novelty, and has much interest attached to it. In the work before us, however, there are several discoveries which we regard as original—certainly we are not aware of their having been anticipated by any former observer. The first is described thus:—

"There is one opinion which has been uniformly maintained by all writers on this subject—viz. that when the teeth of man, or other analogous simple teeth, are extruded, the enamel is divested of all external covering, and exposed immediately to the atmosphere, denuded of both the envelopes of capsule and mucous membrane which it possessed during what has been called the saccular stage; and this denudation has always been supposed to be effected by the disruption of these coverings. My own views, however, on this point, which are contained in a paper read some time ago before the Medical and Chirurgical Society, are different from those generally received; and I have no doubt that I shall be able to prove that it is a

process of absorption, and not of disruption, by means of which the tooth is emancipated, and that when perfected and extruded it is still invested with a capsular covering. This covering, as it is seen to be continuous with the crusta petrosa, I consider it to be analogous to it, as the latter has been found to invest the whole tooth in an enlarged state in many animals, and in a particularly interesting form in the *orycteropus*, *bradypus*, walrus, &c. In my collection are numerous preparations of this covering on the teeth of man, on the incisor of the calf, and on the simple teeth of many other animals. I have detected it, indeed, on the teeth of so many animals, that I presume it will be found universal. By means of acid, I have removed it in the shape of a membrane from the surface of these teeth; and in delicate dry sections prepared in a peculiar manner, I have been enabled, with the microscope, to examine its structure. In man it forms a thin layer, of a darker colour than the enamel; it is continuous with the crusta petrosa which covers the fang, but differs from it in not always containing corpuscles. On the incisor of the calf this covering is very distinct, and generally presents corpuscles. The extreme difficulty which is experienced in getting a fine section of a tooth without this membrane being removed in the process of reduction, is, probably, the cause of its having been overlooked by previous observers."

An entirely new and interesting point in the consideration of these organs is noticed at p. 164, in these words:—

"Retzius states that only three substances enter into the composition of the teeth in their various forms, viz. ivory, enamel, and cement; but I think that a fourth ought to be added to this list, viz. a structure having the appearance of ossified pulp, in which the vessels seem to retain their original position, but are found in a state of atrophy, intermingled occasionally with irregularly-formed ivory. This substance may be considered as constant as any of the other three; it constitutes almost exclusively the simplest teeth, as those of the *ornithorynchus*, *anarrhichas lupus*, &c.; and it is occasionally found to enter into the composition of the teeth of almost every animal, either normally, as in the walrus, *bradypus*, *orycteropus*, *ptychodus polygyrus*, &c., or abnormally, as in some human teeth."

The establishment of the first of these curious and original facts forms a beautiful display of the uniformity of nature throughout the range of the animal kingdom.

The following passage from the preface is very important, and opens up an entirely new field of inquiry:—

"The importance of the study of odontology in a zoological and geological point of view, has induced me to form as complete a collection as possible of microscopic preparations of the teeth of the various classes, both living and extinct, of the animal kingdom. From these I intend, in the course of the present work, when treating of the structure of the teeth, to make a selection calculated to serve as an index of the type of any animal. This part of the work I think will prove of much use to the geologist, in enabling him to state to what class of animal any tooth, or fragment of tooth, belongs."

The effects of time in destroying the remains of organic beings is now divested of its hopeless destructiveness in the eyes of the geologist, who, inspired by a ray of the bright genius of Cuvier, attempts to unfold the natural history of past ages. It is a very curious and interesting fact, that amid the apparent confusion and chaos of fragments, let but one minute portion of a tooth be found, and submitted to an educated eye through the microscope, and the animated inhabitants of a former age at once start up around him, clothed with all the bodily investments of their organization. In order to demonstrate the soil they trod upon, or the medium in which they moved, the student has only to apply a little sagacity and attention to the demonstrations which Cuvier has afforded.

"In the sequel to the present work," (says our author) "it will be shewn that, besides the general conformation and external appearance of the teeth, another distinctive peculiarity by which the Almighty has characterised the different members of the animal kingdom, exists in their beautiful internal, minute, and hitherto hidden organisation, which further demonstrates in a most striking manner the harmony of all created existence."

Here we terminate our notice of Mr. Nasmyth's interesting and important volume. It forms a most striking contrast to the ephemeral and abortive pro-

ductions with which the press teems—professedly upon the same subject, but having no resemblance except in name; and we therefore strongly recommend it to the attention of all who are interested in the scientific investigations connected with our profession.

MEDICAL GAZETTE.

“*Letet omnibus, letet etiam nihil, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”

CICERO.

MEDICAL CONGRESS AT DUBLIN.

A MEETING, designated by our contemporary the Dublin Medical Press as the Great Meeting of the Physicians and Surgeons of Ireland, was held on the 29th of May, at the College of Surgeons, in Dublin. The mere fact of such an assembly, drawn from every corner of the island, coming together to consider the grievances of the profession, is sufficiently interesting; it may be looked upon as an additional instance of the characteristic instinct of our age, which prompts every class to give utterance to its discontent, and to endeavour to probe to the bottom the deep uneasiness which consumes it. Many of the assembled practitioners are names well known to fame; and though we are less acquainted with others, from the circumstance of their not residing in the capital, there is no doubt that among them are to be found many ornaments of the profession, representing most satisfactorily the opinions of their provincial brethren. Corresponding associations seem already to be formed in different parts of Ireland, which will probably soon extend the power of the parent society into every county, and make it strong, if not despotic. Hence we should ill discharge our functions if we gave no account of the proceedings of the 29th ult. But

as it has always been our boast to be not only faithful chroniclers, but impartial commentators, we shall criticize as well as report, not hesitating to expose a fallacy, however high the name by which it is sanctioned.

In consequence of the number of practitioners who had assembled from all parts of the country, it was found necessary to adjourn from the great hall of the College to the theatre. Mr. Carmichael was called to the chair by acclamation, and began the business of the meeting with a speech. He attributed the concourse of practitioners around him, delegated to represent the sentiments of their brethren in all parts of Ireland, to the obvious necessity of medical reform. The necessity is clear, from the constant sinking of the profession in public estimation; and this sinking may be measured by “a sad falling off in the rate of remuneration during the last few years.”

What this rate may be, does not appear. Mr. Carmichael himself has “become accustomed to the usual *honarium*,” or, in plain English, gets a guinea a visit, “a custom which it is not likely I shall now forego;” so that he falsifies Shakspeare’s proverb, and does *not* jest at scars, though he never felt a wound. One slight scratch, indeed, he has felt; he says, “we are now seldom rewarded with the double *honorarium* in consultation, even when held upon personages of rank and fortune.” This kind of luxurious complaint, however, is enough to make the mouth of a poor London doctor water, and lead him to think of the Sybarite in the story, who could not sleep all night because a rose-leaf was doubled under him. At the other end of the medical scale the fees are singularly low; so low, indeed, that Mr. Carmichael refuses to offend the ears of his audience by repeating what he has heard from undoubted authority on the subject. We should be glad to

know what is the precise sum too painful to be mentioned to ears medical. Is the fee five shillings, or three, or half-a-crown? Whatever it may be, we cannot conceal our suspicions that the Dublin minimum is higher than the London one; for although brilliant talent is recompensed in the metropolis of the world by prizes of the highest magnitude, this very splendour of reward attracts such shoals of competitors from all quarters, that there are few towns where moderate abilities are so unprofitable to their possessors; to use a commercial phrase, talent in London is quite a drug, and never looks up. The simile which James I. used when advising the gentry to leave town, "in London you are like ships in the sea, which shew like nothing, but in the country you are like ships in rivers which shew like great things," is exquisitely suited to rustic practitioners of fair ability who wish to plunge into the unfathomable ocean of the metropolis; though, of course, as the learned king would not have given this plain advice to the possessor of twenty thousand acres, so our extension of it is not applicable to the possessor of unrivalled talent. Hence it may be some consolation to our struggling brethren in Dublin to learn that the "ships in the sea" are worse off than they; and if their unmentionable fee should turn out to be half-a-crown, they may rest assured that many practitioners in London receive a guinea for an indefinite number of visits.

The same miserable comfort will apply to the Dispensary question, which Mr. Carmichael next touches on. In Ireland the medical officers get a very small salary, in England usually none at all.

Again, Mr. Carmichael complains, and with reason, of the pitiful remuneration doled out by successive governments, whether Whig or Tory, to the medical practitioners whom they em-

ploy; and contrasts it with the gentlemanly salaries given to barristers. Thus, when the cholera ravaged Ireland, the practitioners employed in the infected districts were paid only ten shillings a-day. This was afterwards somewhat increased, upon the urgent remonstrance of a member of the Board of Health; but in no instance, however distant the field of his exertions, did any one receive more than two pounds a-day, which included travelling expenses; while, at the same period, registering barristers were paid five guineas a-day, and travelling expenses besides.

Yet here, again, marked as is the preference shewn by the legislature to law—clearly as it treats the practitioners of physic like a stepmother, and reserves its affection for the barristers—our Irish fellow-labourers have the advantage over us. When the epidemic cholera raged in England, the salary of an ordinary practitioner was much less than ten shillings a day; and as for a daily revenue of two pounds, a cholera doctor would as soon have thought of getting a bishopric!

If the poet, therefore, be right, when he says,

"Solamen miseris socios habuisse doloris,"

it will be some comfort to our brethren in the green isle to learn that things are rather worse at the seat of government than with them, and that the opulence for which this country is so famous, seldom condescends to visit its medical practitioners. If we were asked why the profession should be better paid in the poorer country, though fearful of broaching a wrong solution of a difficult social problem, we should conjecture as follows:—In Ireland, the lines of demarcation between the different classes of society are far more strongly traced than here; and consequently the lower part of the middle ranks, who, in England, frequently bring up their

sons to the medical profession, will less frequently venture on so bold a step. Moreover, though Ireland is notorious for its "middle-men," yet persons of intermediate fortune are really far less numerous there than in this country; a fact which strikes every traveller who misses the neat dwellings which characterize an English landscape, and feels inclined to think that the gloomy descriptions of the "Deserted Village" have been realized, and that nothing is left but the castle and the cabin. Now if our solution be the true one, as there is every reason to believe, it will not only shew why the rate of medical remuneration is rather better in Ireland than in England, but why there is reason to fear that it will sink still further with the growing prosperity of the former country. The number of farmers, annuitants, and shopkeepers, enabled to give their sons a sort of medical education must be daily on the increase; the young aspirants must live, and have little capital to fall back upon; therefore, if they cannot get half-guinea fees, they must take half-crown ones, or others even more offensive to ears polite.

When crowds of hungry competitors are rushing against the mounds set up to exclude them, the dyke has little chance of withstanding the torrent; and in the present age, candidates are rarely disheartened by parchment difficulties. To say nothing of those facile academics which make correspondents happy by return of post, provided their letters inclose a suitable remittance, more respectable universities manufacture doctors by hundreds annually, to the ever increasing rarity of the double honorarium!

Still in Ireland the surplus population of our profession would not be so great, Mr. Carmichael thinks, if it were not that the apothecaries are beginning to practise physic — an innovation

against which he sets his face most decidedly. So that it appears that across St. George's Channel medical affairs are somewhat in the state that they were here in Queen Anne's time. The progress of society has prodigiously augmented the number of persons who want advice and physic in the cheapest and readiest form. In vain did the physicians of that period attempt to stem the revolution; will the Irish physicians labour in vain likewise? They will, unless they have the wit to see that clerks and factors and petty traders *must* have cheap advice; good, if possible, but cheap at all events. If they will consent to see this, and will allow their junior colleagues to take fees too small to be even hinted at, they may yet smother the nascent practice of their rivals; but if they think this alternative intolerable, they must submit to the other one. *De malis minimum*; we leave them to choose between the two. We will continue our account of this important meeting in our next article.

ANÆSTHESIA IN THE DOMAIN OF THE FIFTH PAIR OF NERVES.

BY DR. ROMBERG.

ALTHOUGH affections of the fifth pair of nerves are common enough, yet cases of them have seldom been published; while descriptions of disorders of the facial nerve have been frequent since the appearance of Bell's works. This deficiency is the more to be lamented, as diseases of the fifth pair afford the opportunity of solving physiological difficulties, for which experiments on animals are insufficient. In this point of view, as well as in reference to diagnosis, the following case is worthy of attention:—

A widow, æt. 42, four years ago, fell backwards on the occiput, from a flight of stairs, while carrying a loaded basket. A year afterwards the catamenia ceased. From this time she suffered under attacks of spasmodic sneezing, which of late increased both in frequency and violence, so as to deprive her of sleep, and were excited by the slightest cause. Nothing irregular was to be found on examination of the nasal cavities; but the occurrence

of the accident made me suspect that there was something wrong within the cranium, by which the nasal filaments of the fifth pair were stimulated. I immediately examined the course of the first and second branch with reference to their sensibility, but found no variation; but the third branch was insensible throughout its whole course. I give the combined result of my experiments, which I often repeated during the last two years before my pupils, as well as in the presence of Professor Müller and my colleagues. The eyes of the patient were bandaged when the experiments were performed, which is necessary when examining the state of the sensibility, both to prevent the patient from deceiving one, and to avoid being misled by the impression which is produced on the patient by the sight of the instrument employed.

The left half of the lower lip, both on its outer and inner surface, and the left side of the chin, were insensible to the pricking of a sharp inoculation needle. In like manner the inside of the left ear and the auditory passage had lost all feeling, and showed no sensibility even when a burning taper was held within them.

The skin of the left temple near the hair, and the left half of the tongue laboured under the same loss of sensation. On the right side all these parts enjoyed their usual sensibility, and even on the left side of the face the other nerves of sensation were perfect, so that the limits of the third branch could be accurately marked out. When the skin of the temporal region was touched with the needle at a spot somewhat nearer the forehead, the patient instantly started back, for I had got into the course of the frontal nerve; and when the skin of the horizontal ramus of the lower jaw, near the chin, was pricked, smart pain was produced, because the upper subcutaneous twigs of the third cervical pair retained their power of conveying sensation. On the other hand, the left side of the tongue had lost its faculty of taste. Substances of all kinds, solid as well as fluid, were not tasted, while the faculty was perfect on the right side. Thus the patient remained quite tranquil while I strewed some powdered colocyath on the left side; but she made a face when it was put on the right, exclaiming "how bitter!" and endeavoured to get rid of the sensation by repeatedly spitting out the powder. It was the same with salt, sour, and other substances.

But though there was a partial disturbance of sensation, there was none of the power of motion on the left side. I could not detect any difference between the left and right side either in imitative,

respiratory, or masticatory movements. The same held good with the articulatory and masticatory motion of the tongue; nor were the nutritive functions of the left half at all injured. The dimensions were the same on both sides as well as the colour and temperature. Blood flowed as quickly and copiously from little punctures on the left as on the right side; the moisture too, and coating of the tongue, were the same. From these points, I formed the following diagnosis:—

The limitation of the anæsthesia to the third branch of the portio major of the fifth nerve indicates an affection of this branch alone; and indeed indicates that it is compressed, because as long as I observed the patient, mere anæsthesia was present, without any painful sensations. The pressure must affect the nervous trunk already formed, the *ensemble* of the primitive fibres, because the loss of feeling extended over the whole course. That the compression was not seated in the Gasserian ganglion, where the elements of the third branch are united with those of the other two sensitive branches of the fifth, was shown as well by the existence of feeling within the sphere of the first and second branch, as from the absence of other characteristic symptoms. Nor could this pressure be supposed to take place after the exit of the nervous trunk from the foramen ovale of the sphenoid bone, because the motor fibres of the portio minor of the fifth pair are there united to its sensitive fibres in such a manner, that pressure must have operated on both, and produced paralysis—a supposition which is disproved by the masticatory movements being unimpaired on the left side of the face. I therefore supposed a compression of the third branch of the fifth pair in its course through the cranium, before the foramen ovale, probably caused by a swelling of the dura mater or the bone; and its extent could be but small, as the portio minor in its neighbourhood was not paralysed.

The patient died of dropsy, March 19th, 1838, when the following appearances were found in the cavity of the cranium.

The upper surface of the brain was covered with gelatinous exudations, white in patches, and opaque. On the lower surface of the posterior lobe of the left hemisphere, corresponding to the floor of the posterior horn of the lateral ventricle, a spot of almost circular shape was found, softened, but without any trace of vascular injection around it. The brain and medulla oblongata were otherwise healthy.

The third branch of the fifth pair on the left side, at the place where it enters the foramen ovale, was externally surrounded by a reddish, vascular web, which consisted partly of fibrils, and partly of

very small transparent vesicles. On closer examination it appeared to be an exudation, or a luxuriant growth of the neurilema; towards the cranial cavity it gradually passed into the substance of the dura mater, and at the other end of the nerve into the regular neurilema. The neurilema was thickened and reddened, as far as the nerve pursued its course in the sphenoid bone, and even a little further downwards as far as the spot where the normal otic ganglion had its place on the posterior surface of the nerve. As far as the neurilema was altered, so far the nerve also was swollen, of a yellowish colour, and perhaps rather harder than in the rest of its course. This alteration, however, was found only in the portion of the third branch which springs from the Gasserian ganglion. The motor root pursued its course unharmed on the inner surface, and vanished with the larger portion below the diseased spot. The nervous twigs belonging to the pterygoid and buccinator muscles, to the temples, tongue, and lower jaw, were perfectly normal, as well as the third branch of the fifth pair on the right side, and the glossopharyngeal nerve on both sides.

The preceding case is extremely opportune at the present time, when the controversy concerning the nerves of taste is so actively carried on. I do not think that I go too far in considering this case of decided importance, as it indubitably shows that the primitive fibrils, which run in the course of the lingual nerves, are capable of conducting the sensation of taste. I express myself thus intentionally, to avoid the common error of supposing the lingual nerve to be made up of homogeneous elements. That this is not the case, and that, on the contrary, both sensitive and gustatory fibrils are found in the course of the lingual nerve, appears from the foregoing case. Here, as well as in the organ of sense generally, far sounder proofs are derived from pathological facts than from experiments on animals; the latter having even been the cause of error, which escaped observation in the dispute as to the share of the glossopharyngeal or lingual nerve in the faculty of taste. The sensitive energies of the tongue were limited to feeling and taste, and another one was overlooked which is shown by the simplest experiment. Let the finger be passed over the point, edge, or middle of the tongue, and the sensation of common feeling alone is produced; but as soon as the papillæ vallatæ and the root of the tongue are approached, the feeling of nausea is excited, and a determinate reflex action—that of *retching*. It is these nervous prominences in which fibrils of the via glossopharyngea are distributed, which

are also found in other places, such as the velum palati for example, the irritation of which also causes nausea and retching. In most of the experiments on animals (compare Panizza and Valentin, in the *Repert. für. Anat. u. Physiol.* 1837. vol. 2, Part 2, p. 220) mention is made of the feeling of nausea and attempts to vomit, the glossopharyngei remaining uninjured; only it seems to me that it is incorrectly ascribed to the influence of the taste. In animals the feeling of disgust and aversion is the guiding principle in eating, in other words the instinct, far more than the taste is. This coincides with the variety in the number, size, form, and situation of the papillæ vallatæ observed by Rudolph Wagner in different genera and species of the mammalia; although he holds the glossopharyngeus to be the nerve of taste; so that a clear parallel is made out between the instinct of nutrition in animals, and the form of the papillæ vallatæ. (*Neue Notizen aus dem Gebiete der Natur. und Heilk.* No. 75.) I do not hesitate, therefore, to consider the glossopharyngeus as the instinctive nerve of nutrition. This explains its constant occurrence in beasts, while in birds no lingual nerve has hitherto been found.

Besides the specific feeling of the sensitive fibrils of the glossopharyngeus, their reflex action when irritated, or *retching*, is also worthy of observation. It is interesting to remark how an irritation causes different reflex effects even in regions which border on each other. An irritation of the sensitive fibrils of the nervous vagus in the glottis is followed by coughing; irritation of the sensitive fibrils of the vagus in the œsophagus, by an attempt to swallow; irritation of the sensitive fibrils of the glossopharyngeus at the root of the tongue, and the velum palati, by retching; and how accurately limited is this specific sensibility and its reflex action may be seen from an example mentioned by Marshall Hall (Lectures on the Nervous System and its Diseases), where, in patients who tried to produce vomiting, and came too near the pharynx with a feather, an effort to swallow was produced, and the feather was drawn into the œsophagus. These reflex actions might be taken advantage of as reagents in examining the energy of sensitive nerves; and as I lately produced coughing in a horse by irritating the nervus vagus in its course along the neck, without touching the larynx, so I am convinced that irritation of the glossopharyngeus would produce retching, however far from the tongue it was applied. This motion also explains the law of neighbouring reflex actions, as far as the sensorial irritation being communicated to the spinal marrow excites into

action the motor elements of the glosso-pharyngeus, which come off in the vicinity of the sensitive fibrils.

The case above detailed, not only explains the powers of the lingual nerve, but affords a commentary on the laws of isolated communication and of combined sensations. The former law gave confidence to the diagnosis of the seat of the disease, while the other explains the appearance of the spasmodic sneezing. For this spasmodic sneezing is best explained by irradiation of the sensations, by a transference of the irritation from the sensitive fibrils in the third branch to the nasal filaments of the fifth nerve (without deciding whether in the Gasserian ganglion or in the central apparatus), and by a respiratory reflex movement. The combined sensation in the cerebral ends of the nasal filaments was so lively, and the tension so strong, that every cause produced sneezing, so that my experiments upon the sensibility of the face in this patient were frequently interrupted by it. This case is not only full of physiological interest, but it is of great pathological value as regards the affections of the fifth nerve, formerly so obscure.

For only a confused idea was formed of the cases of hyperæsthesia (increased sensibility), as appears from the dissertations on Fothergill's Neuralgia Facialis; and paralysis of the fifth pair was a perfect *terra incognita*, until it was discovered by the genius of Bell. Since that time, valuable single cases have come to light which open a clearer view of these conditions. The paralysis may affect either the sensitive or the motor faculty of the fifth pair or both which may be ascertained by simple clinical experiment. With the needle in our hand we mark out the limits of the anæsthesia; and by giving the patient a small bit of bread to chew, we learn the inactivity of the masticatory muscles which are affected. Again, the paralysis may have either a central or a peripheric origin; but the latter must be understood more comprehensively than it generally is. The term "root of a nerve" has led persons astray in pathology, by making them consider the aggregate of nervous fibrils, which go off from the brain at particular spots, as origins or central ends of those nerves, and then refer their affections to the domain of the central apparatus, or brain. This is erroneous, however, since from the spot where the nerve leaves the brain, to the utmost limit of its course, it can be considered only as a peripheric nerve, and is subject to those laws of transmission which govern peripheric nerves. Hence the paralysis of the fifth pair is peripheric, whether its cause is seated in the surface of the face, or in the

sphenoid bone, or in the Gasserian ganglion, or in the vicinity of the pons Varolii. A diagnosis may be made of this difference in the seat; for the more the anæsthesia is confined to single filaments, the more peripheric, if I may so express myself, is its origin. Thus, after the extraction of a grinder in the lower jaw, the anæsthesia was confined to half the lower lip; in other cases to the ala nasi, to the upper surface of the eye, and so on. When the loss of feeling is more extensive—when it affects not only the external surface of the face, but also its cavities—the investigation must be made anatomically; and if the whole course of a given branch is found to be without sensation, as was the case in my patient, then the filaments before they separate and spread, must be affected in their *ensemble*—in the entire branch, before it comes out from the cranium. Finally, if the anæsthesia affects the whole sensitive portion of the fifth pair, the cause lies in the Gasserian ganglion, or in the brain itself; and in such cases there is generally paralysis of the masticatory muscles from injury of the neighbouring motor portion. When the Gasserian ganglion is affected other symptoms appear, which are physiologically interesting—namely, disturbances of the vegetative functions in the parts affected by anæsthesia; the clearest being inflammation, suppuration, and ulceration of the eye, redness and hæmorrhage in the cavities of the nose and mouth, and puffiness of the gums. Such cases are mentioned by Serres, and more lately by Abercrombie, in the last edition of his work on Diseases of the Brain, p. 424.

Not only the seat, but the kind of the cause of the peripheric paralysis, may be conjectured with probability. When some disorganizing cause is present, with irritation—for example, the process of inflammation or softening—the law of eccentric appearance has force. The impression is referred by consciousness to the peripheric ends of the sensitive fibrils, and the patient complains of pain in those parts which have lost their capacity of conveying impressions from without. When a tumor capable of enlargement and extension compresses the fifth pair near the pons Varolii, one or more of the neighbouring nerves are affected at the same time; and this is made out by the relation of the symptoms in point of time, for their relation as regards space might occur from a central affection of the nerves in the brain. The various steps of the paralysis occur in succession, by which the case becomes very instructive in point of diagnosis.

When paralysis of the fifth pair has a central origin, I have always found that

the portio minor and the third sensitive branch are paralyzed at the same time. Partial anæsthesia and paralysis of the masticatory muscles are present, and they are almost always confined to one side of the face, just as when the origin of the paralysis is peripheric. I have always found it so in recent hæmorrhage of the brain, when, by the combination with hemiplegia, the analogy pointed out by Müller (*Handb. d. Physiol. I. Bd. 2 Abth. § 637*) between the third branch and the spinal nerves (the former arising from the union of the motor portio minor and a part of the sensitive portio major), becomes still more evident. This anæsthesia is quite complete, as in the case given above; one half of the tongue is deprived of taste as well as of feeling, and a more frequent opportunity is thus afforded of convincing oneself of the sensitive and gustatory powers of the lingual nerve. But if the patient survives the attack, the anæsthesia seldom lasts so long as the paralysis of the masticatory muscles, just as in the paralyzed extremities feeling returns sooner than motion. The central origin may be recognised as well from the equal participation of other nerves (most commonly the facialis, the hypoglossus, and the nerves of the arm and leg), as from the fact that transmission usually takes place transversely, while in peripheric affections it takes place on the same side. I have set this forth at greater length in another essay, entitled *Neuropathologische Studien*, in the *Wochenschrift für die ges. Heilk. Jahrg 1836.—Müller's Archiv. 1838, Heft. iii.*

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,

AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.

By DR. VENABLES.

Lithic acid diathesis.—It is intended to express by this a tendency to deposit lithic acid, either pure or in combination with some base. It has been shewn in a former part of these lectures, that lithic acid requires ten thousand parts of water for solution; and that it could scarcely exist at all in the urine unless in soluble combination with some base, and that this base is ammonia. We therefore find that when this principle is deposited, it is either in its pure state or as lithate of ammonia, and therefore lithic urinary calculi always consist of one or other of these principles. The deposition, therefore, of these two principles may arise from one or other of the following circumstances:—Either so large a proportion of the substance may be secreted, that the watery portion of the urine is not sufficient to hold it in solution; or some other principle—an acid, for instance—may be secreted in such abundance as to precipitate the lithic. In the first of these cases the lithate of ammonia is the matter deposited; in the second, lithic acid separates frequently in the crystallized form, or as gravel.

Lithate of ammonia sometimes so abounds in the urine, that although it is held in solution at the temperature of the urine when passed, yet separates when it

has reached the temperature of the atmosphere. Here are specimens in which, as you see, it has separated in great quantity, but by heating the urine it re-dissolves. It also assumes various colours, as we have already seen; but it is not necessary to enter at length upon these. It may be either yellow, red, or pink. They do not under common circumstances concrete into stones, but are rather attendant upon particular states of system. They are very frequently associated with fever, and are frequently produced in large quantity when the function of the skin has been much excited.

It may be questionable whether lithic is ever generated alone in such quantity as to be insoluble in the urine. When the quantity of lithic acid exceeds the usual standard, it is probably secreted with a sufficiency of ammonia to hold it in solution. If, then, when the urine abounds in lithate of ammonia, any other acid be secreted in a free state, the lithic will be disengaged, and will separate in the crystallized form. If to this urine we add some acetic or hydrochloric acid, as it contains a large proportion of lithate of ammonia, the lithic acid will separate in the crystalline form. Here is some in this tube which has been treated with dilute hydrochloric acid, so that the lithic acid has separated gradually, and you see it deposited in crystals upon the sides of the tube, especially upon that side which has been a little more dependent. This is probably the way in which lithic crystallized deposits take place. The precipitating acids are perhaps various. The mineral acids—as the sulphuric, phosphoric, hydrochloric—act remotely; that is, they displace the weaker or combustible acids, setting them free; and they in turn displace the lithic. Thus the lactic and sometimes even the carbonic, which, as we have already seen, displaces the lithic. In the specimens of gravel which I shew

you, you see that the lithic acid has a crystalline appearance. If lithic acid be dissolved in potash, and then precipitated, it at first separates as a bulky gelatinous mass, which does not assume the crystalline appearance for some time. "This," says Prout, "is a very important point connected with the pathological history of this principle, as the state above alluded to is that in which it is first separated from the kidneys, and often exists in the urine; and the knowledge of which will enable us to explain almost all the phenomena of lithic acid gravel.*"

We have already stated in a general way the symptoms of calculi in the different parts of the urinary apparatus. But these symptoms alone are equivocal, and therefore it is necessary to attend to the state of the urine, by which our diagnosis will be materially assisted. The deposition of crystallized lithic acid in the urine is usually attended with pain or uneasiness in the loins or region of the kidneys. These pains are very frequently mistaken for lumbago. But they are attended with considerable irritation, and a sense of burning about the neck of the bladder, extending along the course of the urethra. There is desire to void the urine very frequently, which is passed in very small quantity at a time, and leaves a sensation as if something remained behind in the bladder.

The digestion, too, is much deranged; if not constantly so, is very easily deranged by the slightest errors in diet, or even regimen. Hence erudities, acidity, flatulency, upon the slightest errors, as the use of fruit, acids, ascendent wines, vegetables, salads, pastry, and such unfermented grain, fresh bread, fatty and indigestible aliments of all kinds.

With respect to the state of the urine, as to its sensible qualities, it will be found in general to be transparent, and of a bright copper colour, or assumes these appearances on cooling. This condition of urine generally indicates acidity. In relation to the mechanical properties, the quantity, though small at each micturition, yet, from the frequency, it amounts to quite a sufficiency in the twenty-four hours. The specific gravity is generally high—from 1.020 to 1.025, or even more. Chemically, it is distinctly acid. Thus it produces an acidulous reaction upon litmus paper; but as healthy urine does and ought to redden litmus, it will require practice to determine whether the effect be owing to a free acid, or to the lithate and superphosphate, &c. of ammonia which it naturally contains. The separation of the

lithic is a very good indication of the presence of a free acid; and, indeed, even the quantity may be estimated by the time required, and the quantity of lithic acid precipitated. Thus, if the lithic acid is not precipitated for some time, or until the urine has begun to cool, the quantity of precipitating acid is not very abundant. But if no lithic acid at all precipitates, then this has taken place in the bladder, and the quantity of free acid must be considerable, and a very formidable disease is indicated. If, then, the functional signs be assisted by an examination into the state of the urine, we shall not have much difficulty in determining the existence of the lithic acid diathesis.

Causes and pathology.—The causes which, acting chemically on the urine, produce precipitates and the aggregation of these, are obvious enough; but what gives rise to such tendencies, or why the elements of calculous concretions should be generated in such unusual proportion, is matter which seems to be still involved in considerable physiological obscurity. Aretæus solves the difficulty very easily: he says there are but two causes; "in old men the body is cold, and the blood thick; cold, moreover, more quickly inspissates thick matters; of which, the naturally warm springs which are speedily congealed into a sort of callous stone by cold are an illustration; but in children a great quantity of slimy matter, washed out from the blood, affords the origin of the generation of calculi. These are the affections from the generation of calculi*."

Upon the generation of lithic acid, after what has been stated upon it and urea in the commencement of these lectures, it will be unnecessary to traverse over again the same ground. We found that there were some grounds for believing that urea was probably the primitive, and convertible into lithic acid†. Therefore if such views should be ultimately established, the pathology will consist in developing the means by which this conversion takes place to so unnatural an extent; for in the lithic acid diathesis, not only is this principle precipitated, but it is generated in

* *Διτταὶ δὲ αἱ αἰτίαι τῆς πήξις γέρονσι μὲν, τὸ σῶμα ψυχρὸν, παχὺ τὸ αἷμα. ψυχρὸν δὲ τὰ παχέα θάσσον πύρρυνσι τέκμαρ δε, τῶν ἰσθμῶν τῶν ὀστέων φύσει αἰ πηγαί, ἀποψυχθεῖν γὰρ ἐς παροειδῆ λίθον πηγυρίζαι. παιδίοισι δὲ πολλὰν ὑπὸ τῶν αἱμάτων τὸ ἰλυώδες ἐψήθεν γενέσθαι, ὅκως πύρ, τὴν ἰσχυρὴν λίθων μὲν οὖν ἀμφὶ γενέσθαι, τοιάδε πάθη.—De Sig. et Caus. Diut. Morb. lib. ii., cap. 3.*

† Very often in urine from which lithic separates abundantly, or which abounds in lithate of ammonia, there is a very great excess of urea, as may be satisfactorily shewn by nitric acid.

much larger proportion than in health. We know that lithate of ammonia frequently exists in the urine in very large quantity, as you may observe in the specimen which we have here. Evidently the lithic acid separated and estimated would greatly exceed '001 of the urine, and therefore must proportionally exceed at least the admitted healthy proportion.

It has also been stated that urea, and even lithic acid, have been—the former certainly, the latter more doubtfully—detected in the blood. You may also remember that Dr. Prout considers albumen as the radicle the proximate elements of which are urea and lithate of ammonia. These things admitted, there can be no great difficulty in conceiving the presence of lithic acid, and, of course, its precipitation when an excess of any acid is generated by the kidney. For further remarks upon this question I must therefore refer you to the lectures on the pathology of urinary diseases in general.

In considering the causes and general circumstances under which lithic acid appears in the urine, and the constitutional condition with which it is associated, we find the tendency and danger to be greatly modified by the age of the patient. Children, especially those of dyspeptic and gouty parents, are very liable to lithic deposits of whatever form. When of the amorphous character, their appearance is not attended with much irritation in the urinary system; but when there is a frequent desire to pass the urine, and that it is voided in small quantities at a time, if the urine be carefully examined it will be found to abound in lithic acid, and this principle will be found to separate in the crystalline form. The irritation in such cases frequently causes the child to wet the bed. Such cases require immediate attention, to prevent evil consequences.

When arrived at puberty, however, we find from this to the age of forty that the tendency to lithic acid deposits is much less than at any other period of life. Where, however, there is a very strong tendency to derangements of this kind, the period of life offers no obstacle to lithic deposits, and they continue sometimes uninterruptedly, at other times with occasional remissions. This, in fact, is what gives the laminated character to calculi, there appearing to be periods during which the deposition of lithic acid is interrupted; when, after a time, it again separates and gives a fresh coating to the calculus. Except in the more severe cases, the lithic acid is mostly voided in the state of gravel, and consequently the irritation and other secondary symptoms are not severe. They therefore

attract but little notice; and as, at the period when the lithic acid is deposited from the urine, the patient's health is better than ordinary, this serves to lull his apprehensions. Principally from these circumstances, there is less danger of the formation of calculi at this period than at any other. But should it occur, it is generally owing to accident or some other adventitious circumstance, unless, indeed, there is a more than usual tendency to the disease.

After forty, lithic acid will now be found to be deposited in very large quantities at intervals. The deposition is found to be preceded, for some time, by febrile action and general derangement of the health. The acid, too, now separates in the concrete state, and it is thus that renal calculi are frequently originated. These things are most apt to occur in persons who have been subject, generally all their lives, to lithic deposits. The same, too, are apt to occur in those who have lived an indolent, luxurious sort of life, and who may be supposed to have an hereditary disposition to gout, although they may have never had an evident attack of the disease.

We generally find the health of persons subject to urinary affections much influenced by the discharge or non-discharge of lithic acid with the urine. Thus such persons never feel so well nor so free from their ordinary derangements, as when lithic acid gravel is freely deposited by the urine. Thus nervous affections, indigestion, crudities, and other anomalous symptoms which have long harassed the patient, suddenly remit on the discharge of lithic acid gravel or a small renal calculus.

About sixty or seventy, when the constitution has sustained a severe shock, the urinary system partakes of the general decay, and there is a corresponding change in the mode in which the lithic acid separates. Frequently the bladder becomes diseased; mucus in excess, and even pus, are now found in the urine; and hence the urine is neutral, and the earthy phosphates begin to predominate. "Under these circumstances, where the urine had previously for years deposited the lithic acid chiefly in the state of crystals, these will in a great measure disappear, and, instead of them, impure or imperfect lithic acid, in the shape of minute globules of various sizes, will be separated from the kidneys in great abundance. In most of these cases, there is a good deal of pain in the back and irritation about the urinary organs, even when the concretions are only of small size. In others there is much less irritation under these circumstances than one could imagine. In all instances, however, this may be considered as a most

dangerous state of disease, not only from the constant liability of the patient to the formation of renal or vesical calculi, which all other circumstances likewise conspire to render probable, but, on the other hand, from the danger there is of suddenly checking the secretion of lithic acid, which is sometimes followed by great derangement of the general health, and apoplexy*." The same authority likewise asserts, that organic diseases of the kidney, or even of the parts contiguous, are exceedingly apt, in some habits, to be accompanied by the secretion of a large proportion of lithic acid. Thus nothing is more common than to see those who have suffered from hepatic affections in hot climates, &c. labour under gravel; and in such cases, the right kidney is almost always the evident seat of the disease†.

Calculous, and so far lithic, depositions are often associated with cutaneous affections. I have repeatedly seen instances of this kind. Sir Gilbert Blane also states, that calculous affections are often associated with cutaneous diseases, especially impetigo, dependent on an hereditary predisposition, and incident on what has been termed a scorbutic habit‡. Excesses also in eating and drinking, with indolent habits, as in gout, frequently cause a calculous deposit in the urine. "Most frequently, however," says Prout, "the tendency to these diseases is connected with some unknown causes peculiar to certain districts or countries; as, for example, the district of which Norwich may be considered as the centre, in which more calculous cases occur than in the whole of Ireland and Scotland§. In such instances, the water, diet, temperature, &c. of the district has each been accused, in its turn, of being the exciting cause; and that hard waters, in conjunction with other favourable circumstances, have a great influence in producing this affection, I have no doubt¶. In a word, it may be stated, that if lithic acid be generated in excess, either alone or in combination with a base, any thing favouring the generation of free acid, will cause a deposition of the lithic acid, and the formation of this description of calculus. Every agent affecting the health, therefore, will have an effect of this kind. Dr. Prout mentions two instances of this predisposition called into action by sitting on a cold damp seat for some hours. Hard-boiled dumplings and badly fer-

mented bread have a similar operation, and it is necessary to remember these, as correcting or obviating such form an essential part of the treatment.

Treatment.—The treatment properly consists of those means which are best suited to arrest the effects of this diathesis, and to prevent or limit the consequences that would increase if its progress were unrestrained. As we have shewn that lithic acid shews itself under two distinct forms, it will perhaps be the better plan to consider each by itself, therefore that will bring us to consider the treatment of lithic acid in the amorphous and in the crystallized form.

Amorphous sediments.—It has been shewn that these appear in three varieties, viz. as yellow, red, or lateritious, and as pink sediments. The first shews a very great predisposition to all the phenomena and consequences of the perfect and most complete lithic acid diathesis. These consist principally of the lithate of ammonia, coloured by the colouring matter of the urine, but at the same time intermixed with a greater or less proportion of the phosphates, and some lithate of soda. They appear, in dyspeptic persons, upon the slightest errors in diet, and the paler they are the greater the tendency to a deposition of the phosphates. The treatment, therefore, can scarcely be reduced to any formal plan, and must depend upon the circumstances of each particular case. The patient should avoid all errors in diet; should strictly and carefully attend to regimen, as exercise, clothing, &c. Thus the quantity and quality of the food should be carefully regulated; for although errors of this sort may not occur frequently, yet irregularity leaves consequences that are overcome only by a long subsequent repentance. Dr. Prout lays it down as an axiom, that excess in the quantity is more injurious than in the quality of the food. "Any stomach may digest a *little* of any thing, but no stomach can digest a *great deal* of any thing." I have entered so fully into the general treatment of indigestion in relation to urinary disorders, in an early part of these lectures, that I do not consider it necessary to take up any more time here upon the subject.

Red or lateritious sediments.—These, as was before observed, principally consists of lithate of ammonia, or of soda, or sometimes a mixture of both, tinged with the colouring matter of the urine, with a mixture of more or less of the purpurates of the same bases. These sediments generally indicate the secretion of nitric acid, and also the prevalence of fever of the phlogistic or inflammatory character. In fact, in all sorts of derange-

¶ Ibid, 141.

ment, general or local, if these sediments appear we shall find the excitement run high, with hard frequent pulse and inflammatory action. Hence they prevail in rheumatism, gout, hepatic affections, the phlegmasia, and fevers of the synocha type.

The treatment, therefore, it is evident, must be antiphlogistic, but of course modified by the particular circumstances. As general means, we may mention bleeding, and other antiphlogistics, mercury, antimonials, and counter-irritants. The adaptation of other means must depend upon the particular nature of each case.

Pink sediments.—These sediments indicate a broken-down worn out constitution. Their colour is owing almost exclusively to the purpuration of ammonia, as they contain none of the colouring matter of the urine. They evidence a more copious secretion of lithic acid, and consequently the formation of a greater proportion of purpuration of ammonia, while the colouring matter of the urine present in such large proportion in inflammation, or inflammatory fever is almost wholly absent. They also frequently appear in the urine of dropsical patients labouring under organic diseases, in hectic persons, and those suffering from chronic diseases of the viscera.

In such cases it is evident that the treatment, even the constitutional, will depend upon a variety of local circumstances, and which it would be impossible individually to specify. In many cases, tonics and bitters are useful, and opium with other narcotics to calm the extraordinary irritability under which patients of this sort frequently labour. In general, antiphlogistic means, at least to any great extent, are not only uncalled for, but in many cases would be injurious. There may, of course, be cases present requiring the active employment of antiphlogistics, but as a general rule they will be seldom required. Mercurials, so useful in the former case, do not seem indicated here. Indeed, in such cases the urine frequently is loaded with albumen; and I have remarked, that mercury administered to any extent in such cases does a great deal of mischief, producing ulcerations of the surface, disease of the kidneys and of the mucous membrane of the bladder; or if all or any of these already exist, they are much aggravated by mercury, and rendered more inveterate. Upon the whole, therefore, it may be laid down that tonics, narcotics, and antispasmodics, are the best remedies here. I have in some cases found sarsaparilla a useful remedy; and I also think colchicum, judiciously administered, a useful remedy.

LECTURES

ON THE

VENEREAL DISEASE,

*Delivered at the Aldersgate School of Medicine,
March 1839,*

By F. C. SKEY, F.R.S. &c.

LECTURE VII

ON CATARRHAL VENEREAL DISEASE, OR
GONORRHOEA.

Symptoms of gonorrhœa.—Mild and virulent.
—Chordee.—Surface affected often disproportionate to the virulence.—Pathology of gonorrhœa.—Acquired both spontaneously and by contamination.—Difficulty of distinguishing venereal from other forms.—May be produced from leucorrhœa.—Ditto during menstruation.—Case of spontaneous gonorrhœa.—Rheumatic gonorrhœa.—Treatment.—Repellent and pullative.—Inflammation of neck of the bladder.—Excessive depletion objectionable.—Gleet.—Its nature and treatment.—Stricture.—Treatment of gleet by bougies inefficient.—Is gleet communicable?

GONORRHOEA consists in a discharge of purulent matter from the urethra, having for its ordinary concomitants, pain during the expulsion of urine (*ardor urinæ*), frequent desire of micturition, and chordee, or erections during sleep.

The disease commences with an itching sensation at the orifice of the urethra, which some authors have described as not altogether disagreeable; the itching is followed by inflammation of the canal within the glans, indicated by a red and swollen state of the orifice, in passing through which the urine generally creates pain—at first inconsiderable, and subsequently severe. Sometimes, however, pain is not present throughout the entire case to its cure.

In severe cases, a degree of soreness extends over the whole penis, which is greatly aggravated by the nocturnal erections. The fluid which first exudes from the orifice of the urethra, is small in quantity, and of a whey-like colour and consistence: this is gradually converted into pus of a greenish or of a pinkish hue, and of the consistence of cream.

Gonorrhœa arising from venereal contamination, exhibits its first symptom, that of itching and redness of the orifice, at an interval varying from 36 to 48 hours after connexion: these may continue during 18 or 24 hours longer, and the first discharge appears at an average of about three days from the date of the exciting cause.

The disease attains its height in about a week, and is then attended by great pain in making water, referred to the last inch

of the urethra alone, with discharge of thick,ropy, and greenish pus. In this state it will continue during a fortnight, or longer, provided the inflammation be not considerable. The pain then diminishes; the purulent matter becomes thinner and more watery; gradually lessens in quantity; and, at the expiration of about five or six weeks from its first appearance, the disease dies a natural death, leaving no trace behind of its existence, beyond a slight temporary contraction of the urethra, indicated by the diminished size of the stream of urine. This description, however, will not apply to all cases.

We often find it presenting symptoms which, whether caused by constitutional disposition, or laxity of treatment, protract its existence to a much longer period than that I have mentioned.

Instead of the pain during micturition being considerable, it may be so intense as to induce the person to prolong as much as possible the intervals between the act; or, again, irritation being conveyed to the bladder, may create a much more than usually frequent desire to micturate. The case may be complicated with chordee, or painful erections during sleep, spasm of the urethra, pain at the neck of the bladder and orifice of the anus, and discharge of pus discoloured by blood, or even of blood alone. Mr. Hunter divides chordee into inflammatory and spasmodic—a division of which I confess I am not cognizant. Mr. H., however, first explained the nature of chordee, and I shall quote his description, from his work on the Venereal Disease. He says, "When the inflammation is not confined merely to the surface of the urethra, but goes deeper, and affects the reticular membrane, it produces in it an extravasation of coagulable lymph, as in the adhesive inflammation, which, uniting the cells together, destroys the power of distension of the corpus spongiosum, and makes it unequal in this respect to the corpora cavernosa, and therefore a curvature on that side takes place, at the time of erection. The inner membrane being on the stretch, is sometimes torn, which causes a profuse bleeding from the urethra. Chordee arises from a greater degree of inflammation than common."

The spasmodic chordee, he says, comes and goes, but at no stated times.

It seems, perhaps, more reasonable to suppose that the occasional absence of pain during erection, which, by the by, generally occurs towards the latter stages of the affection, is due to the rapidity and degree of distension of the corpus spongiosum: if it be not so, Mr. H.'s explanation of the cause of chordee, which is that generally adopted, is probably erroneous;

but this is unlikely. The inflammation attendant on gonorrhœa may be local, but severe; or more extensive, with a less degree of severity. In the former case, the ardor urinæ is intense, but local, and there is severe and repeated chordee throughout the night, which may be accompanied by the discharge of blood, or bloody matter. In the latter we have the pain during micturition, extending over a larger surface—perhaps involving the whole track of the urethra—with a deep aching pain about the orifice of the anus, pain in the neck of the bladder, and inability to retain the urine beyond the secretion of a few ounces, or even less.

Gonorrhœa may be the product of a poison similar to itself, introduced into the urethra during sexual intercourse, or may arise from other causes, independent of the presence of gonorrhœal matter, in the party from whom it is contracted.

The mode in which it is acquired from an infected person is not very easy to understand, unless we suppose that the mucous orifice of the urethra is the first part affected, and that the disease extends therefrom to its general seat, which occupies the canal within and somewhat below the glans.

I have adverted, in a former lecture, to the identical characters of the disease when arising spontaneously or produced by non-venereal irritation, and when appearing as the obvious result of true venereal contamination. There does exist, however, one point of occasional difference, although, I confess, I have no experience of a character sufficiently positive to justify the belief in the non-identity of the various forms of gonorrhœal or catarrhal disease of the urethra. I allude to the nearly uniform date from sexual intercourse which is believed to mark the true venereal gonorrhœa, and this I have stated at three days; whereas other examples, unequivocally not the product of venereal poison, are more irregular and uncertain in the date of their first appearance, the average, however, being considerably within the above period.

But in order to establish the venereal origin of the class of cases appearing at three days after connexion, rigid inquiry and long continued observation are required; and although I have myself abundant experience of the early and almost immediate appearance of gonorrhœa in men after intercourse, who, tested by a form of evidence that, on any other subject, would carry conviction to the most sceptical mind, were indisputably not the subjects of gonorrhœal contamination, still the origin by venereal contamination of the more regular form, can only be maintained on such evidence as will establish the posi-

tive existence of venereal poison in *all* such cases. It is not sufficient that we observe the irregular date of appearance of non-venereal gonorrhœa, but we must also be convinced of the venereal character of the regular forms. At this experience we have not arrived, and till this is accomplished I shall hold to my former statement—viz. that there exists no distinctive symptoms by which to discriminate the spontaneous from the venereal gonorrhœa.

But setting aside the question as to the date of their first appearance, all the other symptoms are the same, as are the means to be resorted to, for their respective cure; still I cannot entertain a doubt that a very considerable proportion of cases of gonorrhœa, are *not* the product of a specific poison.

The opinion favourable to such contamination by a specific poison, is founded on the analogy of the mode of propagation of apparently similar diseases. Still the power of contamination is no proof of the non-spontaneous origin of a disease, even though venereal; nor is it surprising that the opinion should have generally prevailed that gonorrhœal matter is indispensable to the communication of gonorrhœa. Discharges from the urethra have been known and described, by all authors who have written on this subject, from the date of Mr. Hunter's work. Yet the authority of the old doctrines has, as I conceive, so prejudiced the reasonings of these writers, that the spontaneous origin of gonorrhœa is never admitted; so that whenever the discharge of matter occurs, without evidence unfavourable to contamination, it is pronounced venereal; and when arising independently of connexion, or following connexion with a person declared free from disease, it is termed simply "*discharge from the urethra*;" and yet, coupled with this discharge, we have painful micturition, severe chordee, great irritation in the perineum and bladder, and, I would venture to add, the power of propagating gonorrhœal disease.

It is rather a striking fact, that gonorrhœal disease is greatly limited to age and habit. The disposition appears to become exhausted in the course of years, although the habit of promiscuous intercourse, the liabilities from external causes remaining the same, continues unchecked. We do not frequently see cases of gonorrhœa in persons above 28 or 30 years of age. It is also rare for a person to have had one single clap only; either he has been the subject of two or more, or he has escaped that form of disease entirely.

Do not these facts point to the disease as generated only in some peculiar states of constitution, and often rather deve-

veloped by sexual intercourse, than communicated from external sources of contamination?

The opinions I entertain on this subject, are not the product of mere speculation, and still less of a desire to differ with other and more experienced authorities. They are deduced from, what appeared to my judgment, positive facts, and those by no means few or far between. I may venture to say it is notorious that leucorrhœa will produce gonorrhœal discharge; and if a poison be essential to gonorrhœa, whence comes it? Leucorrhœa is not supposed to contain the elements of gonorrhœal poison. Again, gonorrhœa is by no means an infrequent result from intercourse about the period of menstruation; and it also follows intercourse with women under circumstances of mechanical violence. Either of these conditions may produce the disease in question; and if you will make inquiry in the course of your future practice, you will have no difficulty in obtaining examples sufficient to convince yourselves of the fact. It is an important fact to establish, because its knowledge will teach us caution in unhesitatingly denouncing the sources from which the disease has been derived, and distrusting the positive assurances of persons whose word had been hitherto unquestioned, and whose characters had been spotless. But it has been argued by those who distrust these views, why do not these diseases attack married men? why should either sex be exempt from them? I reply, that they are not exempt; that such diseases do occur, and by no means with the infrequency you may imagine, in the early period of married life. At least I am satisfied that our sex by no means rarely pays this penalty of seduction, more especially of very young women, and even when the act is not completed. I can readily conceive reasons why it is not more frequent in married life, but on them I shall not now dwell. It is sufficient for my purpose, that gonorrhœa does occasionally occur between healthy persons, having intercourse with none others. I mentioned one example in my first lecture on this subject: it was that of a young gentleman who seduced a girl of somewhat youthful years. I knew him well for a considerable time prior to the occurrence; and I will take upon myself to assert, that he had never committed himself to a single act of intercourse with woman till that hour. The parties resided in the same house, and their intercourse was frequent. After indulging their mutual inclinations during three months, he called on me one morning, and, in a state of the deepest despondency, related to me the particulars of his amour, and stated that he had a severe

gonorrhœa. He added, that he did not care for the disease, but he was horror-struck at the idea that his immorality had so soon corrupted the virtue of a hitherto modest girl. Of course I asked him whether the young lady was still attached to him, and whether he had reason to suspect her fidelity. The earnestness of his reply convinced me of the sincerity of his conviction, that her attachment was unabated; and but for this evidence to the contrary, that her fidelity was unchanged. I told him that I would see him safely through the gonorrhœa; but advised him in future to be more cautious, and to abstain from intercourse with that, or any other damsel, about or during the period of menstruation. He pleaded guilty to this surmise. His gonorrhœa was very severe; he was three months under treatment, with chordee, bloody discharge, and general inflammation of the whole urethra and neck of the bladder. His case I treated as I would treat any, and all other similar forms of the same disease, from whatever cause they might arise.

I have selected this, because it was a well-marked case, and more especially because I knew the gentleman intimately, and have the fullest reliance on his word.

This form of gonorrhœa is comparatively uncommon, because peculiar constitutions, or peculiar states of the health, are essential to its occurrence. It is most commonly attendant on rheumatic diatheses, when it is often accompanied by general rheumatism, affecting the joints, the loins, and the sciatic nerve—cases that are known under the title of gonorrhœal rheumatism, from the idea, that the constitutional symptoms are the product of the local cause. They are brought forwards as examples of the constitutional symptoms of gonorrhœa. If such a case present itself to you, you will find on inquiry, that rheumatism has again and again existed in the affected person without gonorrhœa; that discharge from the urethra, more or less acute, has previously appeared during an attack, after long abstinence from sexual intercourse, when the presence of a specific poison was manifestly impossible, and that in truth the rheumatic habit is the exciting cause, and the gonorrhœa the effect, and not *vice versa*. You will, I think, agree with those who accord to this disease the title of *rheumatic gonorrhœa*, which may appear entirely spontaneously, and without the excitement of sexual intercourse, or may appear as the product of such excitement; and if so, its symptoms will generally prove in all respects more severe and more protracted. If you examine these patients critically, they will most frequently themselves express surprise at the appearance

of clap, whether in reference to the source from which they are driven, only by their misapplied confidence in our arbitrary assurance, to suspect it, or to the length of time that had elapsed since they had had connexion at all.

In a number of the *MEDICAL GAZETTE* for January 1839 is a paper by Mr. Lawrence, in which he details a case of the above kind, which had been for some weeks under my care at St. Bartholomew's Hospital, during his absence. The case is quoted as an example of gonorrhœal rheumatism; but in this, as in almost every other, I obtained such information as convinced me, that the view I have taken of this disease fully justified the opinion I have stated. The man was a baker—an employment in which rheumatism is most rife. "He had had," states Mr. L., "an attack of gonorrhœa four years prior, which lasted five or six months, without causing any mischief beyond the primary seat of the disorder." In 1837 he contracted gonorrhœa again; it was attended with profuse discharge, but not much scalding pain. The limbs became affected in a few days. The testicle became inflamed, and the discharge from the urethra ceased with the rheumatic pains; the testicle protruded through an ulcerated opening of the scrotum, and was subsequently detached. The gonorrhœal discharge reappeared after upwards of two months' residence in the hospital, and, with it, the swelling and pain of the joints."

I remember to have made particular inquiry into the early history of this case, and I confess, however unwilling I may be to differ in opinion from Mr. Lawrence, that I did not then, nor do I now, entertain a doubt that the gonorrhœal affection was but a symptom of that rheumatic attack which, with the inflamed testis running on to so very unusual a crisis, formed in reality the staple commodity of the case.

In a work entitled, "*Sur la Non-existence de la Maladie Vénérienne*," a case is quoted which, although fortunately of too deep a tone to accord with examples at the present day, and attended with consequences which, to the honour of our nature, we may hope are rare, yet points to the necessity of exercising caution in our decisions, especially when their moral influence is likely to weigh greatly in the scale. A young man became attached to a young female friend, "*à peine sortie de l'enfance*," and married her after some years of mutual attachment. Some months after this "*hymen fortuné*!" the young man was compelled to take a journey to some distance, and, while travelling, he experienced pain in making water, and shortly perceived a discharge from the

urethra. On arriving at a town, he consulted an eminent surgeon, who assured him he had a gonorrhœa. "Mais, monsieur, je suis nouvellement marié," and assured the learned surgeon, that he had never known any woman but his wife from the hour of his birth. "Comment," replied le chirurgien, en souriant, "vous voudrez me cacher la cause de votre mal : de quelle pays êtes-vous ? Vos jeunes gens rougiroient ; je vous certifie, monsieur, que vous avez une belle et bonne chaudepisse." The youth continued to protest his innocence. Some days after the testicle swelled. The surgeon now assured him that if his wife were virtuous, that he must have had "une affaire" with other women, and that the pox remained in his blood from that period. Between the two alternatives of his own or his wife's purity, of course he could not entertain a doubt. He wrote to her an indignant and passionate letter, and then blew out his brains. The unfortunate woman submitted to an examination, which proved her free from disease—never uttered another word—shortly miscarried, and died. So much for the honour of our noble profession!

Now, that this man was the subject of "une belle et bonne chaudepisse," who can for a moment doubt? and who can hesitate to acknowledge that all the symptoms of virulent gonorrhœa might have followed? So far no wrong was done; but to assert that he had acquired the malady of necessity from sexual intercourse, was a flagrant and unpardonable outrage on truth, and hence the horrible tragedy that followed.

The discharge of gonorrhœa is poured out from the secretory capillaries of the mucous lining of the urethra, occupying generally the upper one or two inches. It is not confined to the follicles or lacunæ, but is secreted from the whole surface of that portion of the canal, which is neither ulcerated, nor even excoriated, although it occasionally presents the appearance of rawness, from the acute degree of the inflammation. As I have before stated, the canal may be affected along its whole extent; that is to say, it may participate in the general inflammation, while the purulent secretion is probably confined to the upper portion.

Treatment of Gonorrhœa.

The treatment of gonorrhœa will be modified by the date—by the intensity of the disease—and by the constitution of the subject. To take the disease in its earliest stage, as the first subject of consideration, we may treat it on the principle of escharotics to certain forms of sore.

But this will only apply to the very early stage, before either painful micturition or purulent discharge is established. It is applicable, therefore, to cases in which gonorrhœa may be expected, rather than those in which it exists. This treatment, which is powerfully repellent, consists in the recourse to the most positive stimulants, which may be applied both locally and internally. As injections, we may employ from three to five grains of sulphate of copper to an ounce of water, or ten grains of sulphate of zinc to the ounce. This should be injected every two or three hours; while a drachm of cubebæ pepper, or thirty drops of copaiba balsam, and the same quantity of turpentine, may be taken in a strong decoction of lignum vitæ, or armoracia root, or even in water, three times during the day.

By these means the disease is diverted from its natural course, and its career may be destroyed; but it is dangerous practice, and should not be resorted to, except in cases of emergency. Swelled testicle is a frequent result; and I have known the discharge to have temporarily yielded under a smart attack of orchitis, and return at the expiration of some days. I apprehend that this treatment by revulsion, can never be warrantable but in the very earliest appearance of the discharge, probably within twenty-four hours.

Gonorrhœa attains its natural crisis more uninterruptedly in a moderately full than in a languid habit; but extremes of both are sources of aggravation; the first as regards intensity—the second, time. I am not aware that the science of surgery affords any means, by which a confirmed clap can be suddenly arrested in its career; and the attempt, if made, is not productive of any but an evil result.

For a period of two or three weeks the treatment should be strictly palliative; the diet should be moderately reduced; the bowels relaxed, but not considerably; the local inflammation, mitigated by frequent fomentation and rest; and under circumstances of great activity, combined with great physical power, and a full and hard pulse, sixteen ounces of blood may be abstracted early. The painful micturition may be relieved by thirty drops of liquor potassæ, combined with five or six of tincture of opium, three times during the day. I find advantage from the following form, which I order to be taken every night in milk:—

Pulv. Jalapæ, gr. x.; Pulv. Acaciæ, ʒij.

Perseverance in these measures during a fortnight will exhaust the activity of the disease; the improvement will be indicated by a diminution of pain in

making water, as also diminution of the quantity of the discharge, which becomes paler in colour, and more aqueous in consistence. As soon as this stage is accomplished, the treatment should undergo a corresponding change, otherwise the disease will become protracted under the form of gleet. The diet may be improved, and the laxative omitted altogether; a moderate quantity of wine is not undesirable, if the person be accustomed to that or similar stimuli while in health.

Should the healthy career of the case be interrupted by chordee, in all probability the cure will be more or less protracted, because its presence indicates a hitherto uncontrolled inflammation of the urethra, which has extended to the erectile tissue of the corpus spongiosum. This condition of that body is not always perceptible on examination, but it usually leaves considerable soreness along the track of the canal. After chordee has existed for some time, we can perceive the presence of lymph by the finger often poured out around the urethra, chiefly in the region of the scrotum, where it presents one or more indurated masses of a roundish form, to which more especially the pain is referred during erection. These swellings become sufficiently large to compress the urethra, and present considerable difficulty both to the flow of urine, and to the introduction of instruments towards the bladder.

Chordee is not a common symptom of gonorrhœa in its early stage; and is, I think, more frequently asthenic in its nature, though not necessarily so. We treat it with opium, to which calomel may be added. The opium will check it without doubt, for a few nights; and as soon as this end is accomplished, the sedative should be desisted from.

The immediate pain may be warded off by local pressure of the hand, if the person is resolute enough to grasp the organ, and relax the spongy portion by curving it downwards. The application of cold is also an important resource.

Sometimes the healthy progress of the case is interrupted, and an aggravation of the symptoms caused, by some act of imprudence on the part of the patient, of which inflammation of the neck of the bladder may be the result. Under these circumstances, the discharge often ceasing, we have frequent micturition from inability of the bladder to hold the urine for a longer period than a quarter or half an hour; pain extends along the track of the urethra, and occupies the substance of the glans, accompanied by dysury; spasm of the urethra, and pain in the hypogastrium, the loins, and the inner and front part of

the thighs; pain is also often referred to the rectum, and around the anus. All these symptoms are aggravated by exercise, and, in this state, patients are incapacitated for exertion of almost every kind.

The treatment should be moderately antiphlogistic. Leeches, in number proportioned to the activity of the pain and strength of the person, should be applied to the perineum. The horizontal position, and the frequent application of very hot flannels to the external organs and perineum, will afford considerable relief, after depletion; and a mixture of *vinum colchici*, sulphuric æther, and tincture of opium, in moderately large doses, will generally arrest the activity of the disease; and, as I said with respect to gonorrhœa in general, so I add in reference to this symptom—that as soon as you have broken the neck of the inflammation, deplete no more, but immediately substitute carbonate of ammonia in five-grain doses, or very small doses of copaiba or turpentine, and the spirit of juniper—*vulgò*, a glass of hot gin and water, *horâ somni*.

One great objection to excess of depletion in gonorrhœa, is the liability of the purulent discharge to degenerate into gleet as the inflammation subsides. This is a great evil, for its inconvenience and its obstinacy are almost proverbial. It is generally unattended with pain, or, indeed, any other symptom.

The secretion of true gleet is serous merely, combined with the mucus of the urethra; but it will vary according to the excitement to which the parts are subjected. It may be occasionally accompanied with slight pain in micturition, and during erection, and, of course, the more active the symptoms, the nearer the approach to the puriform character.

There is obviously, therefore, no distinct boundary which points to the cessation of gonorrhœa, and its crisis in gleet; the change is gradual and imperceptible. If you treat a person habitually prone to large libations of drink, by entire desistance from his ordinary and necessary stimuli, he will have a protracted gleet; and this principle holds in all cases, *cæteris paribus*, in which the depletion, whether positive or negative, has been needlessly persisted in: therefore the first consideration applies to constitutional treatment, which is, at least, equally important to local. I recently had a man under my care, who, when in health, took *per diem* about one gallon of porter, in addition to an occasional glass of gin. He had been the subject of gleet for ten months, for which he had employed the usual catalogue of local remedies. I desired him to leave the gleet to take its own course, and resume

his usual drink. He perfectly recovered in a week, and has had no return of the discharge. First, then, it appears to me necessary to raise the standard of the circulation and nervous power, by resuming ordinary diet and ordinary stimuli; and to this I generally devote a week or ten days; during which, I do not think you will find the local malady to advance, although it may feel the effects of the first increase. The general treatment often, I will not say invariably adopted, I consider objectionable, and chiefly because it fails in its object. It consists in the administration of large and still larger doses of internal stimuli; of which those in most frequent use are turpentine, copaiba balsam, and cubeb pepper; and of local injections of alum, sulphates of zinc and copper, and nitrate of silver. The zinc is used in the proportion of from 3 to 5 grs. to the ounce of water, and each of the other salts in similar proportions. On these failing, the strength is increased indefinitely, often extending to 8 or 10 grains to the ounce.

The consequence of these remedies, both local and general, is that the vessels, weak and exhausted by depletion, are severely constricted, and re-action is the inevitable result, producing a return of the malady.

When a gleet has existed for a considerable time, it becomes, as it were, naturalized to the surface, and not unreasonably resents such violent measures employed to eject it; whereas, by gradually undermining its resources, by giving vigor to the vessels which supply it, and by wearing out its energies by persevering but mild appeals to its forbearance, the vessels will gradually assume a healthier action, and the discharge will cease; and it is not often that this argument will fail. When a patient applies to you with gleet of long continuance, let him desist for a week from all treatment, local and general. Then, if his diet has been low, from the fear of aggravating the evil, enlarge it to the standard of his habits in health, and commence with an injection of sulphate of zinc, in the proportion of five grains to eight ounces of water. He will possibly reply—"Oh, sir, that will do me no good; I've used injections of ten times that strength, and they have failed." The answer obviously is, "They have failed, because they possessed ten times that strength." But now, instead of injecting at night and morning only, you must desire him to employ the remedy sufficiently often to compensate for its weakness; and he should inject it warm every three hours. If it produce the slightest pain, lower the strength to four, or even three grains; but this rarely happens.

At the same time you may order very small quantities of turpentine, &c. I often recommend eight or ten drops of copaiba and of turpentine, to be taken three or four times a day, and with advantage. The immediate effect of these remedies is very slight; but, by repeating their application at short intervals, you confirm the advantage gained, small as it may be, while in the aggregate you will have obtained all you desire. Should these quantities fail, they may be slowly increased, but never to such an extent as to lose sight of the principle on which they are recommended. I cannot say that I have much experience of the advantage of passing bougies in gleet, even when coupled with stricture. I do not think stricture is often a cause of gleet; at all events, that the gleet will subside on the removal of the cause, supposing it to exist in that relation to it. However, there is no harm in the introduction of a bougie, but I would not rely on it as an important resource. Change of air, and improved appetite with its consequences, have cured, in a short period of time, many a case that resisted ordinary treatment, of which I could quote you many examples. There remains one subject on which I wish to say one word.

Applications are frequently made for the purpose of ascertaining at what period of the disease it ceases to be communicable. I recommend you to be most cautious how you commit yourselves on this head, by which, in case of failure, you render yourselves morally responsible for whatever consequences may ensue. In truth, we know nothing about it. What is communicable to one person, is incommunicable to another; and so long as we have no certain evidence by which to draw the line, it is better to adopt the alternative of declining an opinion altogether, or of leaning to the side of good morals, by declaring that, so long as discharge exists, there is no exemption from the liability to communicate it.

In the preceding lectures on the venereal disease, gentlemen, I have endeavoured to introduce for your future consideration, the most important features of each variety, with their most eligible treatment. If a statement of my own opinions has predominated, it has not been made without referring you to other, and far more extensive sources of knowledge, and among which the most unerring, the most practical, and the most indispensable, to us all, is the folio edition of the book of Nature. This I strongly recommend you to read, mark, and attentively study.

OBSERVATIONS
ON
COMPLICATED SURGICAL
INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with
the Auxiliary Forces in Portugal and Spain.

(As delivered in his Lectures at Sydenham
College School of Medicine.)

[Continued from p. 419.]

III.—INJURIES OF THE HEAD.—ON THE
ELEMENTARY FORMS OF INJURY AND
THE CLASSIFICATION OF THEIR EFFECTS.

Concussion and its subsequent Effects.—*The different nervous centres affected.*—*Varying actions of the iris.*—*Lesion by concussion not common.*—*Stertor: its indications.*—*Classification of Mr. Abernethy—only different stages of same degree.*—*How to estimate the different degrees.*—*Effects of concussion—coma occurring some time after, not a sign of extravasation or effusion frequently.*—*General error on this head.*—*Case in proof.*—*Consequences—their degree or order cannot be predicated from knowledge of the injury.*—*Cases.*—*Dispersed or distant effects of injuries of head.*—*Cases.*—*Permanent irritability of fibre.*—*Most common consequences of concussion.*—*Cases.*—*Inflammatory effects of concussion without intervening coma.*—*Cases.*

In pointing out the best mode of observing the various effects of injuries of the head, and in classifying them according to the peculiar nervous system through which they were chiefly manifested, I have already sketched, and to a certain extent defined, this class of accidents. You are thus prepared for a more detailed inquiry into the distinctive features of each particular form, and its appropriate treatment.

I have defined concussion to be “any vibratory shock or jar, whether produced by direct violence to the head, or indirectly through any other part of the frame; producing lesion of function or structure in the brain.”

These lesions, both of function and structure, are of many kinds as well as degrees, and at the commencement we are involuntarily led to inquire, in what does concussion materially consist, or, in other words, what effective or material alteration of structure does it produce? The answer is, none perceptible; we know it only by the outward manifestations of disturbed function in the subdivisions of the nervous system.

If the shock has not been very violent, the cerebral system alone suffers; there is loss of consciousness, sensation, and voluntary motion simply; or even less than this may exist—only a mere sensation of giddiness and obscurity of vision, with an equally partial loss of consciousness, sensation, and voluntary motion, followed on returning power by sickness; involving by that act the excito-motory system through the par vagum and motor nerves from the medulla.

If the concussion be more violent, the loss of consciousness, &c. is not only complete but of long duration; the cerebral is not the only system affected, but simultaneously the excito-motory; there is more or less relaxation or paralysis of the muscles guarding the orifices; the glottis is no longer held widely open, and there is some difficulty of breathing in consequence. Retention of urine, from loss of sensibility in the mucous membranes of the bladder; a languid, slow, and laboured pulse, marking depressed power of probably all the nervous centres, of which the coldness of the extremities may be considered as an indication and consequence. The pupils are generally more or less dilated, the sphincter of the iris being equally relaxed, the sensibility of the retina impaired; and there may or may not be contraction under a strong light, evincing either the total insensibility of the optic nerve in its expansion, or only impaired susceptibility to stimuli.

The most serious degree gives abolition of cerebral functions; nearly complete paralysis of the excito-motory; deficient secretion and nutrition, equally marking the impaired and disturbed functions of the sympathetic or ganglionic. In this degree of concussion, then, there is neither cerebral sensation, volition, nor motion; there is stertorous and laboured breathing; the glottis, far from being held widely open, is allowed to drop, and nearly entirely close the opening into the trachea; widely and permanently dilated pupils; the retina totally insensible to light; paralysis of the sphincters of the anus and bladder; involuntary discharge of feces and, at a later period, of urine; laboured (often feeble) and very slow pulse; diminished secretion from the liver, bowels, &c., marking the impaired action of the whole ganglionic system.

I have said the pupil, in these cases, is generally dilated; but my colleague,

Mr. Dalrymple, has related to me several cases which have come under his own observation, where the pupils have been strongly contracted. This may be explained in several ways:—1st. The contraction of the iris on the application of any external stimulus, such as light, depends upon the sensibility of the optic nerve; the retina communicating the impression from the eye to the brain, when, by the reflex motion so constantly developed in the spine, the motor fibres of the iris are suddenly acted upon and suddenly contract, to exclude the painful stimulus. If concussion has not so affected the brain, or such part of the brain, as to produce insensibility of the optic nerve in its expansion, there will not of course be dilation, but, much more naturally, contraction. On the other hand, although the motor fibres may not be excited by any stimulus of light, owing to the total insensibility of the retina, yet, in consequence of the injury, some internal irritation of the root of the first division of the fifth (from whence, and filaments of the motoris oculi, the ciliary ganglion and nerves arise), may produce precisely the same effect (contraction), in spite of the total insensibility of the optic, from whence, by the reflex function, it usually derives its stimulus. This is far from being a common occurrence; but I have myself, in more than one case, witnessed these anomalies, and it is right you should be aware of them. I may not have given you the true explanation, but such seems to me to be the most natural.

But to proceed with concussion, and the more obvious and common effects. If there be concussion simply, it often leads to no other effects than these derangements of the actions of one or more of the nervous centres; the brain seems gradually to recover; the excito-motory system regains its permanent power over the sphincters and orifices; the glottis is held open; the stertorous and laboured breathing disappears; the iris becomes more natural. The patient, imperfectly conscious, may be partially roused by a loud voice; sensation and voluntary motion returning in nearly the same proportion. The pulse, still slow, rises; the functions of organic life, and of the excito-motory system, cease to be disturbed; those of animal life, or of the cerebral system, alone remaining more or less affected: and now inflammation of the brain or its mem-

branes may be looked for, and it generally supervenes with a violence proportioned to the original injury.

I have not observed, nor can I concur in the opinion of Sir Astley Cooper, that a common effect of severe concussion is lesion. That this does occur occasionally, of course, cannot be denied, but I confess I think it exceedingly rare.

Stertorous breathing has been hitherto, and very erroneously, considered as a distinctive mark of compression, and not a symptom of concussion; but it occurs in both, and is merely indicative of a *degree* rather than a *kind* of injury. It indicates the implication of the excito-motory system—the relaxation of the sphincters—the stopping of the glottis. If the par vagum in addition has any thing to do with laboured breathing, the indication is the same as regards the implication of another system besides the cerebral.

Many cases of very severe lesion and compression occur without any stertor, the mischief or injury apparently being confined to the cerebral system. In a case of very extensive extravasation, tearing through a portion of the cerebrum, the details of which I will give hereafter, “there was no stertor,” and the fact was thus distinctly marked during the patient’s lifetime. In another case of pure ramollissement, to which I shall also refer later, there was distinct and loud stertor for many hours.

Thus neither does the presence of stertor certainly indicate compression, nor its absence prove that no such state exists. I repeat it is an evidence of degree when the injury is in the brain, rather than of kind, and may occur in all forms.

Mr. Abernethy has given a classification of different degrees of concussion, but it is in effect only an arrangement of different stages of one degree, which is not quite the same thing; indeed, it is essentially different. It is of importance to be able to trace the different degrees as well as the different stages of the same degree.

These different degrees are to be estimated, first, by more or less complete abolition of the cerebral functions; perception, volition, and motion, and the time which such state endures. Secondly, by the degree and duration of any injury, disturbance, or loss of power to the excito-motory and to the ganglionic system; and this mode of

appreciation and diagnosis applies equally to all the forms of injury of the head which I have enumerated, and is the only sure basis on which to found a diagnosis.

The most invariable consequence of all severe injuries to the head is concussion. I conceive it of the greatest importance to define in what this consists, and what are the effects which may be truly traced to it. The four elements of head injuries I have stated are, concussion, compression, lesion, ramollissement; and any or all of the three latter may be effects of the first. In this order they are best considered. Earliest in order of these effects is, a frequently-recurring coma, supervening an hour or two after a concussion, though not at first, without any perceptible compression or lesion of structure otherwise to account for it. A question suggests itself—

“May not concussion lead to a subsequent comatose state, not depending on pressure or lesion, or any perceptible alteration of fibre or structure, an effect of concussion simply and only?”

The frequency of a comatose state supervening shortly after the shock, but not at the time, gave me this impression; but on careful investigation I failed in satisfying myself of the soundness of such a conclusion; but I succeeded in assuring myself, that the drowsiness, lethargy, or stupor, thus supervening, was *not* the result of compression, as that term is usually understood.

These cases do not admit of explanation by ocular demonstration, for either the patient gradually recovers, leaving us in doubt whether he recovers from mere concussion, or by the absorption of matter or other fluid which might have caused pressure; or if, on the contrary, he dies, there is such extensive disorganization or mischief, that the post-mortem evidence still fails to decide the question.

Close observation, and the fair use of our reasoning faculties, will often surmount greater difficulties than these. Attention to many such cases showed me, before long, that this supervening comatose state certainly did not arise from any pressure by effused fluid or coagulum, still less by formation of matter; first, because it came on too suddenly; and secondly, it might by treatment be as promptly dispelled.

Absorption of any matter effused, secreted, or extravasated, could not possibly be the agent or mode of relief.

I conceive this effect may arise from the pressure of turgid and over-distended vessels throughout the substance of the brain—and the prompt relief, although often only temporary, produced by copious bleeding, further confirmed me in this opinion—or otherwise, the fibre may be so debilitated in its power of resistance, that it will not bear the pressure of even the normal quantity of blood in its substance: in either case it would be a case of compression; but compression not as it is usually understood or defined, nor possibly even congestion.

The following case bears upon this point:—

CASE, showing the Secondary Coma of Concussion by pressure from fluid within the vessels.

Philip Thorne, æt. 24, on the 16th of March, 1837, walked into the hospital from the field, and conversed intelligently for some time after he was placed in the ward; he had been struck by a musket-ball on the os frontis, which was fractured. Soon after, he became quite comatose. Pulse slow and weak; surface pale and benumbed. His head was shaved; cold applied. About nine in the evening a small arterial branch bled very freely, which speedily relieved the appearances of compression, and the next morning he was free from all bad symptoms.

Spoon diet. Sharp purgative of calomel and jalap administered.

3rd day there was a little pain in the head; pulse slow.

4th.—He said he felt occasionally light-headed; pulse rather jerking, but easily compressed; secretions free from the bowels.

5th.—No change.

6th.—Unusually sluggish and languid pulse, 56; complains only of local pains; sore unhealthy; bone denuded beneath.

7th.—Pulse 52, same character.

8th.—Right pupil slightly dilated; pulse 48, soft and irregular; very little pain, and merely local. During this period a saline mixture cum Ant. tart. was directed for him.

9th.—Says he feels perfectly well; all natural but pulse, which, up to the 15th, remained at 52, during which time

he continued rapidly improving. It then became 70, regular, and perfectly natural.

He was discharged on the fourth month perfectly well, save that exposure to the sun, or much exertion, brought on pain and giddiness in the head.

This case then shows that a blow of no common violence did not produce any loss of consciousness, or serious inconvenience in the first instance; that in a few hours complete coma supervened, and was almost instantly relieved by loss of blood; the same state, in a lesser degree, returning the second day after, and the pulse continuing to the fifteenth day to indicate disturbance of the circulation, but in no other organ or division of the nervous system.

It would be easy to select many cases where stupor supervened, sometimes after concussion and not at first, as readily relieved by bleeding, returning again, and that two or three times in the treatment of the same case; but as they are cases complicated with lesion of brain, &c., they give less simple, and therefore, perhaps, less conclusive evidence on the particular points under discussion. This tardy or "secondary comatose condition," as I have termed it, quickly relieved by bleeding, again recurring, and again relieved, it must be evident, is the result of the shock, the concussion. It does not occur by any extravasation of fluid; and if from pressure, apparently can only arise from the pressure of fluid in the blood-vessels, whether in ordinary or extraordinary quantity.

That this distinction in the causes of comatose state should be established is most important, pointing at once to the best and only remedy, and adding greatly to our knowledge of the true causes of symptoms in these complicated injuries.

The first most obvious and most general effect of violent concussion is, total or partial loss of consciousness instantly following the blow. In this symptom there is no variation but in degree; it is sometimes accompanied with disturbance, not only to the cerebral system and animal life, by which we have loss of consciousness, sensation, and motion, as I have shown, but to the excito-motory or true spinal, and to the ganglionic or sympathetic—the systems of organic life, and the functions of those organs essential to existence, are

disturbed, and more or less impeded. Then there is impeded, laboured, or stertorous respiration; there is laboured and slow pulse, disturbed function of liver and kidneys—all the vital organs suffering under depression, derangement, or destruction of their functions.

The first degree of injury affecting animal life only; the second, the excito-motory presiding over the involuntary motions; the third degree involving organic or vegetative life in addition to the other two.

By clearly defining this distinction we at once obtain a scale by which, with very tolerable accuracy, we may measure the degree of violence in the injury, for even in the order in which the functions are impaired we may further obtain valuable guides for diagnosis. The heart seems to me always the first organ disturbed in its functions after the cerebral; next in order the respiration, depending chiefly on the reflex function of the excito-motory system; and it requires a third or greater degree of injury to involve the sympathetic, nutritive, and secretive.

Thus the pulse, in its slow, laboured, and sluggish beat, will give indication of the heart's depressed power and impeded function, while the respiration is free, and the bowels and kidneys act naturally.

On the other hand, the disturbed functions of the excito-motory in respiration, always implies the heart's disturbed function, or immediately involves it, for I have never observed the former to exist without the latter.

As the liver and kidneys will give but slight indication, or none at all, of disturbed functions, even when the two former derangements are sufficiently marked to be distinct, so it seems natural to place them in the last order of functions disturbed, suffering, in fine, only from a greater degree or amount of injury. The skin, in the last stages, leading to death, often acts inordinately, producing a cold, copious, and clammy sweat.

In the case related (*Thorne*), it may be seen, that although the heart was seriously disturbed in function, and remained so for fifteen days, yet the respiration did not sympathize nor become implicated. The liver and kidneys never ceased their action, and answered as usual to the stimuli of purgatives, &c. administered.

Let us proceed to another point of

interest, viz. to the question of how far the consequence of the relative degrees of injuries, even when these are satisfactorily ascertained, can be predicated. This, I think, is very distinctly answered by two closely parallel cases, which I will relate, to place this subject in a strong light.

Two Cases of precisely parallel injuries producing different consequences.

Edward Elam, æt. 23, on the 16th of March, 1837, was struck by a musket-ball, which entered two inches above the left ear and passed down to the occipital bone, abrading the periosteum, and making its exit behind the ear. Loss of hearing on that side immediately ensued. He was ordered a dose of cal. cum jalapæ, and cold lotion to the head. About ten in the evening pain and heaviness of the head had come on, with some febrile excitement.

V.S. ad 3xi.

Next day all these symptoms had been relieved.

No further return of pain or heaviness, except that he had a troublesome cough, which, shaking him, always caused pain.

On the 20th day he had fully recovered; his hearing had returned. He said the left eye was a little injured in power of vision; both, however, presented the same appearance; and he was liable to vertigo if he walked in the sun.

CASE II.—Sergeant Flynn, æt. 45, on the same day was struck by a musket-ball, about three inches posterior and superior to the left ear: the ball merely impinged, abrading the periosteum.

Pain in the head followed on the second day; somewhat relieved the next day, after having been freely purged and a cold lotion had been applied to the head. He continued improving for some days, but on the 10th complained again of headache, with a furred tongue; pulse exceedingly rapid, calculated at 200.

V.S. ad 3xx. Pulv. Purg.

Next day much relieved again; the pain in the head slight; tongue still furred; bowels freely opened; pulse reduced to 95.

12th day.—An incision was carried

through the wound to the bone, and next day there was decided improvement.

14th.—Headache increased. Twenty leeches were applied to the temples, and they bled freely; purgative also acted well.

15th.—Relieved.

16th.—Intellect slightly disturbed. Cupped to twenty-four ounces; free secretion kept up from the bowels; again relieved, and up to the 26th day he seemed steadily improving, when he felt increased weakness, inability to sit up, and a general sense of *malaise*.

On the 41st day he vomited a considerable quantity of bilious matter; mind rambled a little during the night; bowels open; pulse weak and *slightly intermittent*.

Emp. Lyttæ Nuchæ.

No puffiness or erysipelatous inflammation of scalp, but vital powers seemed sinking. From this time to the 48th day, when he died, he was much harassed by diarrhœa, but retaining his consciousness and power of answering rationally to within a few hours of his death.

Post-mortem.—Body much emaciated. On removing the calvarium the following appearances presented:—The dura mater was considerably thickened, and there was deposition of serous fluid between that membrane and the arachnoid. An absorption of the inner table had commenced beneath the point where the ball had impinged, and the part was covered with a thin layer of matter; this was close to the squamous suture. A portion of the dura mater, extending from immediately beneath the seat of injury for an irregular circle of from two to three inches in diameter, presented an appearance like that of a crab's back as to mark and colour—was of a thicker texture than the rest—and at its inner surface gave marks of inflammation. These effects may be observed in the preparation before you. On cutting into the substance of the brain, it was found generally vascular, freely speckled with blood, and a considerable quantity of turbid fluid lay in the base of the skull, descending into the theca vertebralis. The right hemisphere of the brain was more generally injected with blood than the left. Both lateral ventricles were distended with turbid fluid.

The lungs were found studded with tubercles, and on the right side the pleura costalis and pulmonalis were closely adherent.

The liver was very much enlarged, and filled with abscesses containing an extraordinary quantity of pus. The alimentary canal presented no unusual appearance.

Here, on the same day, two as nearly similar injuries presented themselves as could have been inflicted, had similarity been the design. The one runs a course of twenty days, presenting the usual symptoms of a not very violent concussion; the other induces absorption of bone, inflammation and disease of membranes, injection of the brain, effusion of fluid, and if not tuberculated lungs—on which, probably, some of the pernicious influence had been expended—extensive suppuration in the liver.

If I had merely wished to shew the different results of two perfectly similar injuries, it would not have been necessary, however, to go so much into detail. I wished to establish another class of the effects of injuries of the head, and probably of concussion chiefly—viz. what I shall term its “dispersed or distant effects on the system;” and before I enter further into this subject, it shall be illustrated by two more cases.

Second Case, shewing the dispersed or distant effects of Injuries of the Head.

M'Lellan received in the night of the 26th December, 1833, two wounds on the scalp from a bayonet, one of which divided some arterial branch, producing considerable hæmorrhage. At the time of receiving the wound he was intoxicated. The ruptured vessel was so troublesome in its frequently recurring hæmorrhage, that it was secured by ligature two or three days later.

His case attracted little attention afterwards, there was no prominent symptoms. On January 3 he complained of worms, saying he was much subject to them; and small doses of the ol. terebinth. were ordered, which seemed to develop considerable irritability of stomach; and observing him attentively on the 5th, the eleventh day after the injury, I found some febrile action of an obscure character, a yellow

tinge of the eyes and skin, and evidence of a dogged comatose disposition.

Cold applications were ordered to the head: five grains of calomel, and fifteen of jalap, which was followed some hours after by a dose of castor oil, and a few drops of tincture of opium.

On the succeeding (12th) day the fever was increased, tongue much furred, and there was great pain in the head.

13th.—Tongue still foul; bowels freely opened; skin hot, but moist; full pulse; pain of head unabated.

15th.—After a restless night he complained of general pains; the left thigh and knee much swollen and painful; tongue brown and dry; skin moist, yellow; pulse feeble; urine in fair quantity and high coloured; thirst urgent.

16th.—He died.

Post-mortem.—There were two wounds on the head, one of which was situated near the middle line, and about midway between the frontal and occipital protuberance; and the other on the middle of the temporal arch. Both of an unhealthy appearance, but not puffy. The cranium was denuded of its periotenium to a small extent, in the situation of the two wounds.

On the external surface of the dura mater, and along the course of the left middle meningeal artery, there was a good deal of healthy-looking matter. This membrane throughout was very vascular, and thicker than natural, but more particularly so along the course of the middle meningeal of the left side. The glandulæ Pacchioni in the superior longitudinal sinus, corresponding with the situation of the wound, were much enlarged, red in colour, and very gritty in consistence. At the situation of the wound, near the median point, the inner surface of the cranium to a small extent was much whiter than the surrounding parts, and on the dura mater there was lodged some little pus.

The same appearances were seen internally at the situation of the wound on the temporal arch; but besides, there was here situated, between the dura and pia mater enveloping the brain, about two tea-spoonfuls of well-formed purulent matter. The substance of the brain was not affected, and in a healthy-looking state.

The liver was much enlarged, gorged with blood, of a deep red colour. In its

substance were found a great number of tubercles, and one large abscess occupied the greater part of the right lobe. In various parts the cicatrices of old abscesses, of a small size, were seen. The lungs, perhaps not very minutely examined, seem by my notes to have been considered healthy.

In this case the concussion was probably only very slight, although I suspect he was thrown down also in the scuffle, during which he was wounded.

Third Case of dispersed or distant effects of Injuries of the Head.

William Mead, æt. 20, a tin-plate worker, always had good health, a stout, muscular, middle-sized man, of lymphatic temperament, on the 1st of August, 1836, was struck by a musket-shot behind the left ear, which passed downwards and forwards to a short distance below the angle of the jaw, from whence it was cut out. Mastoid process considerably injured, the ball having shattered it in its course. Some hæmorrhage occurred from the wound made by the knife; suppressed by a pledget of lint, bandage, and cold lotion.

3d day.—Had slept badly; throbbing pain of ear; considerable swelling of parts; pain of the left side of the neck, about the centre, over the carotid artery, felt on full inspiration; some febrile action and diarrhœa.

The febrile action continued high and severe, but with no head symptoms, for the succeeding fifteen days, when the pulse gradually lost its sharp and thrilly beat, became less frequent; tongue pale or foul; when gradually his appearance indicated great heaviness.

On the 24th day it was remarked that for some short time he had continued in a dull, heavy, but weak state, scarcely answering when spoken to, and without amounting to stupor there was an evident dulness in his faculties; anxious expression of countenance, although without any pain of head, and with the wound healing; pulse low, but still febrile.

Again on the 31st, I made the following note, endeavouring accurately to describe his state:—"His general appearance conveys an impression of drowsiness and heaviness; pupils are natural, and have lost none of their contractile power. The wound made to

extract the ball is healed, and where it entered there is little more than a pin-hole. Diseased bone is felt beneath; pulse hard, and rather sharp and harsh, 94; tongue pale, and slightly loaded; bowels acted upon twice yesterday; his chief complaint is "right downright weakness;" notwithstanding which I ordered a small bleeding at night.

On the 44th day, without much previous warning, a large collection of matter was discovered extending from the lumbar region over the hip and down to the middle of the thigh. It was opened, and two pints of matter discharged.

He was ordered a good diet, a few ounces of sherry daily, and bark.

For three days the discharge continued excessive, while carefully bandaged with compresses; it suddenly closed, and next day reopened and discharged three pints of matter; the succeeding day the same quantity.

On the 50th day this enormous abscess was much diminished, and the discharge, which amounted to several pints daily, very suddenly became reduced to as many ounces. The pulse became full and stronger; tongue white, but the heaviness of the head better.

On the 53d the sides of the abscess had adhered, and it became obliterated.

On the 56th another deep-seated abscess under the deltoid muscle was discovered and opened, and for five days about half a pint of matter was discharged daily.

On the 62d day very little matter was discharged, but head symptoms, giddiness, and confusion, came on. A large blister was applied to the neck. In three days more this second abscess healed up, and he had a good appetite and aspect.

On the 66th day he seemed convalescing rapidly; but two days later he again complained of dizziness and pain of the head. The blister was repeated.

From this period he had constant returns, in greater or less force, of pain and giddiness in the head.

Dec. 22d.—Nearly five months after he was wounded he was discharged to his duty. All pain and giddiness, as a constant symptom, had entirely disappeared, and he only felt uncomfortable on a change of weather, but said he was quite well enough for duty, and was anxious to join his regiment. There

was still constant and considerable discharge from his ear, but no pain. His face was rather stultified, and his mouth distorted on the side where he was wounded he said, less than it had been. The wounds were perfectly healed, and the surrounding parts looked sound and healthy.

This is perhaps the most interesting case of this last series, for the relative action of the head and the distant disease seems more clearly established; and I think there can be no doubt that the cause of these large abscesses and formations of matter was the injury of the head, which seemed to require for its relief the vast drain on the system which was thus established. One thing was very clear, that the head was signally benefited by the immense discharge.

Here concussion rather shews its effect on the whole system, or on remote parts, than in the head itself; for the febrile action set up in the first instance was general, and but little implicating the head.

Consideration of these effects shews that all subsequent to concussion require most careful watching, and can rarely or never be safely prognosticated: they are very various, not only in relative degree to that of the injury, as has been already demonstrated, but in character and nature.

The various characters of its effects, it has appeared to me, might be thus defined:—

1. It produces an irritability of fibre, rendering the brain morbidly sensitive to all stimulus; and this, I am led to believe, is by far the most common effect of serious concussion. Any excitement—much exertion of mind—exposure to the rays of the sun—spirituous liquors, &c., quickly producing headache and giddiness: if persisted in or carried to excess, violent disease in some form is developed in the brain. I have almost invariably found this to be one of the effects, more or less permanent, of serious concussion, and often the only one remaining after treatment.

The following are instances selected from a large number of parallel cases. The one already given of Thorne equally bears upon this point:—

First Case of Concussion, producing a more or less permanent effect, irritability of cerebral fibre, shown by

increased and morbid susceptibility to impressions.

James Boase, admitted October 1st, 1836. A musket-shot had struck the outer angle of the forehead, above the eyebrow on the right side, and fractured the frontal bone. The ball fell after it struck. No symptoms of concussion or other internal injury to brain, during the first three days, made their appearance.

Sulphate of magnesia, cold lotion, spoon diet, were directed.

On the 4th day uneasiness felt in the head; pulse small, but not frequent; bowels open; skin acting.

Sulphate of magnesia mixture continued.

Next day he had recovered, and between this and the 17th day pain of head recurred at intervals, marking, apparently, slight irritability of fibre.

Free from all complaint when discharged on the 18th day.

Second Case of Concussion, &c.

William Wilson, æt. 34, was struck the same day, at exactly the same point, but on the opposite side. The outer angle of the forehead on the left side was the seat of injury, and the bone was slightly fractured. Free from all bad symptoms; same treatment as in the first.

Second day, a little pain of head; third, easy; no fever; tranquil pulse.

On the fourth day complained of a great deal of pain and uneasiness about the head.

A sharp purgative of Cal. and Colocynth, followed by Magn. Sulph. and Ant. Tart.

On the succeeding day was found to have passed a restless night; eyes heavy; pupils dilated; pulse slow, laboured, and full in volume. Bowels had been freely purged.

V.S. ad 3xvj. Emp. Lyttæ Nuchæ.

6th day.—Little change; no sleep, but feels heavy; pupils dilated, and vision of left eye (below the wound) impaired.

7th.—Improved a little; less heaviness of head; bowels open; pulse calm and soft; tongue clean; thirst; pain in the head still; eyes suffused.

Repeat the blister.

8th.—Pulse more sluggish. Pain continues.

9th.—Better; less pain and heaviness of head; pupils contract slowly; redness of eyes continues; pulse soft, and nearly natural.

10th.—Upon the whole feels better. Pupil of left eye widely dilated—less redness. Pulse soft and tranquil; tongue moist and clean; skin cool; extremities warm.

From this period to the end of the third month, pain of the head, conjunctival disease, sluggish action of bowels, and impaired vision of left eye, continued. He was at this period sent home, when I made the following note of his state:—

“Dec. 31st.—Invalided home. He complains of constant pain in the head, more or less severe. Injury to the sight of the left eye—a sparkling before it. Pain shooting from the point where he was wounded, across the forehead; giddiness. Both pupils appear more dilated than natural. No other indication of disease or variation from healthy state. His tongue red, clean, and appetite good. Pulse 92, full, and regular. A trifling cicatrix marks where the ball struck and apparently glanced off.

This case is an example of a high degree of irritability of fibre, and to this I refer the almost unceasing and long-continued pain of the head, without any other indication of disturbed health. Here no unusual stimulus was required to produce the headache, &c.

Not to multiply cases, the one already given of Thorne (p. 446) may be taken as a good example of an intermediate degree between these two: the first of which being an instance of this irritability in its slightest form, the second in its highest degree and worst shape. In the case of Thorne you will remember that this peculiar symptom or effect was only developed by the application of some stimulus, although the brain remained permanently susceptible to a morbid extent.

Continuing the classification of the effects of concussion, there sometimes will result inflammatory or mixed inflammatory and irritable symptoms, without any intervening coma, stupor, or loss of consciousness, of which I will give you an example. Let me observe, first, that this effect collaterally proves the fact I have assumed, that the secondary coma (*i. e.* a violent effect) may proceed from irritability, a state of cerebral fibre induced by concussion; al-

though that concussion may not, in the first instance, have produced lesion of functions, organic or animal.

Case of Concussion, inducing Inflammatory Effects, without any intervening Coma from the Blow.

George Davis, æt. 30, of general good health, middle sized, of dark complexion, was struck, on the 1st of October, 1836, by a musket-ball, which penetrated the face, fractured the zygomatic process of the malar bone on the left side, having entered over the centre of the mastoid process. Pulse unaffected on admission.

8 P.M.—Asleep, and seems perfectly easy.

On the second day complained of great pain in the head. Pulse hard, and wiry; bowels constipated.

V. S. ad 3xvj. Pulv. Purg. st.

On the fourth day the bowels had been acted upon freely; he felt easier, but complained of pain of forehead, with a low pulse.

C. C. Nuchæ, ad 3xij.

5th.—Pain of forehead; restlessness; flushed face; eyes bright, and excited in expression.

V. S. ad 3xx.

6th.—Great pain of head, with giddiness; bowels constipated.

Eup. Lytta Nuchæ.

These symptoms, with febrile action and pulse, continued to resist vigorous antiphlogistic measures until the 13th day, when he began to feel somewhat relieved. By the 17th he was entirely free from pain, and seemed convalescent.

On the 26th he had another attack. On Nov. 9th and Dec. 19th again.

Dec. 31st.—He was invalided home, having entirely lost his hearing on that side, in apparent good health, and without injury to the motion of the jaw.

Here, in the first instance, as the consequence of a severe shock or concussion, for to this must be attributed the obstinate and troublesome sequences, we find no stupor, no drowsiness, but a febrile inflammatory action, chiefly developed in the head; and the frequent recurrence of which would seem most naturally to depend on that irritability of fibre which I have endeavoured to shew is a very common effect of concussion.

ON THE
DIURNAL VARIATIONS OF THE
PULSE.

By WM. AUGUSTUS GUY, M.B., Cantab.

Professor of Forensic Medicine, King's College,
London.

To the Editor of the Medical Gazette.

SIR,

THE following observations on the diurnal variations of the pulse were originally intended to form a part of my paper published in the last number of the Guy's Hospital Reports. If they seem worthy of a place in your valuable journal they are at your service. Almost all that is yet known of the subject is here brought together, and some of the facts are new to the English reader.

I have the honour to be, sir,
Your obedient servant,
WILLIAM AUGUSTUS GUY.

15, Bloomsbury Square,
June 10th, 1839.

Before the publication of Dr. KNOX'S Essay*, in the year 1815, it was the received opinion that the pulse is more frequent in the evening than in the morning. This opinion was not without support from facts, though it rested on a basis far too narrow to support a general theory. The following quotations will show how implicitly the facts, which I shall presently adduce were received as evidence that the pulse becomes more frequent as the day advances. Haller† says, "Matutino tempore, quando a salubri somno expergiscimus, et primus ille ab operimentis natus, nimius que calor dissipatus est, pulsus in dato tempore omnium paucissimi solent esse. Consentient hic Cl. Rye et Thomæ Schwenke, viri Ill. et mea experimenta." Gregory‡ is more minute in his description. He says, "Horis matutinis, quum primo expergiscimur, pulsus rarus est, paulatim frequentior evasurus propter multa quibus obgicimur irritamenta; post cibum, excarnibus imprimis, aut acrem, aut conditum, intenditur; sub vesperem

levis quasi febricula accedit, cui requies et somnus remedio sunt. Hæc, in sano homine vix observanda, in ægroto, febricitante, hecticæ præsertim, satis manifeste se produunt." Zimmerman§ states, that in all subjects the pulse beats more slowly in the morning than at night. Hufeland|| speaks of a diurnal evening-fever, accompanied by increased frequency of pulse. During sleep this fever subsides, and the pulse, in common with the other functions of the body, is restored to that quietness and regularity which it had lost during the excitement of the day.

Quetelet** says, that in the evening we usually find ourselves a little more excited than in the morning; and the action of the heart, as well as the respiration, takes place more rapidly. To show that this opinion still prevails among physiologists, I may quote the words of one of the latest writers on the pulse. Dr. Bostock†† says, "It is generally admitted that the pulse undergoes a kind of periodical revolution during the course of the day, and this, independent of any of those circumstances, external or internal, which might be supposed to affect it. This subject has been attended to by various physiologists, and among others by Bryan Robinson and Falconer, who have given us tables of the results of their observations. We are, however, scarcely able to draw any conclusions from them, except that the pulse is less frequent in the morning, and that it has a general disposition to become more frequent as the day advances; but it appears very difficult, if not impossible, to determine in what degree the increased quickness is to be attributed to food, exercise, or to other exciting causes."

Though the majority of authors have contented themselves with stating that the pulse is more frequent in the evening than in the early part of the day, there are not wanting those who describe the diurnal variations of the pulse with still greater minuteness. Fodéré‡‡ says, "Relativement à la différence du jour de la nuit, on remarque que le pouls de l'homme adulte bat de

* "On the Relation subsisting between the time of the day and various functions of the human body; and on the manner in which the pulsations of the heart and arteries are affected by muscular exertion. By Robert Knox, M.D., Edinburgh." —*Ed. Med. and Surg. Journal*, vol. xi. p. 53.

Quoted by Knox.

60 à 65 fois par minute, au commencement du jour, et qu'il va continuellement en augmentant jusqu'à battre 80 fois dans le même temps, chez les plus excitables, sur la fin de la journée; dans la nuit, les pulsations diminuent de nouveau, jusqu'au matin, on elles se trouvent revenues insensiblement au nombre de 60 à 65." It is clear that this statement is based entirely upon Bryan Robinson's table. According to Double*, the pulse in the morning is tolerably quiet; at two o'clock observably quicker; from that hour it diminishes in strength and frequency till eight in the evening, and then again increases till bed-time. Cullen speaks of an acceleration at noon, and another in the afternoon.

I know of no observations on healthy persons which bear out these minute statements of Double and Cullen. In all probability their opinions were founded on the analogy of febrile diseases, in which some such diurnal changes, at least in the sensations and general appearance of the patients, take place. Although it is confidently asserted that the pulse, in febrile affections, is more frequent in the evening than in the morning, I know of no author, except Fordyce, who has been at the pains to put the general opinion to the test by actual observation, and his experience is opposed to the prevalent belief. He says†, "In rheumatic and other inflammatory fevers, I have examined the pulse by the watch two or three times a day, for seven, fourteen, seventeen, twenty-one, or even more days together, without finding it vary three stokes in a minute, not even at noon and midnight, when sensible alterations have been said to be observable in the pulse." It is true that in health, as well as in disease, there is an appearance of febrile excitement, accompanied by febrile sensations towards evening. These sensations I have often myself experienced, combined with flushing of the face and considerable cerebral excitement, but have been surprised to find the pulse not more frequent than in the more calm and tranquil states of the system.

There is no doubt that sensations such as these, probably experienced in a greater or less degree by healthy per-

sons in general, and constituting the "*levis febricula*" of Gregory, and the "*abendfieber*" of Hufeland, have led to the belief that the pulse partakes of the general excitement of the system, and have caused greater confidence to be placed in the few observations which we possess than, on careful examination, they are found to justify*.

That no such variations as those described by Cullen and Double take place in health, is sufficiently proved by Knox. He says†, "Amidst many hundred experiments, performed under a great variety of circumstances, I could never perceive any such phenomenon. The time of the day at which the first spontaneous acceleration is supposed to happen is noon. My own pulse never shewed any symptoms of such acceleration, but, on the contrary, always diminished in velocity. Thus—

| | |
|-------------------|----|
| Exp.—11 A.M. | 72 |
| 12 noon | 71 |
| 1 P.M. | 65 |
| 1½ P.M. | 64 |

The other paroxysm, according to the same author (Cullen), occurs in the afternoon, and that, too, totally independent of any excitement by food, &c. This opinion is equally erroneous with the former.

| | |
|-----------------------|----|
| Exp. 1. — 3 P.M. | 68 |
| 4 | 66 |
| 5 | 64 |
| 6 | 62 |

| | |
|------------------------|----|
| Exp. 2. — 3½ P.M. | 67 |
| 4½ | 67 |
| 5 | 64 |
| 5½ | 63 |
| 6 | 63 |
| 6½ | 62 |
| 7 | 62 |
| 7½ | 60 |
| 8 | 58 |

These observations of Knox, coupled with others to be presently adduced, prove that there is no foundation whatever for the theory of Cullen and Double; we may therefore turn from these supposed variations to the more tangible question—does the pulse increase in frequency as the day advances? The earliest observations, made with a view of determining this question, are those of Bryan Robinson, and they form the principal authority to

* Quoted by Nick.

† New Inquiry, p. 76.

* Guy's Hospital Reports, No. VIII.

† New Inquiry, pp. 53, 54.

which subsequent writers have appealed. The observations of Falconer are less known, and more rarely quoted. The following table from Bryan Robinson* "contains the number of pulses in a minute of two healthful men, A and B, when sitting, at the several hours from eight o'clock in the morning to eleven at night. These numbers are means

drawn from a large number of observations; those of A from the observations of twelve weeks; and those of B from the observations of three weeks. A ate his breakfast between nine and ten, B his before nine; they both dined together at two, at which meal B ate more plentifully than A; and they ate little or no supper.

| MORNING. | | | | | | | | | AFTERNOON. | | | | | | | | | | |
|-------------|----|----|----|----|----|----|----|-------|------------|----|----|----|----|----|----|----|----|-------|--|
| Hours... | 8 | 9 | 10 | 11 | 12 | 1 | 2 | Mean. | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | Mean. | |
| Pulses of A | 65 | 67 | 70 | 73 | 71 | 69 | 70 | 70 | 77 | 77 | 77 | 77 | 76 | 76 | 74 | 74 | 76 | 76 | |
| Pulses of B | 66 | 71 | 72 | 68 | 69 | 67 | 67 | 68½ | 75 | 81 | 84 | 81 | 79 | 77 | 78 | 78 | 79 | 78 | |

"From this table it appears that the pulse is slower in the morning than at any other time of the day; that it grows something quicker before breakfast, and a little more so after it; that it grows slower again before dinner; and that the quickness acquired by this meal continues for about three or four hours, and then abates a little, and continues in that state, without any considerable change, in bodies which eat and drink little at night till they go to rest." The results of these observations are more generally expressed in the following sentence:—"The pulse is quicker and greater in the afternoon than it is in the morning; and from many observations, taking one hour with another of those two times, it is quicker in grown bodies, one with another, in the proportion of about 80 to 70."

These observations seem to have been made with care; they were frequently repeated, and the same posture was maintained in all. We are not informed

whether or not the persons whose pulses were examined remained at rest in the intervals of the observations, or were subjected to the various excitements which occur in the course of every day. As it is not distinctly stated that the persons examined did remain at rest during the time of the experiments, there is every reason to believe that they were exposed to excitement from exercise and other occasional stimuli. However this may have been, the above table gives strong reasons for supposing that the pulse is more frequent in the evening than in the morning.

The experiments of Falconer* lend confirmation to those of Bryan Robinson. He gives a table "founded on an almost daily examination of the pulse for more than three months successively." The subject of the experiments was a male, aged 50, healthy, and of temperate habits. Breakfast was taken at 10 A.M. The time at which the other meals was taken is not specified.

| S A.M. | 9 | 10 | 11 | 12 | P.M. | 2 | Mean | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | Mean |
|--------|----|----|------|----|------|------|------|------|----|----|-------|----|----|----|------|------|------|
| 63.5 | 64 | 66 | 78.9 | 79 | 68.5 | 67.5 | 69.6 | 69.4 | 74 | 75 | 71.75 | 74 | 76 | 85 | 79.5 | 80.5 | 76 |

Here there is an increase from 8 A.M. to 11 P.M. of 17 beats—a difference much more considerable than that of Bryan Robinson's table. But it is not stated that the pulse was always felt in the same posture, nor is the time of taking the meals, the breakfast excepted, specified. Whether, again, the subject of the experiments remained at rest, or was excited by exercise or other stimuli, we are not informed. These observations, therefore, have much less value than

those of Bryan Robinson, although they confirm the result at which he arrives, and seem to justify the belief universally entertained by medical men up to the time at which Knox's Essay appeared.

The observations of Knox lead to conclusions altogether opposed to those of Bryan Robinson and Falconer. He

* Observations respecting the Pulse, intended to point out with greater certainty the indications which it signifies, especially in feverish complaints. By W. Falconer, M.D. F.R.S., Physician to the General Hospital, Bath, 1796. p. 26.

found that the pulse, instead of becoming more frequent towards evening, decreased in frequency. The instances which Knox adduces are "taken at random from a great number of others." The sitting posture was preserved in all the observations, and the pulse was felt in the morning before breakfast, and a short time after rising from bed, and in the evening after a light supper, and generally some spirituous liquors taken, however in small quantity, and much diluted. Period, summer. Person submitted to experiment aged 22, slightly muscular and excitable.

| | |
|------------------------------------|-------|
| 9 A.M. (average of 18 experiments) | 68.5 |
| 12 P.M. " " " | 64.38 |
| Difference..... | 4.12 |

The author invites attention to the circumstance of the morning pulse being felt before breakfast, and the evening pulse after supper—the former in a tranquil state, the latter after all the excitement of the day, added to the stimulus of the meal. The following are averages of 18 experiments made after breakfast, dinner, and supper, respectively:—

| | |
|---|--------|
| After breakfast, before 10 A.M. | 72 |
| After dinner, before 5 P.M.... | 74.22 |
| After supper, between 10 and 12 P.M., generally near 12 ... | 64.388 |

Dr. Knox remarks that though the dinner was much more stimulating than the breakfast, consisting, as it did principally, of animal food, with a small quantity of vegetables, to which porter or spirits were frequently added, whilst the breakfast was of coffee, bread, and eggs, yet the pulse after dinner was more frequent than that after breakfast by only 2.22 beats. Again, the supper was at least as stimulating as the breakfast, and yet the pulse after supper is slower than that after breakfast by 7.612, or nearly 8 beats. "The difference between the pulse after breakfast and after dinner would have been 10 or 15, had the case been reversed; at least I am inclined to think so, from some experiments which I afterwards instituted directly to ascertain the point*."

Another average of six observations made on the author's own pulse gives still more striking results. He had walked three miles before breakfast.

| | |
|----------------------|-------|
| After breakfast..... | 79.33 |
| After dinner | 76 |
| After supper..... | 63.3 |

Hence the pulse was more frequent after breakfast than after dinner by 3.33; after dinner more frequent than after supper, by 12.7; and after breakfast than after dinner, by 16 beats; a result directly opposed to that of Robinson and Falconer's experiments, and nearly equal in amount.

Four experiments made in the morning, and three in the evening, on Mr. S., aged 20, in good health, and of regular habits, gave the following averages for the sitting posture:—

| | |
|---------------|-------|
| Morning. | 79.25 |
| Evening..... | 66.66 |

Difference.... 12.59

The following are the results of seven series of fourteen observations each, made on the same gentleman at different times in the day. (I have omitted two observations made the one in the recumbent and the other in the erect position, all the rest being taken in the sitting posture.) Meals taken at 7½ A.M., 5½ P.M., and 8½ P.M.

| | | | | | | |
|--------|------|--------|------|------|------|-------|
| 9 A.M. | 11 | 3 P.M. | 5 | 7 | 9 | 11 |
| 94.6 | 82.6 | 74.9 | 72.9 | 73.6 | 71.6 | 65.78 |

Here there is a difference between 9 A.M. and 11 P.M. of 28.82 beats—a difference much more considerable than that which occurred in the experiments of Robinson and Falconer.

These observations of Knox appear to justify the conclusion at which he arrives. "If we regard," he says, "as accidental circumstances the acceleration of the pulse at various times by our diet, and that, too, according to the caprice of the individual, the pulse shall be found gradually to diminish in velocity from an early hour until midnight, and generally later." This conclusion is confirmed by a friend of Dr. Knox, who made similar experiments without communicating with him. The Essays of Dr. Knox seem to have met with little attention from the profession, and since his time little has been done either to confirm or to invalidate his observations.

Nick* is the next author who claims our attention. He made some observations on his own pulse and on that of another healthy male, which are pecu-

* Loc. cit. p. 56.

* Nick über die Bedingungen unter denen die Häufigkeit des Pulsus verändert wird. pp. 5—13.

liarily valuable, as they appear to set the question at issue between Robinson and Falconer on the one hand, and Knox on the other, completely at rest. The following series of observations closely resembles those of Robinson and Falconer, and leads to a similar result. It shows

| | | | | | | | | | | | | | | | | | | | | |
|---------|----|----|----|----|-----|--------|----|----|----|----|----|----|----|----|----|----|----|----|-----|----|
| 7½ A.M. | 9 | 10 | 11 | 12 | 12½ | 1 P.M. | 2 | 3 | 4 | 5 | 6 | 7 | 7½ | 8 | 8½ | 9 | 9½ | 10 | 10½ | 12 |
| 59 | 67 | 69 | 65 | 69 | 78 | 78 | 86 | 84 | 68 | 71 | 83 | 73 | 79 | 75 | 70 | 72 | 66 | 64 | 72 | 64 |

The observations in the following series were commenced at 5 A.M. :—

| | | | | | | | | | | | | | | | | |
|--------|----|----|----|----|----|----|----|-----|--------|----|----|-----|----|----|----|----|
| 5 A.M. | 6 | 7 | 8½ | 9 | 10 | 11 | 12 | 12½ | 3 P.M. | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
| 59 | 66 | 66 | 84 | 69 | 67 | 67 | 92 | 90 | 78 | 70 | 84 | 110 | 70 | 71 | 75 | 64 |

In each of the foregoing tables the pulse is more frequent at night than in the morning, by five beats. The same position of the body was not preserved in the several observations; but in the following tables this source of fallacy

was excluded. The first table gives the average of three series of observations made in the sitting posture; the last, of a single series made in the same position.

TABLE I.

| | | | | | | | | | | | | | | |

| 6 A.M. | 7 | 8½ | 9 | 10 | 11 | 12 | 12½ | 3 P.M. | 4 | 4 | 7 | 8 |
| 66 | 66 | 84 | 69 | 67 | 67 | 92 | 90 | 78 | 70 | 84 | 70 | 71 |

In the first of these tables, the pulse is more frequent at 10½ P.M. than at 9 A.M. by two beats; in the second there is an increase, from 6 A.M. to 8 P.M., of five beats. These tables, taken by themselves, would seem to strike the balance in favour of the opinion that the pulse increases in frequency towards evening; but more careful observations, made also upon his own pulse, lead to an entirely different conclusion. During all these

observations, the recumbent posture was preserved; all mental and bodily excitement was avoided; no food was taken; and the same temperature was maintained. An average of six series of such observations (from which three experiments have been omitted, as the pulse was raised above its natural frequency by smoking), give the following results:—

| | | | | | | | | | | | |
|--------|------|------|------|------|--------|------|------|------|------|------|----|
| 8 A.M. | 9 | 10 | 11 | 12 | 1 P.M. | 2 | 3 | 4 | 5 | 6 | 7 |
| 63.8 | 62.6 | 62.8 | 62.2 | 62.2 | 61.4 | 61.6 | 60.4 | 58.6 | 58.2 | 58.2 | 58 |

Here then, there is a diminution of 5.8 beats in 12 hours. A mean of two similar series of observations, made on the pulse of a healthy male, aged 32, gives a decrease, during the same period of 12 hours, of 6.5 beats; the difference in the first experiment being 3 beats, and in the second 10 beats.

These observations point to the true explanation of the increase in the frequency of the pulse towards evening, observed by Robinson and Falconer. The body, instead of remaining in a state of rest, and in the same circumstances in each observation, was submitted to various exciting causes, and the pulse betrayed the influence of these causes. Precisely the same irre-

regularities of pulse are observable in the first tables, extracted from Nick's work, but they disappear as soon as the body is placed at rest; and all the observations are made in precisely the same circumstances. We are justified, therefore, in stating, that, in persons who remain at rest during the day, the pulse becomes less frequent as the day advances.

Some experiments made by Hohl*, with no view to the determination of the question which we are discussing, lend confirmation to the conclusions drawn from the observations of Knox and Nick. On comparing the mean of 25 experi-

* Die geburtshulfsche Exploration bey Anton. Friedrich Hohl.

ments made on the pulses of pregnant women in the morning, with a mean of the same number made on the same women in the evening, I find that the pulse in the morning is 83.28, and in the evening 80.88. The pulse, therefore, is more frequent in the morning than in the evening by 2.40 beats*. The same rule holds good in the new-born child. Thus Hohl states, that if we examine the pulse of the new-born child *during sleep*, in the morning, evening, and night, we find early in the morning a greater frequency than in the evening, and a continual diminution up to midnight†. The observations made on the new-born child hold good also with regard to the fœtus in utero. Thus an average of 25 observations on the pulse of the fœtus in utero, made in the morning, gives 138.08 beats, whilst an average of the same number of observations made on the same fœtus in the evening, gives 135.76. The fœtal pulse, therefore, is more frequent in the morning than in the evening by 2.32 beats‡. Hohl himself recognizes this fact, and expressly states that the fœtal pulse is more frequent in the morning than in the evening§.

If we compare the detailed observations of Knox, Nick, and Hohl, with those quoted from Robinson and Falconer, it will be readily conceded, that as the former exceed the latter both in number and accuracy, the balance of evidence is in favour of the theory first advanced by Knox — that the pulse diminishes in frequency as the day advances. The general statements of Haller, Gregory, Zimmerman, Häfeland, and Fodéré, are not entitled to much attention, as they might all have been derived from the experiments of Robinson and Falconer. The observations cited from Nick seem the most conclusive as to the question which we are considering; for when made without care, and in different circumstances of excitement and repose, they yielded the same result as those of Robinson and Falconer; but when made in the same position of the body, and under the same circumstances, they led to the same conclusions as those of Knox. In the absence, therefore, of any careful and accurate observations, tending to prove that the pulse becomes more frequent as

the day advances, we are justified in regarding the theory of Knox as the correct one.

That I might place this theory beyond doubt (as far, at least, as experiments made on a single individual could do so), I undertook the series of experiments which are published in the last number of the *Guy's Hospital Reports*. I may refer those who take an interest in the subject of the pulse to my original essay. I shall conclude the present sketch by stating the general results to which my experiments led me.

"1. The pulse of a healthy adult male, in a state of rest, unexcited either by food or exercise, is most frequent in the morning, and gradually diminishes in frequency as the day advances.

"2. The pulse diminishes in frequency more rapidly in the evening than in the morning.

"3. The diminution of the frequency of the pulse is more regular and progressive in the evening than in the morning.

"4. The effect of food is greater and more lasting in the morning than in the evening; and in some instances, the same food which in the morning produces an effect considerable both in amount and in duration, has no effect whatever in the evening."

As this difference between the effect of the same food on the same frequency of pulse in the morning and evening obviously admits of being applied to all other stimulants, and to the remedies which we employ in the treatment of disease, the diurnal variations of the pulse have a practical bearing as well as a physiological interest. Some idea of their practical importance may be drawn from the fact, that the mean effect produced by the same food on the same frequency of the pulse in the morning is to the mean effect produced in the evening as 13 to 7, or nearly 2 to 1; whilst the duration of the effect at these two periods is as 3 to 1. This proportion will probably vary in the two sexes, and at different ages, and it will not be constant for any two individuals of the same sex or age. The difference in the frequency and excitability of the morning and evening pulse will probably be less marked in the young subject than in the adult, in the female than in the male. The fact can be determined only by numerous observations, judiciously planned and carefully performed. The science of the pulse is yet in its infancy

DIAGNOSIS OF ADHERENT PERICARDIUM.

To the Editor of the Medical Gazette.

SIR,

MAY I claim a page in your valuable journal, for a few remarks upon a subject which has occupied, not undeservedly, much attention in the profession of late years—viz. the diagnosis of the lesions of the heart and appendages. Of these, none has enlisted a greater variety of opinions—none has a more scanty literary history—than *adhesions of the pericardium*. In an art like ours, founded upon observation, the contradictions of authors, both in the diagnosis and results of this disease, are scarcely intelligible; some stating it to be a necessarily and speedily fatal disease, others treating it as a matter of trifling import. Amongst the former we recognize Corvisart and Hope. The latter opinion emanates from Bertin and Laennec. In the diagnosis, almost every author of note has fixed upon some one exclusive sign, and rejected those of his predecessors.

Lancisi, and also Vicussens, fixed upon *palpitations* as their sign; Meckel upon a *small pulse*; Senac upon *frequent syncope*; Dr. Saunders upon *epigastric undulation*; Dr. Rutherford upon *jarring action of the heart*; Dr. Hope upon *increased impulse towards its base*; Bouillaud, in his first edition, could fix upon *none*. Of these I can, after much studious examination, only approve of the two latter—*epigastric undulation* and *increased impulse towards the base*; and should add to them, contraction of each intercostal space in the *præcordia*, except at the apex, where a contrary phenomenon is witnessed; the latter resembling that of health, only more marked. The intercostal contraction is synchronous with that in the epigastrium, and attends the ventricular systole. Another symptom of adherent pericardium, is diminished variation of the space in which the apex beats, on assuming different postures.

In a healthy adult, notwithstanding the attachment of the pericardium to the diaphragm and mediastina, a varied posture occasions considerable difference in the point of impulsion of the apex: when lying on the right side, its beats approximate the sternum; when on the left side, nearly in a vertical line with

the nipple. During adherence of the pericardium, this motion, though to a certain extent prevailing, is perceptibly more confined.

There is another symptom not unfrequently present, where the pericardial cavity is obliterated—a *frottement*, when single, attending the ventricular systole.

My attention was drawn to this several years ago, whilst watching the case of a patient in Guy's Hospital, and which at the time I recorded in the books of the Clinical Society. I shall detail it, as it involves several interesting points.

Margaret Virapham, æt. 14, tall, stout, of bony make, delicate skin, florid complexion, admitted into Lydia's ward, under Dr Beck, July 1835. She exhibited a perfect type of that temperament in which the rheumatic diathesis becomes easily established. She was labouring under acute rheumatism, and it appeared that two years and a half before, she had suffered in a similar way with pericardial complication. The history of the second and fatal attack ran thus:—Five weeks before admission she went to a situation, where she was exposed to damp and draughts; in consequence of which she left in a week, suffering from febrile disturbance, with pain in the chest and slight palpitations. On the day following her removal, she awoke in great pain; the soles of the feet and the ankles, particularly the right, being the seats of acute rheumatic inflammation. Severe pyrexia now became developed.

On the eighth day of the disease the swelling, pain, and redness, left the feet, and the symptoms of pericarditis became urgent. There was acute præcordial pain, dyspnœa, palpitations, livor of the lips, and marked distress of countenance. Her mother now noticed frequent muscular twitchings, chiefly affecting the left arm. She was bled, blistered, and cupped; but the urgency of the symptoms continued for a week, declining on the appearance of rheumatism in the left wrist. When admitted, her aspect was dull, though occasionally wild; tongue furred and dry; skin hot, and devoid of moisture; palpitations very perceptible, with strong carotid pulsation, and undulation of the scapulars. No pain in the chest, denied having any difficulty of breathing, but the respirations were 34 in the minute,

forcible; the elevation of the parietes very manifest at a distance through the bed-clothes. The pulse was 120, full, strong, and incompressible, occasionally intermitting. There was occasional delirium and persistence of the chorea movements, continuing whilst she dozed, but ceasing during sound sleep. Left wrist acutely rheumatic. The stethoscope indicated a loud and rather rasping bruit at the left of the nipple, occupying the interval between the first and second sounds. She was bled, put upon a mercurial course, and leeches on the temples.

On the next day, 29th, the bruit considerably marked; the first sound was more harsh, and occasionally followed by a second. Her symptoms became daily more severe.

August 1st.—Another change in the physical signs, the original bruit-de-scie maintained its intensity near the sternum, between the third and fourth cartilages; a soft bellows-sound also, with the first natural sound, and in addition to these a distinct rubbing.

This case having attracted considerable attention, numerous examinations were made to verify these particulars. She died on the following day; the last words she uttered being a complaint of severe pain in the region of the heart. Cough and mucous rale present for a few hours before.

Sectio cadaveris.—Inflamed bronchi; recent and old lymph on the pleuræ. Pericardium universally adherent by old false membranes, less firm over the right than the left cavities. In the cellular meshes of the former, a tolerably firm deposit of recent lymph. This was mingled with a great deal of injection and ecchymosis. The original serous membrane thickened and opaque; substance of the heart thick and capacious. On the ventricular aspect of the anterior curtain of the mitral was a ridge, half an inch long, one-third of an inch wide and high, formed of lymph, which, from its closeness and firmness, was evidently of some little standing. The lines of attrition of the aortic valves were beset with rows of coarse granules, recently deposited.

This case exhibits, as the reader will gather, the following interesting circumstances:—Rheumatism, commencing in the heart; the limbs becoming secondarily affected; acute pericarditis going on to a fatal termination, un-

checked by the previous occurrence of adhesion, shewing that this pathological condition does not, like adhesion of the pleura, tend so much to prevent the recurrence of inflammation. It exhibits chorea and pericarditis in conjunction*. Several bruits of varying character, appreciable at the same time, distinctly localised; two of them being valvular, heard at different cavities, the valves themselves being in close approximation; and lastly, an adherent pericardium, and a distinct rubbing sound.

The leading features of the next case singularly resemble the preceding:—

John Price, æt. 24, admitted into the Clinical ward, at Guy's, Nov. 1837. He was an intelligent-looking man, of clear florid complexion, and rather stout make. As a sailor, he had worked and drank hard, and undergone much exposure. From the earliest period to which memory carried him, he had never been free from palpitation during exertion, but had never experienced dyspnoea till his last illness. A month before admission, an unusual exposure to weather, and a blow upon the chest, were followed by thoracic pain, cough, and dyspnoea. Unremitting palpitations and fever soon appeared. These symptoms had somewhat subsided when I first entered him in the clinical books. The pulse was 96, jerking, vibrating, and occasionally intermitting. Heart's action vehement, and attended with the following abnormal sounds:—To the left of the nipple a short scraping bruit, a murmur over the aortic orifice, both attending the systole, and a distinct and diffused rubbing sound. The upper portions of the lungs afforded bronchophony, but most extensively so in the right: here the rubbing was heard distinctly double, and much more distinctly than in any other part of the chest. He lived for two months; the pulse became extremely irregular, and he emaciated rapidly.

The phenomena mentioned as diagnostic of adherent pericardium—the impulse at the base, the undulations at the præcordia and epigastrium, and the fixed character of the beats of the apex—were here well developed. Having exerted himself one day by sitting up to dictate a letter, he was suddenly

* Dr. Bright, in his lectures, mentions this connexion as more than accidental.

seized with a paroxysm of dyspnœa, extreme restlessness, and struggling for breath; his face assumed a cadaverous pallor, and a profuse cold perspiration bedewed the surface. Stimulants for a time revived him, but he only lived for an hour or two.

Section.—Both lungs exhibited considerable traces of bronchitis, emphysema, and in the upper third of the right, and upper fifth of the left, pneumonia recovering. The heart was immensely hypertrophic; the pericardium every where adherent, more so on the right side, where were several patches of bone, the largest of the size of a penny-piece, and three lines in thickness. Slight deposits of recent lymph and ecchymosis in the looser cellular adhesions. Mitral thickened, and rather contracted, its tendons ossified, and four of them ruptured, the torn ends covered with recent fibrin. (To this lesion we attributed his rather sudden death.)

The anterior curtain of the valve was roughened by an oval deposit of recent fibrin, to the extent of more than half an inch, and corresponded exactly with a deposit on the opposing endocardium of the ventricle. The aortic valves thickened; the anterior drawn somewhat upwards by a firm round band, connecting it with the aorta.

I venture to request a correspondent in your journal of May 11, Mr. Perry Dicken, to peruse the above cases. After some interesting remarks upon the disease in question, he asserts as a fact that allows of no discussion, that a *frottement* with adherent pericardium is a physical impossibility. In his position I grant he is borne out by the highest authorities*; but our records are not sufficiently ample to enable us to decide definitively on many stethoscopic points. Carefully recorded facts, and Louis's method, will, we may presume, reduce stethoscopic diagnosis to as much certainty as any within the range of medicine.

The cases of Mapham and Price are only two out of many in which I have heard a *frottement* where adherent pericardium existed; but in only one other have I had an opportunity of examining, *post mortem*, the condition of the organ,

and I therefore pass them by, that there may be no ground for cavil. In the two cases the *frottement* was so distinct from any valvular bruit as to allow of no difference of opinion.

The rationale of the phenomenon is puzzling; but the following case, which fell under my own observation soon after the Price's death, may throw some light upon it:—

Michael Kelly, æt. 14, admitted into the Clinical ward, labouring under rheumatism of a month's standing. There was great hypertrophy of the heart, probably the sequelæ of inflammation two years before. He was put upon the ordinary treatment, and seemed going on favourably, when he was attacked with severe pain in the region of the heart, extending to the shoulder. He complained of dyspnœa, and the respirations were short and hurried. About the third day, the existence of a very loud to-and-fro sound over the præcordia, and modified bronchophony over the whole of left lung, left no doubt of the existence of pericarditis, and its constant attendant pleuritis. He was treated actively, and pain and febrile disturbance declined. The *frottement* rather suddenly disappeared, and was replaced by a morbid commotion in the præcordia. The space opposed to the apex was impelled outwards more forcibly than usual during the systole of the ventricle; at other points the intercostal space was as violently drawn in. The same phenomenon was present in the epigastrium. Some time after, the left lung having evidenced better respiration for a few days, a marked *frottement*, ascendant and descendant, engaged the whole of the (left) pleural cavity, being synchronous with in- and expiration: at the same time a similar sound, near the heart, attended each ventricular systole. The physical evidences leave no doubt in my own mind that, on the cessation of the *frottement*, the pericardium became adherent; and as little doubt that, on its reappearance, its seat was the pleural cavity. Is it unreasonable to account for the other case in a similar way?

Several other abnormal sounds are produced in the pulmonary structure by the action of the heart. In one instance a distinct sonorous rale was audible at the anterior edge of the right lung at each contraction of the heart, which allows of solution from the fact, as proved

* Except Dr. Addison, who, without being aware that the question was in agitation, more than suspected that an adherent pericardium need not exclude a *frottement*. The opinion of such a stethoscopist as Dr. Addison I consider the highest confirmation of my position.

by Dr. Mollison, that at each contraction of the heart a certain quantity of air is expelled from the chest. Such being the case, it is not at all improbable, *a priori*, when the viscera, by their respective hypertrophy and emphysema, tend to encroach one upon the other, that such sounds should occur synchronously with the pulse during bronchitis. Tubular respiration is, under some circumstances, heard around the heart. These circumstances are a lung somewhat transgressing its natural limits upon the pericardium, the latter being distended with fluid. A hypertrophic heart will displace the lung altogether; but the figure of a distended pericardium will be moulded somewhat by the lungs, and, by pressing behind them, prove a legitimate source of this sign. I have met with it twice; and in the second instance had an opportunity of examining, *post mortem*, the condition

of the thoracic viscera through the kindness of Dr. Guy, who attended the patient after he left Guy's Hospital. I cannot but think it a point of some value, as the evidences of hydropericardium, especially where of gradual access, are often obscure.

The cases of Price and Mapham tend to illustrate some remarks which you favoured me by inserting some months back, respecting the tendency of the mitral valve to become diseased, where the pericardium is adherent to the heart, hypertrophic, and active.

Before concluding, allow me to draw attention to the increase of heart disease in this country (in the metropolis at least) during the few last years. On examining the pathological records of Guy's, it appeared that the years 1826 and 1836 might be taken as fair averages of the periods.

| Year. | No. of Cases recorded. | Medical. | Surgical. | Heart Diseased in— |
|------------|------------------------|----------|-----------|--------------------|
| 1826 | 159 | 108 | 51 | 17 |
| 1836 | 157 | 103 | 54 | 59 |

The increase is a multiple of about $3\frac{1}{2}$. Trifling lesions, as circumscribed thickenings of the pericardium, &c. have not been taken into account. The difference cannot be accounted for by inadvertence or oversight, as Dr. Hodgkin, under whose superintendence the examinations were made, was collecting materials for a paper on disease of the aortic valves. It is notorious that the revolution caused a fearful increase of

the disease in France; and the political agitations of the last few years, with the intemperance engendered by them, and the epidemics that have visited the country, will probably explain our increase.—I am, sir,

Your obedient servant,
ALFRED ASPLAND.

Ashton-under-Lyne,
June 14, 1839.

TUMOR CONNECTING THE FÆTUS WITH THE WOMB.

To the Editor of the Medical Gazette.

SIR,

If you should consider the following case worthy of a niche in your widely circulated journal, you would much oblige by inserting it,

Your constant reader,
JOHN HALL,
Surgeon.

West Kilbush, Scotland,
May 31, 1839.

J. S. ætat. 28 or 30 years, of a robust plethoric constitution of body, has had, previously to becoming pregnant of this her first child, invariably good health.

About two months subsequent to her conception, which happened in the month of June, 1838, she first complained of lingering pains, circumscribed on the left side, described them as of a gnawing character, accompanied by a burning sensation. Not being then in this neighbourhood, my professional neighbour, Mr. Speirs, was called, and prescribed a mustard cataplasm; but

what else (if there was any thing else done) I know not. However, by this method of treatment she seems to have been relieved, *pro tempore*; but a short time afterwards the symptoms returned, and continued without intermission the whole period of utero-gestation.

On the morning of Sunday, 10th March, 1839, I was summoned to her bedside, when, upon questioning her, I found she had been painfully distressed for about 18 hours prior to my call, and upon making vaginal examination, I discovered the os uteri to be soft and dilatable, but not in the least patent, and pronounced the pains to be of a false character; prescribed an anodyne, and returned about the middle of the day. Found she had received considerable rest, and continued yet drowsy. Made no examination. Returned in the evening; was informed the pains had again supervened, had been stronger, and more regular in their nature. Instituted an examination per vaginam; the os uteri dilated a very little; thought I discovered the head of the infant, but when I searched for the fontanelle was baffled. This head had a most uncommonly spongy and corrugated feel; and, from the circumstances of the case, could not be satisfied as to its nature, nor of its relative position to the womb and circumjacent localities. Was ill at ease with myself at the termination of my examination, on account of the discovery, or rather puzzle, I had made for myself; resolved, as soon as the os uteri should become more patent, to set about a more thorough and more satisfactory investigation.

An injection meantime had been administered, the feet immersed in tepid water, and a warm gruel stimulant drink given; the pains, however, continued, on an average, much the same. About midnight I again made examination, and found the os uteri dilated to the dimensions of half-a-crown piece. When the pain was on, I recognized the same spongoid corrugated body I before described; but while I continued my investigation of this, which I now satisfied myself was not the child's head, as the pains subsided, it gently rolled away from my touch, and the real head presented itself. I could not be mistaken; here was the anterior fontanelle, and there the sutures. The real head was now presenting quite naturally.

What was the nature—what the pretensions of the first “unwelcome guest?” became the all-absorbing questions. I resolved to probe the mystery to the bottom. Having ordered my patient some wine negus and two or three drops of laudanum, I allowed about an hour or so to elapse, when I passed my hand into the vagina, and partly into the womb, and discovered a tumor of a pyriform shape, attached to the left side of the womb by a small pedicle, and also connected by a thin skin to the prepuce and scrotum of the infant. The former attachment, without much difficulty, was destroyed; but the greatest care had to be exercised, for fear of injuring the infant: nevertheless, I succeeded in loosening the tumor; and finding it free entirely of any holds, I now made a motion to the door, when the womb made a vigorous contraction, and the head of the child was forced with considerable violence against my hand. It was impracticable for me now to move my hand; but, whenever the pain abated, I made my way good, bringing my strange discovery with me.

In the meantime the draught (anodyne) was repeated, the pains after the operation having almost or entirely dwindled away to nothing. Latterly, this was succeeded by constant shooting pains, which were productive of no effects in furthering the process of parturition. Injections three times over were administered, composed of castor oil, salt, and croton oil. Ergot of rye was also given; but it was not till it had been administered the third time that any thing like regular contractions of the womb, and of an efficient nature, came on. About two or three o'clock on Tuesday morning, regular pains, and accompanied with strong involuntary pressure, changed the aspect of affairs, and gave high promise of an easy, expeditious, and safe accouchement; but in the second stage of the process, owing to the head of the child being large, and the comparative diameters of the pelvis being of such dimensions as not to permit a free transit—after waiting till such time as a fair trial had been given to nature, and every assistance that the lever could give, or manipulations afford, was gone through—the forceps were applied, and the child forthwith ushered into the world. The mother, for at least two weeks thereafter, was in a very weak condition, requiring her

water to be drawn off by means of the catheter. At the present date she is quite recovered.

With respect to the tumor, it I preserved, and carried home for inspection. It is of a pyciform shape, of a cartilaginous sebaceous consistence, and does not seem to be organized. It measures about 6 inches from apex, where it was attached to the child, to fundus, and $3\frac{1}{2}$ inches in diameter. It presents externally the corrugated appearance which it felt *in situ* in the womb, but when cut into is of a homogeneous structure, unorganized throughout. It weighs about $6\frac{1}{2}$ ounces.

The child's privates continued very sore and inflamed, where the tumor had been attached; had to be leeches, bathed with evaporating lotions, poulticed; and are now quite well.

In the present letter I do not intend to philosophise on the origin of such growths; how, without apparent organization, they exist, and attain different degrees of magnitude. This I leave to others more disposed and more able to give a correct theory than I am; for all attempts at explanation of such phenomena must be founded on the principles of theory and conjecture. They cannot be accounted for on any known data of any ancient or modern science, with which the student of nature is acquainted; they are, unquestionably, all several modifications of the thousand freaks that wayward nature plays off, at the expense of the "foolish wisdom" of man, and to evince, to his admiration and wonder, her powerful superiority.

Tumors are extremely common, and are very often met with in various parts of the human body, particularly about mucous membranes; and this case is alone remarkable for its anomalous character, and the peculiarity of its attachments. Attached they are oftentimes to the sides of the womb and side of the vagina; but attached to either of these in the one place, and to the preputium and scrotum of the infant in the other, is a circumstance which, in all my experience, I have never fallen in with, nor heard of its being seen by others, nor even read of it in books. It, therefore, merits the earnest attention of the profession at large, and more particularly the young practitioner, about to make, or having just effected, his *début* on the dangerous, often fatal, sea of public opinion.

N.B.—The phenomenon of the tumor being at one time felt, at another the head, in my examination, is explained by the way this transpired. During the labour, when the pains were on, the body of the child being ambient in the waters of the womb, its lower part, where the tumor was attached to it, was dragged down, and the head of the child swung towards the side of the mother, the tumor being thus pressed into the os uteri. Again, when the pains subsided, things assumed their natural relation to each other respectively.

CASE OF VERY EXTENSIVE ABDOMINAL DISEASE.

By E. H. WEALE, M.R.C.S.L.

Assist.-Surgeon, Royal Naval Hospital, Plymouth.

[For the Medical Gazette.]

THE following particulars of a post-mortem examination, which I had some time since an opportunity of witnessing, through the kindness of the medical attendants, Sir George Magrath and Mr. Taylor, seem to me deserving of notice, from the extent of disease, the number of organs affected, and especially from the alteration which had taken place in the left kidney.

The appearances are, I trust, accurately described; and the following brief sketch of the symptoms is drawn from the communications of the medical attendants, and partly from my own observation, having been acquainted with the subject of the case.

Mr. E. æt. 57, had been subject for several years to occasional attacks of hæmaturia, which, after continuing for some days, ceased; and he was again able to resume his occupations in a public establishment. The attacks were latterly more frequent, and at last became alarmingly profuse; and his health becoming too much impaired, to allow him to continue longer in active employment, he retired about two years ago; but under the treatment of Sir David Dickson and Mr. Rae, and the strictest attention to his general health and quietude, he recovered sufficiently to perform the ordinary duties of life, and even to enjoy the society of his friends, occasionally visiting the country for change of air. For some time I had not seen Mr. E., and was

surprised at hearing of his death. I learnt that an examination would take place, and accompanied Dr. Armstrong, of the Naval Hospital, who had seen him two or three times previously to his decease. For some time a large circumscribed tumor had been evident in the left side, which could be partially emptied by pressure, and was unattended by pain. The bowels were obedient to medicine. He had latterly no appetite, and indeed a distaste, especially for animal food; and the stomach was very irritable. Of this case I know nothing further, not having seen the patient during the illness preceding his death; but the post-mortem appearances are most interesting, both as accounting for some of the symptoms, and as showing how long the constitution will struggle against disease slowly advancing, and at length attaining to enormous extent.

Sectio Cadaveris. — The body was very much emaciated, and had a greenish unhealthy aspect. On opening the abdomen, the great omentum was found to adhere to the anterior parietes, and to be thickly studded with tumors deposited in the subserous tissue, varying in size from a bean to a walnut, and externally mottled with red tints. They differed in consistence; some being like foetal brain, streaked with blood, others of a much firmer character. On raising the omentum, the whole of the intestines and peritoneal processes were found closely covered with similar productions, which were so thickly crowded together in the pelvis, and on the top of the bladder especially, that none of the healthy serous membrane was apparent; indeed, they were like clusters of small potatoes, having the same tuberculated and mottled red appearance. The mucous coat of the alimentary canal did not seem to be diseased, nor even the muscular; for several of the tumors were carefully peeled off, and the muscular bands could be seen unengaged in the disease, which was distinctly seated in the cellular tissue, under the peritoneum, which formed its outer covering, and from which numerous minute vessels could be seen running into the diseased parts. The serous membrane covering these growths, though much more delicate than normal, was highly vascular. Wherever the subserous cellular tissue most abundantly existed there was the

greatest deposit; for an immense mass of almost cartilaginous firmness was attached to the spine, and surrounding the great vessels and extending into the duplicatures of the peritoneal processes. A large tumor situated in the left hypochondrium, and discernible before the abdomen was opened, now attracted attention: it displaced the stomach upwards and to the right side, and closely compressed the descending colon, (which wound round and was attached to it) against the abdominal wall. The coats of the tumor were bluish, and it was distended with fluid blood, which escaped on its being punctured. The whole mass was carefully removed, and on examination was discovered to be the left kidney, changed in the following manner. It was upwards of seven inches in length, and lobulated, assuming a scaphoid form, its internal concave side forming the external wall of a sac, which was the enormously dilated pelvis, and in which the calyces formed such deep depressions, (of a size sufficient to admit the point of the thumb) as to render its inner aspect best comparable to the anterior surface of the sacrum, with one row of its foramina. The coats of the sac were greatly condensed, and the lining one glistening and fibrous, except where it had softened into brain-like matter. The papillæ had disappeared, and in their place was a highly vascular pulpy mass, through which a probe readily passed to the capsule of the gland. On section the organ was found to consist of two structures; one firm and brownish, contained in cells; the other like the cortical substance of brain, but more vascular, and as before described, opening into the calyces, and probably the source of the hæmaturia under which the patient had occasionally suffered for several years. In one of the calyces a cicatrix was distinctly seen; evidently the seat of an attempt at reparation. The coats of the renal veins were remarkably thickened, and were patent as arteries, but did not contain any carcinomatous matter. Some traces of disease were observable on the surface of the right kidney, which was otherwise normal. The liver was large, pale, and the seat of numerous depositions, on the surface assuming the form which has been likened to the head of the radius; their centres white, their circumferences

purplish. They varied in consistence, but were generally firmer than brain. The disease could be traced through its different stages; in the very early appearing like minute pearly or opaline spots, and then becoming cerebral in appearance and consistence, and more vascular. The secretory powers of the organ did not seem to be materially affected by these depositions, though so numerous; the gall bladder being distended with healthy bile.

The lungs did not present any adhesions. The right was quite healthy, but the left was congested with blood, and its serous membrane of a deep grape colour, and studded with growths similar to those in the abdomen, but not larger than black currants, to which they bore a strong resemblance. The heart was quite normal. The head was not examined. It is worthy of remark that in this case the absorbent system seemed unusually free from a disease in which the excrements had performed so active a part.

ON HYDROPHOBIA.

By ROBERT HULL,

Licentiate of the Royal College of Physicians.

[For the *Medical Gazette*]

THE hydrophobia seems to have been very merciless in the metropolis of late. But I have for many years entertained an opinion that a considerable number of the fatal cases were simply nervous, and that the patients have died of terror. The influence of the mind on the body is an omnipotent influence; it saves or kills: and the nervous system allows an infinity of morbid variations, so that there is no disease which may not be precisely imitated in the freaks of this marvellous structure. Some years ago, a French lady, whose case I saw reported, displayed all the symptoms of genuine hydrophobia. She was nigh unto death; but a shrewd physician being summoned, he made it his first business to inquire whether the dog which had bitten his patient was really mad. He found the animal healthy, and cured the lady, hydrophobic through imagination, by opiates, which tranquillized her nerves.

I believe there are very many similar cases, where the patients are mad, and not the dogs; and that when the ani-

mals have been rabid, many bitten patients have died, not of the canine poison, but through nervous excitement. Nay, I have read of but few cases which might not be solved philosophically by this supposition. It is true that children have died of this disorder, too young, it is said, to have been killed through mental influence. But who shall define the juvenile æra, when the mind of a vivacious child has not begun to play upon his body?—and in almost all the adult cases it has been clear that the *idea* of the rabid dog had been quietly but continuously haunting the patient. Let your readers look on these cases, and on inquests by coroners, with a sceptical yet inquisitive attention, and they will recognize, not seldom, the moral cause.

This metaphysical influence I suspected, not long since, in the instance of one Sarah Johnson, on whom an inquest was held, by Mr. Payne, at the Gentleman and Porter Inn. I saw the narrative in the *Evening Mail*. This ill-starred woman probably died of terror. "She had got wet, which accounted for her symptoms." Her surgeon had not, at first, "the slightest idea that Mrs. Johnson was affected with hydrophobia;" but the idea, latent in her own breast, begins to act; and on the second day she tells him of "a dog which some time since struck her on one of the upper teeth with his nose, with such force as to loosen it. No mark whatever was left externally; but part of the saliva from the dog's nose" (saliva from a nose!) "was left on her lips, and she fancied" (fancied!) "some on her tongue." Who does not detect the mental apprehension—the monomania? Saliva from a dog's nose, without a breach of surface, contaminating a human frame! But the surgeon thought it possible, and that "there is no difference between swallowing saliva and being bit"—a most questionable, a much questioned, or rather, a discredited doctrine. Upon this the surgeon bled and leeches her; but the *idea*, now declared, cannot escape by the venous orifice, as the souls of the Homeric heroes slipped through the lance-wounds—Τοῖο δ' ἄμα ψυχὴν τε καὶ ἔγχρεος ἐξέρυσ' ἀνιμν. No wonder, then, that at five o'clock her manner perfectly satisfied her surgeon and another medical man "that it was a decided case of hydrophobia."

"She shewed terror at the sight of toast and water; on Saturday discharged an immense quantity of saliva from her mouth," "and died about one o'clock"—died, I suspect, of mental influence, because Mr. Johnson had testified that "she was alarmed at the time of the accident, but, finding no wound, took no further notice:" no further outward notice, until she mentioned the dog to the medical man. He previously had thought a cold would account for the pulmonic symptoms, but immediately upon this narration recognizes hydrophobia, and excites his patient with this diagnosis;—a patient long secretly gnawed by this very idea of rabies: feminine—susceptible—feverish, with inflamed lungs. Is it marvellous that she should die about one o'clock the day following, even had the lungs been healthy, and not, as they were, "gorged with blood"?

Now there is no strict evidence that even the dog was mad, or that he was killed in Bridge Street as mad; there is none that the patient was lyssamaniac. If, as I believe, pneumonia was Mrs. Johnson's physical malady, the good sense and skill of her surgeon would probably have cured her, had not the unlucky idea of rabies been thrown across his path by her own story, and too easily appropriated.

In this credulity he is not alone, nor culpable, unless the greater part of our profession are so. There seems scarcely ever in the mind of the British practitioner a suspicion that the phenomena may be all due to terror; yet nobody will deny this influence generally. If there be such a sceptic, he has only to peruse Mr. Winslow's paper in this very work; and if he question it in these lyssic cases, let him only read the article Hydrophobia in Cooper's Dictionary—a performance which it is impossible to quote without a sentiment of deep gratitude for the triumphant labours of that indefatigable compiler.

Since it is certain that moral influences will simulate physical, in their pernicious and even fatal effects—since rabies has, in some cases, existed when the biting animal has not been rabid—no harm can possibly result if the practitioner assumes the moral character of the symptoms. Either the patient is rabid, or he is not. If he be not, the therapeutic treatment must be only

mental, or rather moral; if he be, since it is ascertained that all treatment of physical rabies is unsatisfactory or useless, it is best to leave the process of cure to nature *entirely*; not interfering with her miraculous agencies, by suffering the mind of the patient to be engaged. Rather, as the French would say, keep the *morale hors de combat*.

Quoting the case above detailed, I had no wish especially to refer to *that*. It fell in my way. In this city, and within nearly as short a period, a case of fatal hydrophobia, so called, was reported. This case I suspect to have been one of the nervous or metaphysical class. I enter into nothing of details, because I perused only the statement of a newspaper, and I impute no blame. My simple desire is, that the profession should be reminded that a man may possibly die mad from the bite of an *unmad* dog; that even the bite of a rabid animal may be abstractedly innocuous; that even here the tremulous mind may be the cause of the virus operating and destroying; that the best chance of life is afforded by the *tranquilla mens*; and that the practitioner of tact will, at times, even use his scalpel to produce that tranquillity. It is said that the enormous success of Boerhaave was owing to his constant remembrance of the mental influence; whilst the tendency of the present times is to forget the immaterial, and to solve all by the *physique*. Post-mortem phenomena are considered to be ante-mortem causes; vascularity is regarded, and nervous influence forgotten; and from the French school, which has always, in every department, been comparatively superficial, the distended vein, the injected apparent capillary, has been paraded as the mortal ensign; whilst the latent, the mysterious, the potential agency, of the nerve, has been overlooked.

Norwich, May 29th, 1839.

DROPPING TUBE FOR THE TEETH.

To the Editor of the Medical Gazette.

SIR,

ALTHOUGH we must all acknowledge the value, and almost perfection, of dental surgery in the present day, still re-

sort will necessarily often be had to different remedies for the alleviation of toothache.

These remedies being for the most part of an acrid or highly stimulating character, often occasion considerable inconvenience, and also injury, from their coming into contact with the gums or neighbouring teeth in the act of applying them.

Having found a little instrument, a modification of the dropping-tube (of which I subjoin a sketch), of great utility, and very convenient, I venture to recommend it, through the medium of your valuable journal, to the profession.

It consists simply of a glass tube, having a bulb at one extremity, and bent and drawn to rather a fine point at the other.

The fluid to be used—say, creosote, which now seems to be generally and deservedly the favourite—is introduced into the bulb by driving out the air with a spirit-lamp, in the manner that thermometer tubes are filled. (It is desirable that the bulb should not be more than one-third full).

When required, the bent extremity is to be inserted into the hollow of the tooth, and a little of the creosote allowed to pass into the tube. On applying the warm hand to the bulb, the expanded air will drive the drop or drops gently on to the orifice, through which it will pass gently on to the bottom of the cavity.

The advantages of this little instrument consist, 1st, in the ease and surety with which the remedy can be applied at the bottom of the diseased cavity, and immediately upon the nerve; 2dly, in being able to avoid any unnecessary contact of the application with the gums, or neighbouring teeth; and 3dly, in its convenience. A stock of the remedy is contained in the bulb, and is ready for instant use; and so sure and delicate is its action, that when the bulb is cold, and the hand tolerably warm, the approach of two fingers towards it is enough to drive on the fluid.

For the application of nitric acid, to which, when

— “thee — thou hell o’ a’ diseases,
— mocks our groan,”

we may be induced to resort to, it will be found exceedingly convenient.

I am, sir,
Yours, respectfully,
J. D. JEFFERY, Surgeon.

Sidmouth, May 28th, 1839.

ANALYSES AND NOTICES OF BOOKS.

“L’Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D’ALEMBERT.

A Treatise on the Nature of Club-foot and analogous Distortions; including their treatment, both with and without surgical operation. Illustrated by a series of Cases, and numerous practical Instructions. By W. J. LITTLE, M.D., &c. London, 1839. 8vo. pp. lxii. and 274.

WE learn from Dr. Little that Thilenius was the first who proposed the cure of club-foot by division of the tendo Achillis. The operation was performed, at his suggestion, by a surgeon named Lorenz, in 1784, and succeeded perfectly. It was afterwards performed by Sartorius, Michälis, and Delpech; but the difficulties and inconveniences attending it appear to have prevented its general adoption until its revival by Stromeyer, in 1831. It has now been frequently performed in this country, chiefly, we believe, by Drs. Little and Krauss, and promises to become a standard operation. Dr. Little himself suffered under the infirmity which he describes so well, and was cured by Dr. Stromeyer.

There are three kinds of club-foot; in *varus* the patient walks more or less upon the outer ankle; in *valgus*, he treads upon the inner ankle; and in *pes equinus*, the sufferer treads upon the toes alone. We are always sorry to see additions to the endless nomenclature of medicine, and regret, therefore, that Dr. Little uses the terms, *Talipes varus*, *Talipes valgus*, and *Talipes equinus*. In some cases, he tells us, a cure may be accomplished by the use of ferri-sesquioxylum, hydr. c. cretâ, rhubarb, and counter-irritation along the spine, with frictions and manipulations. In others, mechanical treatment alone will effect a cure, without relapse, in a few months. There is a third class in which the division of one or more tendons is necessary:—

"In most cases of *Talipes equinus*, and in many of *T. varus*, which require an operation, the *tendo Achillis* only is required to be divided; in other cases of *Talipes equinus* I have sometimes found it necessary likewise to divide the tendons of the *tibialis posticus* and *flexor longus pollicis* muscles. In severe long-standing cases of *Talipes varus* the section of the tendons of the anterior tibial, posterior tibial, extensor proprius and *flexor longus pollicis* muscles, is requisite, in addition to division of the *tendo Achillis*, in order to facilitate the restoration of the foot to its natural shape and position. The case of congenital *Talipes valgus* already mentioned will indicate the parts which it may be found necessary to divide in that form of disease.

"I will not detain the reader, either by instituting comparisons between the mode of performing this operation and the subsequent treatment adopted by those who preceded Dr. Stromeyer, of Hanover, or by stating my objections to the plans of those who have succeeded him. As I regard Stromeyer to be the regenerator of this important addition to our means of curing club-foot, with other contractions of the ankle, and similar deformities of various parts of the body, and having experienced in my own person the success of his method of treatment, corroborated by the numerous cases which I have cured by the same means, I shall here only briefly enumerate the principles recommended by Stromeyer to be followed.

"The tendons of the muscles which maintain the deformity should be divided with as little injury as possible to the skin and neighbouring parts.

"No attempt should be made to force the foot into its natural shape immediately after the operation; but the necessary extension for that purpose should be commenced as soon as the external puncture or punctures are completely healed: this occurs about the second or third day.

"The lymph which is effused between the ends of the divided tendon or tendons, with the muscles that are not divided, and the ligaments and fasciæ which may impede the replacement of the foot, must be gradually extended until the foot assumes its natural shape, and the ankle can be bent to its fullest extent.

"The application of the apparatus by

which extension is effected must be continued for a certain period after the cure, notwithstanding that the patient has been enabled to stand firmly, and has improved in walking, in order to obviate the tendency to contraction evinced by the intermediate substance or lymph effused between the ends of the divided tendon.

"We may explain the reason of the safety of dividing so large a tendon as that of *tendo Achillis*, or of puncturing the fascia of the sole of the foot and dividing the tendon of the *flexor longus pollicis*, by the facts, that no inflammation follows the infliction of so small a wound, that the skin immediately agglutinates, and the severed tendon is placed in the comparatively safe condition of that of a ruptured tendon, between which and an exposed wound of tendon there is the same difference as exists between the simple and compound fracture of a bone, with reference to the probabilities of suppuration or sloughing. I have had under my care seventy-three cases of contractions of the ankle and knee joints, treated by division of various tendons, amongst which there was no instance of the puncture not having immediately united by adhesion. This result is solely attributable to the smallness of the wound, and the non-disturbance of the healing process by precipitate attempts to straighten the limb*."

The following history is very curious: the patient was Dr. Inglis, who was afterwards successfully operated upon by our author:—

"Fifteen years since, and prior to the commencement of his medical studies, he became convinced, solely from his sensations, uninfluenced by any anatomical knowledge, that his lameness depended upon a shortening of the tendon behind the heel, and consequently that if that were cut his lameness would cease, by the heel being allowed to reach the ground. He communicated his opinion and suggestion to the medical attendant of his family, who discount-

* "I have expressed the intention not to institute comparisons between the Stromeyerian method of cure and the mode of operating pursued by the predecessors of Stromeyer; but I may be permitted to remark, that the slow advance of our art with respect to the division of tendons for the cure of contractions mainly arose from the extensive suppurations, sloughings of tendons, and consequent failures, which frequently followed the large incisions made by Sartiarius, Michaelis, Delpech, and others."

tenanced them, and explained to him the danger which he supposed would arise from the division of a tendon, and especially of that of the tendo Achillis, and advised him to abandon the idea of his lameness being curable. Not being discouraged by this adverse opinion, he communicated his ideas to other members of the profession: they, however, concurred in the advice given by the physician first consulted. Being still dissatisfied with the decision, he determined to put in execution his own project; and contriving an appropriate apparatus for drawing down the heel, he secretly divided the tendo Achillis with a surgical instrument. Considerable bleeding ensued; his family were soon aware of the circumstance, and directly sent for their medical attendant, whose advice had been so pertinaciously rejected. That gentleman treated the patient as monomaniac (certainly not without some reason, as he was ignorant of the safety of dividing large tendons, even with the greatest skill and care bestowed upon the operation); and ordered the careful adjustment of the lips of the wound, so as to obtain cicatrization. The treatment subsequently pursued was that deemed applicable to an accidental division of the tendon; the foot being bandaged in a state of extension, in order to keep the edges of the divided tendon in close contact, and to prevent the patient from walking until the union of the tendon was complete. The consequence was, that on obtaining permission to walk he found the elevation of the heel and the state of the deformity the same as they were before division of the tendon. Had permission to walk been granted immediately on the healing of the skin, whilst the lymph which united the divided tendon was soft and susceptible of extension, it is probable that the operation performed by the patient would have been successful. As the elevation of the heel was not very great, the weight of the body being thrown upon the tarsus would have sufficed to force the os calcis to the ground, and the act of walking might have induced a greater range of motion of the ankle. The cicatrix where the operation was performed by Dr. Inglis is distinctly visible, and about an inch in length transversely over the tendon, shewing that the incision was considerable. Dr. Inglis informs me that he cut from without inwards, doubtless through

skin, fascia, and tendon. It is fortunate that so extensive a wound healed by adhesion; a suppurating wound of the tendo Achillis, such as accompanied the first and only operation upon the tendo Achillis performed by Delpech, of which an account was published, would have been attended, as was the case treated by that surgeon, with sloughing of the tendon, a wound tedious in healing, and consequently a protracted and imperfect cure."

We will content ourselves with one short extract more, containing a valuable hint:—

"I am convinced of the justice of an observation made to me by Dr. Strömeyer, that rupture of the tendo Achillis is an accident from which, but for the needless interference of our art, the patient would always perfectly recover, without pain during the treatment, or subsequent inconvenience when walking. The application of the slightest bandage, in order to prevent motion of the ankle-joint during the first few days after the accident, is all that is requisite to ensure perfect union: indeed I think it probable that the application of bandages might be dispensed with."

Thirty-six cases are narrated by our author, with comments, and they are illustrated by forty-one well-executed woodcuts.

He has already treated eighty-two cases (among whom were nine members of medical families); some required division of the tendo Achillis only; others, that of two or more tendons. Dr. Little's treatise will be consulted by every operator, and is unquestionably one of the most useful books of the season.

MEDICAL GAZETTE.

Saturday, June 22, 1839.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL CONGRESS AT DUBLIN.

THE progress of society, as we remarked in our last article, has produced an enormous and irresistible demand

for cheap medical advice. The question to be settled is, whether it is better to have physicians like the continental ones, whose fees may suit the slender means of the very humblest of the middle classes, or whether their place should be supplied by apothecaries? In England the question is decided for the present, and probably for years to come; in Ireland it is still a debateable point. Now Mr. Carmichael (by far the best speaker in the Congress) has not the smallest relish either for minute fees or for apothecary practice. What he would have, or how he would solve the professional problem which is now offered to our Irish brethren, does not appear. Perhaps some dim vision of a Medico-Chirurgical Act, stringent as the Apothecaries' Act of 1815, may float before his imagination. He may be assured, however, that it would be difficult even to get any one to bring in such a bill, and that its passing would be too wild a supposition for a dream. The extreme inconvenience that must have been suffered in this country for ages, through the want of cheap advice, is obvious to every one who has studied the history of the profession. When a fee was equivalent to half a year's rent of a large house in London, and the College of Physicians checked the practice of surgeons and apothecaries with the iron hand of the law, where could an ordinary man seek for medical assistance? No doubt the surgeons and apothecaries did practise in spite of verdicts and censures; but the deficiency must have been chiefly made up by the host of farriers, midwives, herbalists, and all the minor professors of leechcraft, as well as amateur practitioners of every grade. Yet all these semi-professional and voluntary aids must have proved insufficient; and there can be little doubt that more persons perished for want of medical succour

in England during those ages, than now suffer from the same cause in Styria, Carinthia, or Dalmatia. In time the defect was supplied, not perhaps in the best manner, but sufficiently so to content the public. In Ireland it would seem that social instinct is supplying the same want in the same way; but Mr. Carmichael cannot see that it is a want—just as people riding in their well-hung chariots talk of “the omnibus nuisance.” A certain physician in high practice knows better, for he told Mr. Carmichael that “Families will have a cheap medical man, a person whom they can call upon at all hours, a kind of male gossip, often taken out of his bed at night on the most trivial occasions; besides, he must be advanced in years, and married.” After making due allowance for a little railery in this description, we think it much more exactly fits the apothecary of 1780 than the English general practitioner of 1839; but for this very reason it may be an accurate picture of the Dublin apothecary of the present day; as it is natural that in copying the phases of English society, something like chronological order should be observed.

Mr. Carmichael, however, thinks the physician in high practice quite in the wrong. He believes the apothecary to be a more expensive attendant than the physician or surgeon; “and as to the objection that grave elderly physicians and surgeons cannot be had on moderate terms, I am sorry to observe so many hoary signs of advanced life, whitening the temples without filling the pockets of numerous meritorious *confères* around me, who, perhaps, would be well satisfied at receiving a guinea every second or third visit, or to be paid annually a regular stipend for attendance on families,” &c.

Perhaps would be well satisfied with a guinea every second or third time!

We wish they may get it. This method of untying the knot by the invention of half-guinea or seven shilling fees is wonderfully like the plan for escaping famine, devised by the princess in the story: rather than die of hunger, she said, she would eat bread and cheese. If the petty shopkeepers of Dublin or Limerick can give seven shilling fees, we acknowledge that the difficulty is cleared up, and the apothecaries may be sent back to their mortars. The scheme of an annual stipend will do in many instances, provided the salary is a very small one; but if it is, surely Mr. Carmichael will dislike it as much as the half-crown fees; if it is to be considerable, the middle classes will not be benefited; and even if moderate, the poorer among these classes will shrink from an insurance, and run the risk of a bill.

The speaker, indeed, carries the art of not seeing so far, that he does not see the necessity of being married, in order to gain the confidence of families, but assures the public "that far greater security is afforded them in the moral, religious, and honourable principles of well-educated gentlemen," &c.

If a first-rate practitioner like Mr. Carmichael, learned in all the varieties of human frailty, habituated to the confidence of every class, from the uneasy heads that wear a coronet, down to the hewers of wood and drawers of water, does not know why the married are preferred, we will not pretend to teach him *, but will pass on to another point.

Mere druggists, adds Mr. Carmichael, have now become doctors, "and even prescribe with impunity for those who have the consummate wisdom to consult them." No doubt of it, for

many patients who have no honorarium for a practitioner of the first class, nor seven shillings for a white-headed doctor of the second, nor even half-a-crown for a married apothecary, have ninepence for a druggist. This is a very prosaic fact, but fact it is; and unless we can teach the ninepence to fructify in the patient's pocket, we must either connive at cheap practice coming in a very questionable shape, or persuade regular practitioners to pouch the tiniest fees without blushing.

Why did you go to that ninny of a druggist, when you might have had Mr. Carmichael? *Res angusta domi* is the unanswerable reply.

We agree perfectly with the speaker, that it would be most desirable if the practice of physic could be entirely separated from the practice of pharmacy; it would probably have the double effect of improving the practitioners of medicine, and of creating a race of apothecaries who, by returning to the art which they have left, might vie with their brethren of the continent. But to effect this happy disjunction, we see but one method, and to this he has an invincible repugnance; to put down the omnibuses, you must drive your coaches at omnibus fares—and this he will not hear of.

Mr. Carmichael touches a little on medical police, and supposes that the vaunted regard for British freedom which is professed on this point, is a mere pretext for raising a considerable revenue by the stamp-duties on quack medicines.

Our readers who recollect how fully we treated this subject a few months ago, will readily excuse our not entering upon it again now; but we will just warn them, that the less they expect from any application to parliament concerning nostrums, the less they will be disappointed.

* Yet we have a mind to teach part of the theory in a note. A settler in Australia, some years since, writing to a friend in England, lamented the deficiency of women in the colony, and begged that they might be sent over, "for a wife robs a man more than two sermons a-day."

Sydney Smith, in one of his pamphlets, tells a pleasant anecdote of the trial of some notorious smugglers, which took place in Guernsey. They were acquitted, to the surprise of every one out of the island, but of nobody in it; the fact being, that judge, jury, counsel, and witnesses, were all concerned themselves in the contraband trade. Now, when we consider how many lords of parliament, burgesses, and knights of the shire, drink balm of Gilead, swallow antibilious pills, or besmear themselves with infallible ointment, we cannot help fancying that the Guernsey case is renewed, and that the jury have a passion for moonlight trade.

The great object of the meeting, however, appears to have been the fusion of the physicians and surgeons into one body, by means of an act of parliament;—a plan, therefore, much resembling the notable One-faculty Scheme, which afforded us so much diversion in England a few years ago. "What," said Dr. Lushington, at that time, to certain applicants, "is not the physician the physician, the surgeon the surgeon, and the apothecary the apothecary? Gentlemen, I wish you good morning." The difference between the two schemes is, that the Britannia metal was to be formed of three ingredients, while the Irish pinchbeck is to consist of two only; for the two higher estates refuse a union with the third, and drive it away from the melting-pot. Yet we have gone rather too far, in allowing that the two estates are willing to dissolve into each other; for, in truth, the surgeons have been joined only by a few individual physicians, the College of Physicians having wholly rejected their proposition.

To the unspeakable astonishment of Mr. Carmichael, the most desirable match ever projected is balked by the foolish obstinacy of one party: the ring

is bought, the travelling carriage hired, the bridegroom has his own consent, and nothing is wanting but—the bride's! The Fellows of the College have actually declined to be swamped! As the old couplet runs,

"Charles at this time having no need,
Thanks you as much as it he did."

There are, it seems, only about thirty Fellows eligible to four professorships, the lucrative situations of librarian and registrar, and two or three hospital appointments; so that the arguments against swamping are of a very solid kind. Mr. Carmichael, indeed, alleges that the entire number in the College of Physicians, including honorary Fellows and Licentiates, is scarcely a hundred, while the College of Surgeons contains more than six hundred; and the probable number of physicians and surgeons admissible into the proposed united College amounts to about two thousand three hundred more; yet the surgeons are willing to allow one-half of the Council of the new College to consist of members of the College of Physicians for the next ten years, or even longer. But it certainly does not require the acuteness of a Graves or a Stokes to see that long before the ten years were over, the process of swamping would have been completed; the hundred could never resist three thousand; each bony obstacle would have been removed by so many absorbents. "Is it rational or just," continues Mr. Carmichael, "that, opposed to this great body, thirty gentlemen, no matter what their merits may be, should be permitted to thwart or prevent the accomplishment of a great national object of vast utility?" Why, this is precisely what would be said, after the union, by the surgical to the medical half of the Council:—You represent only a hundred physicians, and we are the delegates of all the practitioners in

Ireland, and *you* pretend to oppose *us*!

But how can the thirty gentlemen at present thwart the three thousand? Suppose thirty officers, prosperous and powdered, were to refuse to be balloted for at the United Service Club, would this ruin the society? Now our opinion is, that the best and perhaps the only method in which physicians and surgeons can be advantageously united, is by a society in the nature of a club, the United Service Club offering the best possible example of such a junction. Physicians and surgeons might here meet for all the objects of scientific intercourse and good fellowship, without any petition to Parliament, without any swamping of the thirty gentlemen, and without broaching the indivisibility of physic and surgery—a bit of sheer nonsense, falsified alike by history and common sense*.

We more than suspect that, when the amalgamationists go up to Parliament with their swamping petition, they will be answered as the one-faculty people were by Dr. Lushington, "Good morning to you, gentlemen!"

We will conclude this subject on an early occasion; meanwhile we subjoin the Resolutions passed at the meeting.

EXAMINERS IN THE UNIVERSITY OF LONDON.

Anatomy and Physiology—Mr. Kierman, F.R.S.; Dr. R. B. Todd, F.R.S. The number of candidates amounted to nineteen.

Comparative Anatomy and Physiology—Dr. Roget, Sec. Royal Society. The number of candidates—eight.

Medicine.—Dr. Billing; Dr. Tweedie, F.R.S. The number of candidates—nine.

Surgery.—Mr. Bacot; Sir Stephen Hammick, Bart.

Materia Medica and Pharmacy.—Mr. Pereira, F.R.S. The number of candidates—seven.

Midwifery.—Dr. Locock. The number of candidates—eight.

Chemistry.—Mr. Daniells, F.R.S. The number of candidates—four.

RESOLUTIONS

PASSED AT THE GREAT MEETING OF THE PHYSICIANS AND SURGEONS OF IRELAND, MAY 29TH, 1839.

Richard Carmichael, Esq. in the Chair.

Moved by Professor Porter; seconded by Sir James Murray:

Resolved—That we, the physicians and surgeons of Ireland, having expended large sums of money and much time and labour in the acquisition of professional knowledge, and many of us being engaged in the performance of important duties to the public, we feel that it is not unreasonable for us to expect from the government and the legislature protection equal to that afforded to the members of the liberal professions.

Moved by Dr. Kidd, Armagh; seconded by Professor Hart:

Resolved—That it is the opinion of this meeting that we are not protected, inasmuch, as while we have voluntarily submitted to a lengthened course of medical study, and trying examinations; and while we have contributed large sums to the revenue in the form of stamp duties, yet our services are constantly enforced in the administration of public justice, without any, or with insufficient, provision being made for our remuneration.

Moved by Dr. Macartney; seconded by Professor Hargrave:

Resolved—That it is the opinion of this meeting that the cause of all these evils is to be traced to the existence of divisions and separate interests among the members of the medical profession; and that their effectual remedy is to be sought for in a permanent union.

Moved by Dr. O'Beirne; seconded by Dr. Jago, Kinsale:

Resolved—That the true basis of such union should be a similarity of studies, pursuits, and interests; and that we, the physicians and surgeons of Ireland now assembled, do declare that medicine and surgery are one branch of science and one profession, and that the separate practice of certain departments by distinct individuals is merely an expedient division of labour, having no reference to education or to general professional interests.

* The Hippocratic oath says, "I will not perform lithotomy, but leave it to those skilled in the operation."

Moved by Dr. Bullen, of Cork; seconded by Professor Williams:

Resolved—That it is therefore our opinion that a legislative measure should be sought for by us to unite the medical profession of Ireland into a corporation upon such principles as shall constitute them one national faculty, and thereby identify in feeling and interests the great mass of provincial practitioners with their metropolitan brethren.

Moved by Dr. Orpen; seconded by Dr. Jones, of Waterford:

Resolved—That to promote so desirable an end, steps be at once taken to form district medical associations throughout Ireland, which shall be composed of all practitioners in medicine holding degrees or diplomas in medicine or surgery from any of the colleges, corporations, or universities, at present legally authorised to grant the same, who are of irreproachable moral and professional character; and who are not engaged in the business of retailing drugs, or compounding the prescriptions of others.

Moved by Dr. Cranfield, of Enniscorthy; seconded by Dr. Cane, Kilkenny:

Resolved—That the members of such district associations shall elect from among themselves a president, vice-president, secretary, and committee; that they shall have the power to nominate delegates to represent their interests at the general meetings of the profession; and that the duties of such associations shall be to obtain local information regarding all matters of medical police; to settle disputes among their own members; to watch over their local interests; and to communicate with a central metropolitan council.

Moved by Dr. Jacob; seconded by Dr. Dunn, of Drumsna:

Resolved—That the following are the principles which should be held in view in constructing the constitution of the new college, which it is proposed to establish:—

A. Fundamental regulations with regard to the education of all persons proposing to enter the profession of medicine, to be permanently established.

B. Compliance with such fundamental regulations to be rewarded with the licence of the college, conferring free and equal rights to all professional practice, offices, and emoluments.

C. All persons so licensed, to be enrolled as members of the corporation, upon the expiration of a certain probation, provided only they can produce evidence of an irreproachable moral and professional character.

D. Every individual so enrolled to be thenceforward free to vote, and act in the

college, in every corporate capacity whatsoever.

E. A general meeting of the whole college to be held on the last Wednesday in May in each year (being the anniversary of the present congress), to which it may be lawful for the district associations to send representatives, the business of such general meeting being to elect a president, secretaries, and an executive council, which shall carry on the government of the College during the ensuing year; but shall at all times sit, deliberate, and vote with open doors.

F. A general meeting to be called at any time by the council, or upon a requisition signed by at least twenty members.

The title of this college shall be the *Royal College of Medicine and Surgery in Ireland*; and it shall be to all intents and purposes a union of the two branches of medicine and surgery into one faculty.

Moved by Dr. Tuohill; seconded by Dr. Reardon, Tipperary:

Resolved—That at the first formation of the new College, all persons holding degrees or diplomas in medicine or surgery, from any of the colleges or universities at present legally authorized to grant the same, who have been five years in the practice of their profession, not following the business or profession of a retail druggist or apothecary, and who can produce evidence of irreproachable moral and professional character, shall be enrolled as members of the corporation, upon payment of a sum not exceeding 20 guineas.

Moved by Professor Benson; seconded by Dr. McCormac, Belfast:

Resolved—That persons similarly circumstanced, but who have not been five years in practice, shall, on the payment of a like sum, not exceeding 20 guineas, be enrolled as Licentiates of the College, and shall be held qualified to be enrolled as members of the corporation, upon the completion of the full term of five years from the date of their original degree or diploma, without further expense."

Moved by Dr. Blackwell, Dunleer; seconded by Dr. Bradley, Castlecomer:

Resolved—That members and licentiates of the College of Surgeons, and fellows and licentiates of the College of Physicians (provided the latter body join the union) shall be exempted from any such payment, they having already paid large sums, and now possessing exclusive rights in the present colleges.

Moved by Dr. Macdonnell; seconded by Dr. Langley, Nenagh:

Resolved—That persons now enrolling their names, and pledging themselves to support the foregoing resolutions, shall

together with the members and licentiates of the College of Surgeons, and of the College of Physicians (in case that body join in the union), constitute an association to continue in existence until the new charter or act of incorporation shall have been obtained, and that the provisional body so framed shall be constituted as to its officers, meetings, &c., as nearly as possible upon the principles already laid down for the constitution of the new College.

Moved by Dr. Nugent, Cork; seconded by Dr. Healy, Eunis:

Resolved—That a provisional council, secretaries, and president, be now elected, and that the business of organization be at once commenced.

Moved by Dr. O'Grady, of Swords; seconded by Dr. Colohan, Galway:

Resolved—That Richard Carmichael, Esq., be president of the provisional council; that Dr. Maunsell shall be secretary; and that the council shall consist of the committee of correspondence of the College of Surgeons, with the deputies of the local associations now existing, or hereafter to be appointed, with power to add to their number, and to communicate with medical associations in the sister kingdoms.

Moved by Surgeon White; seconded by Dr. Kingsley, Roserea:

Resolved—That it is our firm conviction that the interests of the public, and of the medical profession, require that encouragement should be given to a class of scientific apothecaries, whose time and attention would be exclusively devoted to the preparation and compounding of medicines, and who would thus have an opportunity of raising the profession of pharmacy from its present degraded condition in Ireland, to a level with that which it occupies in France and Germany; and that we think such encouragement would be best afforded by the establishment of a college of pharmacy; by the prevention of medical practitioners from keeping shops for the sale of drugs, or compounding the prescriptions of others; and by affording to regularly educated apothecaries protection, by giving them an exclusive right of dealing in medicinal articles, and such other advantages as could fairly be granted to them by the legislature.

Moved by Dr. Walsh, of Tullamore; seconded by Dr. Morrison:

Resolved—That we disclaim all intention of interfering, by any of our proceedings, with vested rights now enjoyed by any individuals.

Moved by Dr. Tabuteau; seconded by Sir A. Clarke:

Resolved—That the establishment of a relief and widows' fund be recommended to the attention of the provisional council.

(Signed) R. CARMICHAEL,
Chairman.

H. MAUNSELL, M.D.
Secretary.

Mr. Carmichael having left the chair, and Dr. Macartney having been called thereto, the following resolution was moved by Dr. Bewley, of Moate, and seconded by Dr. Montgomery, of Carrickmacross, and unanimously agreed to:

Resolved—That the best thanks of the meeting be given to Mr. Carmichael for his admirable conduct in the chair.

(Signed) J. MACARTNEY, M.D.
Chairman.

H. MAUNSELL, M.D.
Secretary.

PROCEEDINGS OF COUNCIL.

Wednesday, June 12th.—Resolved: That the day of meeting be in future Saturday.

June 15th.—Resolved: That the Council recommend district associations to be immediately established, as nearly as possible according to the general plan laid down in the following resolutions passed at the Congress:—

Resolved,—That to promote so desirable an end, steps be at once taken to form district medical associations throughout Ireland, which shall be composed of all practitioners in medicine holding degrees or diplomas in medicine or surgery from any of the colleges, corporations, or universities, at present legally authorized to grant the same, who are of irreproachable moral and professional character; and who are not engaged in the business of retailing drugs, or compounding the prescriptions of others.

Resolved—That the members of such district associations shall elect, from among themselves, a President, Vice-President, Secretary, and Committee; that they shall have the power to nominate Delegates to represent their interests at the general meetings of the profession; and that the duties of such associations shall be to obtain local information regarding all matters of medical police—to settle disputes among their own members—to watch over their local interests, and to communicate with the central metropolitan council.

And that the secretaries of such associations be requested to put themselves in communication with the council as speedily as possible.

SMALL-POX AT SYDNEY.

THERE has never been, in the memory of the oldest colonist, so long continued and so severe a visitation as that under which the island has suffered for the last month. We regret to state that although its virulence occasionally abates, yet relapses are constantly returning with increased severity. We may almost say that no individual has experienced one single attack; no sooner does he consider himself convalescent, than he finds himself struck afresh by the disease with renewed vigour. We believe we are rightly informed when we state that there is no one house in this town or its vicinity, all the inmates of which have escaped attack in a more or less degree. The whole of the inhabitants, from the oldest to the infant, have passed through it—many with unspeakable suffering of weeks' continuance, all with much pain and inconvenience. Those in the decline of life, or of exhausted or injured constitutions, have experienced longer and more virulent attacks than the young and healthy. Perhaps the best method of exhibiting the nature of the disease upon the former will be by relating what we experienced, and which was also experienced by some of our friends. The attack commenced in the usual manner:—Difficulty of breathing, particularly through the nose, a sense of fulness stopping up the passage, an acrid fluid distilling therefrom—an oppressive weight in the forehead—a distressing uneasiness in the uvula, the throat, and the tonsils, attended for some days with loss of the voice—the cough increasing, producing at each paroxysm an excretion of mucus, brought up with great difficulty and exertion. As these symptoms increased, their severity was particularly felt at the approach of evening, until at last the patient being unable to remain in the horizontal posture, was compelled to pass the nights in a chair, for the last hours of which the difficulty of breathing was attended with a sensation in the chest which can be somewhat understood by imagining a dry honey-comb to be there, through the cells of which every respiration passed, and which were destroyed and replaced with a loud crackling noise at each inhalation and exhalation. After continuing in this state for some hours the paroxysm abates, the cough is easier, expectoration of mucus takes place, and exhausted nature sinks into a sort of convulsed repose. During the day the mental and bodily powers are so devorated that the patient, incapable of exertion, seeks only not to be disturbed, until the night

again coming, the above scenes of suffering has again to be undergone. As it would be impossible for the human constitution to stand up long against such attacks, so, after a few nights, the paroxysms diminish in severity, until little by little the mucus becomes thicker, less in quantity, is discharged with more freedom, the wheezing crackling in the throat and head is less felt, and convalescence approaches. The medical treatment which has been found most serviceable in this terrible disease, is simply and alone to alleviate the symptoms, for experience shews they must and will work themselves out. The constant use of thick mucilage of gum arabic, a teaspoonful of laudanum added to a ten-ounce phial when the cough is troublesome—attention to the bowels by saline aperients—if continued pain in the chest, blister. The syrup of white poppies, taking a few drops into the throat when the cough is violent, affords considerable relief. The acetate of ammonia and the nitrate of potassa are usefully administered, as is that best of diaphoratics—the solution of tartarized antimony, in small frequently repeated doses. The free use of demulcent drinks, barley water, &c., and above all, the most rigid abstinence. This course, with the most guarded caution against taking fresh cold, is perhaps as efficacious as any which can be adopted towards the removal of a disease which would appear to submit only to alleviating treatment—to subdue it promptly seeming to be quite impossible.

We have already stated that this affection is evidently atmospheric, dependent entirely upon some constituent with which the atmosphere becomes empoisoned; and until that ingredient is wholly removed by the restoration of the ordinary qualities, in their ordinary proportions, the lungs and perhaps other sources of the vital supply to the human being not being suitably furnished therewith, disease and (in the case of cholera) death too frequently follows.

V. D. L.

Sydney, Jan. 1, 1839.

ON PATHOLOGICAL SECRETIONS
IN GENERAL.

By DR. R. MARCHAND.

IN regard to the inorganic constituents of pathological secretions, these are always the same, unless a peculiar variation in them has been produced by some accidental external influence. Iron exists in all, but I have sought for copper, manganese, and titanium, in vain. I have universally found the idea, that titanium

forms a constituent of the blood and of the renal capsules, to be ungrounded. Potash is present in greater quantity than soda; ammonia is never absent. Among the acids the phosphoric is very frequent; and I have in two cases found fluoric acid, once in ascites, and once in hydrops ovarii. There is no general rule, and, as might be expected, the relation of the urinary and cutaneous secretions has a remarkable influence. Lactic acid, whose formation appears to be almost primary in the animal organization, seems to be always combined with the basis.

The separation and distinction of the organic constituents of pathological secretions, is much more difficult than those of the inorganic. The constituents are tolerably constant, but they vary very much in quantity. Thus, in the fluid of ascites, I find the proportion of albumen varying from $\frac{1}{2}$ to 14 per cent; but the latter is a very large and very rare proportion, and whenever it is present there is great difficulty in completely separating any other principles.

I have closely examined the combination which is produced by corrosive sublimate and albumen. It is never composed of calomel and albumen, neither does it contain deuto-chloride, but oxide of mercury. The free acid which is found in the filtered fluid, and which appears to indicate the presence of calomel, is thus much more simply explained. I have never found fibrin.

Among the unquestionable substances one may enumerate various kinds of fat. I have demonstrated the existence of the Couerbian cerebral fat, and have found the views of that chemist for the most part correct. Are these kinds of fat found in the spinal cord, or in the nervous substance? I cannot yet convince myself. Most of them have no definite distribution, though in encephaloid tumor, which I have twice analysed, fat containing phosphorus was found. The part which the phosphorus plays is very remarkable, but as yet unexplained. Cholesterine is more generally found than the phosphorized fat. I have demonstrated it in gall-stones of the most varied kind, in a hydrocele, in a human brain, in hydrocephalus, in encephaloid tumor, and in ox's bile. I believe we must assume that it exists previously in the blood. Salivary matter is very rare. Colouring matters are very frequent: that of the bile is rare; those similar to that of the blood are most common; and without doubt real blood not unfrequently occurs.—*Müller's Archiv*, 1839, Hft. 1.

ON THE FORMATION OF UREA IN THE ANIMAL BODY.

IN illustration of this subject, Dr. Marchand has employed a modification of the experiment of removing the kidneys from dogs that had fasted for many days, and then seeking for urea in the blood (see Müller's *Physiologie*, Bd. 1. p. 586.) He has not starved the dogs on which the experiments were performed, but has fed them on perfectly pure sugar, which he had ascertained by the most careful examination to be entirely free from azote. He fed a large, healthy, and strong sheep-dog for 14 days with milk, to see how large a quantity of urea the urine of an animal thus simply nourished would contain. After the first five days he found 2.6 per cent. and in the next five days 3 per cent. at which proportion it remained stationary. The animal was now fed with perfectly pure distilled water, and pure sugar, of which he took 10 ounces daily. After six days, in which the dog appeared in very good health, the urine contained 2.8 per cent. of urea; in the next five days only 2.4 per cent; and after five days more only 1.8 per cent. The animal was now very thin and rather weak, but there were no ulcers on the cornea such as Magendie speaks of. He was now fed again with milk and *bouillon*, on which he rapidly recovered himself; and it was interesting to see that the proportion of urea in the urine did not keep pace with the improvement of condition, for the dog had recovered his *embonpoint*, while the urine still contained only 2.4 per cent of urea. After 14 days of recovery under this diet, when the urine contained from 3.2 to 3.35 of urea, the dog was again fed on pure sugar and distilled water. After 8 days the proportion of urea fell to 2 per cent. The renal nerves were now tied, an operation followed by the same suppression of urine, with less danger than that of extirpation of the kidneys. The wounds soon healed, and for six days no particular symptom occurred; then vomiting and diarrhoea set in. Ten days after the operation the jugular vein was opened, and three pounds of blood drawn; from this blood urea was extracted, in a quantity amounting (in its combination with nitric acid) to 4.88 grains.

This fact seems to prove that the urea proceeds from the animal substances already formed in the body, and not, or at least not only, from unassimilated nutriment containing nitrogen.

Dr. M. has also obtained almost a direct proof of the presence of urea in healthy blood. The most remarkable property of

this principle being its power of producing by its mere presence a different crystalline form in common salt than that which is usual, he has used this as a test of its presence. He found this test so delicate, that he could discover by it from 1-10th to 1-20th of urea, in from 100 to 150 parts of water. He mixed 20 pounds of serum of cow's blood with absolute alcohol, and filtered the fluid from the albumen. The fluid was then evaporated to dryness in a water-bath, and the residue was completely exhausted with absolute alcohol; the latter was then distilled off, and the residue was dissolved in water and mixed with some common salt. After a few days some octohedral crystals formed, which were found to be pure hydrochlorate of soda; and as no other substance is yet known capable of producing this change of crystalline form, the presence of urea in healthy blood, may fairly be assumed.—*Müller's Archiv*, Hft. 1, 1839.

SOURCE OF THE NITROGEN IN PLANTS.

At the séance of the Institut of January 22d, M. Boussaingault (whose researches on this subject we have before noticed) communicated a further account of his investigations, from which he argues that certain plants derive nitrogen, not only from the soil and manure in which they are cultivated, but from the atmospheric air. That they abstract this principle from the soil and manure is evident, from the facts that corn grown from the most azotized manure, yields the greatest quantity of gluten; that soils are deteriorated by the growth of plants in various degrees, and that the most nourishing plants (that is, those which contain most nitrogen) are those which weaken the soil the most and the most rapidly. The most fertilizing manures are those that contain most azote; and the most nutritive fodder is also that which contains most azote; and therefore the plants which obtain most nitrogen from the soil are those which also most impoverish it.

But if the stems and roots, or still more the whole plants of part of the crop, be again ploughed into the soil, it is improved; and this seems to show that the plants which have thus served as manure, must have acquired nitrogen from the atmosphere, because they have returned to the soil more of that element than they took from it. In many farms where manure can be had only in small quantities, and where there is no deposit of organic matter from a river, the greater

part of the manuring is affected by ploughing vegetable matter into the soil in which it has grown. Thus in those farms from which, by the growth of corn and the supplies of cheese, meat, &c. which they export, there is a constant removal of large quantities of nitrogen, there is little or no other mode in which it can be replaced and its supply maintained, except from that which the plants ploughed into the soil have abstracted from the atmosphere.

The results of M. Boussaingault's late experiments and analyses, is, that in germinating, neither trefoil nor wheat grain or lose nitrogen; that at the same time they lose carbon, hydrogen, and oxygen, in various proportions; that, in further culture, the trefoil, in a soil of silicious sand entirely destitute of organic or other manure, and only under the influence of the atmospheric air and distilled water, acquires carbon, hydrogen, oxygen, and a quantity of nitrogen, appreciable by analysis; and that wheat, under the same circumstances, acquires oxygen, hydrogen, and carbon, but (in a period of three months) not a sufficient quantity of nitrogen to be detected by chemical analysis.

RESEARCHES RELATIVE TO THE CAUSES OF SUDDEN DEATH.

The opinion is still entertained by most physicians that apoplexy is the most frequent cause of sudden death. M. Alphonse Devergie, who has the medical direction of La Morgue—the place where the bodies of unknown persons who die suddenly in the streets of Paris are carried—has endeavoured to ascertain how far this opinion is founded in truth, and has found that sudden death from an affection of the brain is rare. Of forty cases which he has examined, he has found four only in which death resulted solely from an affection of the brain; three in which there was congestion of the brain and spinal marrow; and twelve in which the lungs and brain were simultaneously affected. Sudden death from affection of the lungs alone is the most common. M. D. met with twelve cases of this out of the forty; and if to these we add the twelve examples of sudden death in which the brain and lungs were both affected, we shall have twenty-four out of forty in which the lungs were affected in cases of sudden death. Death from affection of the heart is the most rare. M. D. met with it but three times.

It results from these researches that sudden deaths are occasioned, arranged according to the order of their frequency,—1, from an affection of the lungs; 2, of the

lungs and brain; 3, of the brain and spinal marrow; 4, from hæmorrhage; 5, from an affection of the heart. It is consequently an error to regard apoplexy, that is, circumscribed cerebral hæmorrhage, as the most common cause of sudden death; since of forty cases M. D. has observed an apoplectic collection of blood but once. Sanguineous congestions of the meninges should not be ranked among cerebral hæmorrhages. M. D. has further ascertained that sudden deaths are much more frequent in winter, and more common in men than women. Among the forty deaths noted, but five were of females; and finally, that sudden deaths occur principally in persons from 40 to 50, and from 60 to 70 years of age. —*American Journal of Medical Sciences.*

BOOKS RECEIVED FOR REVIEW.

Elements of the Practice of Medicine. By Richard Bright, M.D. and Thomas Addison, M.D. Physicians to Guy's Hospital, and Lecturers on the Practice of Medicine. Vol. I. Longman and Co. 1839.

A Treatise on the Operation of Cupping. 2d Edition, enlarged. By Monson Hills, Cupper to Guy's Hospital.

A General Outline of the Animal Kingdom, and Manual of Comparative Anatomy. By Thomas Rymer Jones, F.Z.S. Professor of Comparative Anatomy in King's College, London.

Royal School of Medicine and Surgery, Birmingham. Report, 1838. Appendix: the Wareford Trust Deed.

The Analysis and Medical Properties of the Tepid Springs of Buxton: with Cases and Observations. By Sir Charles Scudamore, M.D. F.R.S. &c. &c. Third Edit. corrected and enlarged.

Vegetable Organography; or an Analytical Description of the Organs of Plants. By M. Aug. P. de Candolle, Knight Commander of the Legion of Honour, &c. &c. &c. Translated by Boughton Kingdon. Parts I. to IV. inclusive. With Plates.

The Danger, Irrationality, and Evils of Medical Quackery; also, the Causes of its Success; the Nature of its Machinery; the Amount of Government Profits; with Reasons why it should be suppressed: and an Appendix, containing the Composition of many Popular Quack Medicines. Addressed to all Classes. By Charles Cowan, M.D. E. & P. M.R.C.S.E. &c.

The Physiognomy of Mental Disease. By Sir Alexander Morison, M.D. Fellow and late President of the Royal College of Physicians of Edinburgh, &c. No. X.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.
BY DR. VENABLES.

Crystallized sediments or gravel.—This may be regarded as a distinct indication of the disposition to the formation of lithic acid calculus. Therefore, it is of the utmost consequence to attend to this state of things, for if it be neglected, and permitted to proceed uncontrolled, it will sooner or later terminate in something much more serious. Every means, therefore, of eradicating this diathesis should be adopted. Consequently, any deviations from the healthy performance of the different functions, should they exist, are to be immediately attended to and corrected. We have shown, in the previous observations, that frequently the digestive functions are so deranged, that slight errors in diet cause the appearance of lithic acid, in combination with ammonia, in abundance; and when there is a tendency to deposit crystallized lithic acid, they will appear from the same causes. Therefore, a strict attention to regimen, and perseverance in the plan of treatment formerly recommended, will be found essential. It is, however, in this form of the lithic acid diathesis that the use of the alkaline remedies is so beneficial. However, they are not to be relied on solely, but with their use other means, to correct the habit, must be instituted. Thus, alteratives and

purgatives become highly necessary. Of the alterative remedies we may use the blue pill, with a little James's or antimonial powder and tartar emetic*, or combined with ipecacuanha; or the Plummer's pill, Pil. Hyd. Chlorid. comp., of which five grains may be given for a dose with advantage. This alterative may be given once or twice a week, at bed-time, and a purgative given the following morning.

The purgative may consist of any active purgatives; but alkaline salts, with a vegetable salifying principle, tartaric acid, for instance, are preferable. Thus, a draught consisting of from ten to twelve drachms of the infusion of senna, holding in solution from half an ounce to six drachms of the tartrate of potass may be given the following morning; or, as Dr. Prout recommends, a mixture of Rochelle salts (potassio-tartrate of soda), and magnesia, or carbonate of soda. By these means the bowels will be kept regular, the digestion improved, and at the same time the tendency to generate lithic acid in all probability greatly controlled. Sometimes sulphate of magnesia will answer better, as those salines mentioned before will not in all cases act as purgatives; but the sulphate of magnesia being formed with a mineral acid, does not undergo decomposition, and therefore excites the bowels instead of the kidneys.

This is the form of the disease in which the use of alkaline remedies, administered

* Antimonial powder, though intended as a substitute for the James's powder, is certainly deficient in some way. I remedy this defect by rubbing together from half a drachm to one drachm of the antimonial powder and one grain of potassio-tartrate of antimony. This forms an excellent combination, and acts energetically, though not harshly, even with children. In some cases, two or three grains of this powder, combined with five of blue pill, or one or two of calomel, make a very good alterative. In peculiar idiosyncrasies, ipecacuanha may be advantageously substituted.

with the necessary circumspection, proves so serviceable. It is evident that the lithic acid is deposited, either because it is secreted in excess in relation to its solvent, or it is precipitated by some other acid, secreted either in the free state, or separated from its base by some more powerful acid, which had been previously secreted in the free state. Hence the urine will, in such cases, present all the characteristics of an acidulous reageny. Now as it is highly probable that lithic acid is seldom secreted in the free state in such excess, but in combination with ammonia, it is evident that the lithic acid separates in the solid or insoluble form, because deprived of its solvent, namely, the ammonia, by the stronger acid. Upon this theory the principles of practice are evident. We must endeavour to neutralize or prevent the agency of the precipitating acid, by altering the condition of the urine. The obvious inference, therefore, is, that we must endeavour to combine the precipitating acid with a base by which we shall prevent its effects. But as the exhibition of some base forms the appropriate means of neutralizing these effects, we must take care that we do not introduce a base which will itself in any way form an insoluble salt, or cause the separation of some other insoluble compound from the urine. Now the alkalis, from their chemical properties, that is, as they form soluble compounds with the most extensive series of salifying principles, are unquestionably best suited to this purpose. The first consideration, therefore, is, can acids or alkalis introduced into the stomach reach the kidneys, so as to influence its chemical constitution at the moment of its separation from the blood? The fact, that acidulous urine may be rendered alkaline by the ingestion of these agents into the stomach, has been long since admitted, and indeed proved. In a previous lecture* I pointed out the fact, that the alkalis might be detected in the urine of those who took those substances internally; and it was shewn that the salts of the alkalis which were formed with a vegetable or destructible acid, were found to have been decomposed, and chemically altered *in transitu*, and the organic acid was changed into the carbonic. And, indeed, we found that these salines might be administered in such quantities as to render the urine absolutely alkaline, and so cause the precipitation of the phosphates. Therefore, these remedies will enable us to produce such a condition of the urine as will prevent, or is inconsistent with the separation of the lithic acid. Then the question pre-

sents, to what individual of this class should we give the preference? These are those which have been most recommended, namely, soda, potass, and magnesia. Soda, perhaps, is objectionable, because lithate of soda not only forms the composition of those gouty concretions, named "chalk stones," but has been found constituting the greatest and chief portion of urinary calculi. I here show the lithate of soda, as forming those "chalky concretions," as they are called, thrown off from the joints of gouty patients. Sir B. Brodie shows a specimen of a urinary calculus of lithate of soda*, formed, probably, by the too free use of soda to correct the lithic acid diathesis. But such a result could only occur from very great inattention, and from a neglect of the common precaution of examining, from time to time, the chemical condition of the urine in relation to acidity or alkalinity. The object of the alkali, as already stated, is merely to neutralize the precipitating acid, and to prevent its depriving, either directly or indirectly, the lithic of its ammonia. Beyond this the exhibition of alkaline remedies should never be pushed. Still, however, in many cases, the lithic sediments in the urine contain an intermixture of lithate of soda. Therefore, perhaps, upon the whole, although soda may form the more agreeable alkali, yet potass may be the safer.

Potass, it has been already shown, may be detected in the urine, more particularly as a carbonate, and consequently if administered in proper doses, will prevent the separation of the lithic acid, and allow of its passing in combination with ammonia in solution in the urine.

How, then, are these alkalis to be administered? Are they to be given in their caustic or their carbonated state? But few stomachs can bear the necessary quantity of caustic alkali; and, indeed, it has been found from experience, that all the benefit to be derived from the exhibition of alkalis may be obtained from their milder compounds. It appeared that all the suitable alkaline combinations, that were constituted with an organic acid, were decomposed and converted into carbonates; consequently it would here appear that we might as well administer at first the salt which is ultimately formed; and

* "Lithate of soda.—This is a rare calculus, of a white colour, like the chalk stones of gout, probably formed where a patient, having a lithic acid diathesis, takes large quantities of soda. I was first informed of the existence of this kind of calculus by Dr. Prout. In our collection of calculi you will see a fine specimen of it, with a deposit of pure lithic acid on its surface. Probably there is a nucleus of pure lithic acid also." —Brodie on Calculous Diseases; also, MED. GAZ., vol. viii. p. 130.

* In the GAZETTE, Feb. 16th.

this, indeed, has been frequently practised in the administration of the beverage known as soda-water. In this a quantity of bicarbonate of soda is dissolved in a large proportion of water impregnated with a considerable excess of carbonic acid, condensed under pressure. Bicarbonate of potass may be given in a similar way; and the *Liquor Potassæ Effervescens* of the *Pharmacopœia*, in which a drachm of bicarbonate of potass is dissolved in a pint of distilled water, highly impregnated with carbonic acid, forced in by compression, affords a convenient formula. Perhaps these, and especially the preparation of potass, are the best antilithic agents. But it will often happen that the stomach, especially of the more dyspeptic patients, will not bear the severe distension caused by the great expansion of the superfluous carbonic acid now relieved from pressure, and still further increased by the temperature of the stomach; and yet such stomachs will not endure the alkalies in their caustic state, nor yet in the state of bicarbonates. I have known very many instances of this sort, and where so much irritation was produced, that the alkalies could be exhibited under neither form of preparation. In such cases neutral alkaline salts, such as the citrate of potass or soda, will be borne readily, and without that distressing flatulency and eructation which results from the hypercarbonated alkalies, or that urinary irritation which in some constitutions is invariably produced by the carbonates, and even the bicarbonates, of these bases. This must depend upon some peculiar sympathy of the kidneys and bladder with the stomach, for from either formula the result is the same—viz. carbonates; but yet in that resulting from the decomposition and conversion of the citrate there is not that liability to urinary irritation which occasionally results from the carbonates themselves. I think, too, the citric acid* preferable to the tartaric, the use of which is so general under the form of Seidlitz powders, to which there is the same objection as to

the carbonates surcharged with carbonic acid

It is sometimes necessary to add some narcotic, hyoscyamus, or even opium, to the citrate of potass or soda, and the irritation which they might otherwise occasion will be thus prevented. In many cases, too, where the alkaline carbonates can be endured, they may be given with some of the vegetable bitters, as infusions of gentian, quassia, colombo, &c.; or many prefer to take the alkalies in the malt drink or beer which they use at their meals. But upon such points no invariable rules can be laid down; and the application of individual methods must, in the great majority of instances, be left to the discretion of the practitioner himself. All that can be done is to lay down general principles for his guidance.

When the alkalies disagree in every form, some of the alkaline earths have been given. Lime-water has been given as a lithontriptic, or, more properly speaking, as an anti-lithic; but the very great insolubility of lime—the only form in which it can well be effectual—renders it objectionable. A pint of water dissolves only about 11·6 grains of caustic lime; and the lime in its caustic state is so harsh and injurious, that it may be considered as even worse than the alkalies themselves. The great mildness of magnesia would naturally induce a trial of its efficacy as a substitute for the alkalies, when these cannot be used. We have two preparations in the *Pharmacopœia*—namely, the carbonate; and magnesia (the *magnesia usta* of the old *Pharmacopœias*). These, though not so efficacious, yet have been found capable of arresting the growth of calculi, or preventing the separation of lithic acid from the urine. The dose is from one scruple to one drachm. But there are some objections to these medicines:—First, if administered in a healthy state, they are liable ultimately to induce acidity, for the stomach seems to adopt this mode of getting rid of the earth. Thus the earth is dissolved by the acid generated, partly voided as a soluble magnesian salt, and partly carried into the circulation, so as to affect the chemical condition of the urine. If this do not take place, magnesia is apt to congregate into calculous masses in the intestines, which become consolidated by means of the mucus. Thus Dr. Marcet says, “Some human intestinal concretions, entirely composed of common carbonate of magnesia, were described some time ago by Mr. E. Brande, who satisfactorily accounted for their formation, the patients having been in the habit of making a daily and most wanton use of magnesia, which,

* I have found the following formulæ both efficacious and so mild, that even children will readily take them:—

R Potassæ Carbonat.; Acid. Citric. utriusq. scr. j.; Aquæ Cinnamom. dr. ij.; Aquæ Destillatæ, oz. j.; Syrupi Rosæ, vel Sacchari Alb. q. s. ad grat. saporem. *Fl. haustus ter 4ve in die (vel p. r. n.) sumendus.*

The slight excess of citric acid renders it more grateful to the stomach, and more palatable to children; but it is evident that a slight predominance of either acid or alkali may be given, according to the views of the prescriber. Soda may be substituted for potass, merely adjusting the equivalent of acid.

with the assistance of a little animal mucus, had consolidated into masses of a formidable magnitude*." It is further objected, that as magnesia forms a principal part of the triple phosphate—a species of calculus—that it does not seem so well suited to the object in view as the alkalies. Dr. Marcet observes upon this:—"But there is another and more important objection to the indiscriminate use of magnesia, which is, that this earth being the base of one of the most common species of calculi—the ammoniac-magnesian phosphate—there is nearly an even chance, when magnesia is prescribed without any previous knowledge of the nature of the calculus, that it will prove injurious, not only by affording the principal element of that calculus, but also by neutralizing in the *primæ viæ* any portions of uncombined acid, by means of which the calculous matter might have been held in solution†." And he further states, that he had seen within a few years several instances of patients who, either under the direction of their medical attendants, or impelled by popular practice, for the removal of gravel or calculi of the fusible or magnesian kind, persevered in the use of magnesia, till an examination of the sand deposited by the urine shewed them the error of their practice.

Upon this, however, it may be observed, that the objection here urged against magnesia would apply equally to every alkaline remedy. For instance, if I add to this urine a little potass or its carbonate, the triple crystals, as you see, precipitate. This I shall prove to you by the blow-pipe; for, as you see, the precipitate fuses and gives off ammonia. Here they act by neutralizing that excess of phosphoric acid which holds the triple or the fusible crystals in solution. Also, the dangers arising from the ignorant exhibition of remedies in calculus, are incidental to all the species, and therefore the same objections will apply to acids as well as to alkalies.

Notwithstanding, therefore, the objections to magnesia, yet it is by no means an altogether useless remedy in the lithic acid diathesis; and, as in the case of the alkalies, we have only to obviate the objections to its use by remedying its inconveniences. We have seen that, in the uncombined state, and as a carbonate, it is

objectionable from its insolubility, and consequent liability to be aggregated into masses by the mucus of the stomach and bowels. This may be prevented by combining it with citric acid. If carbonate of magnesia be dissolved in a solution of citric acid, a very agreeable solution of citrate of magnesia may be obtained; and there are but very few stomachs with which it will not agree*. It is, however, to be clearly understood, that the alkalies, and of these the potass, are by far the more effectual.

The use of the alkaline remedies is to be persevered in for an adequate, and frequently a considerable, length of time. The time required will depend upon a variety of circumstances—the severity and obstinacy of the disease, and the condition of the urine. Indeed nothing but the strictest attention, and the occasional examination of the urine as to acidity or alkalinity, can justify any practitioner in continuing the use of alkalies or acids in the treatment of urinary diseases. A want of attention in this particular may be attended with a decidedly alkaline condition of the urine, than which there can be nothing more destructive to the bladder. When we find that the urine has by these means become neutral, the use of the alkali should be suspended for a time, or the quantity diminished; and by this means we shall be able to prevent the farther separation of the lithic acid. During the above plan, the occasional use of the alterative will prove very serviceable, and should not be neglected, as also the occasional exhibition of the purgative.

I have in some instances, where the crystallized form of lithic acid seemed associated with an inflammatory tendency, found general bleeding, with cupping or leeching the loins, with counter-irritants—for instance, ammonia or mustard sinapisms—applied to the same locality, productive of the very best results. Mercury, too, in such cases may be more freely used, as well as antimonials.

During the above treatment, the patient should avoid all those things which experience has proved to be prejudicial, or to favour the separation of the lithic acid in the insoluble form: such are hard indi-

* The following formula makes up a very pleasant acid, which will prove almost as effectual, if not equally so, as either the carbonate or the pure magnesia, and is not liable to the objections urged against them:—

R Magnesia Carbonat. gr. x.—℞j. Acidi Citrici, gr. xv.—℞ss. Aquæ Cinnamon. ʒij. Aquæ Destillatæ, ʒj. Syrup. Simp. ʒij. Solve Magnesie Carbonatem Ope Acidi Citrici, et finita effervescencia fiat haustus ter quaterve in die sumendus.—This may be rendered slightly aperient by the addition of a little Rochelle salts.

* Marcet, p. 136. The account by Mr. Brande may be seen in the first volume of the Journal of the Royal Institution. Henry also, some years previously, described similar concretions. The reader, too, may consult Monro's Morbid Anatomy of the Gullet, p. 34; and several of the periodicals.

† Ibid. p. 172.

gestible food, doughy dumplings, and the use of hard waters. Dr. Prout says that he has known warm sea-bathing particularly beneficial, though, in other instances, he has known the gravely deposit to be increased under its use; but this he is disposed to attribute rather to the use of the hard waters which generally abound along the coast. By these means, in all probability, the diathesis at this period may be kept in check.

Now here, perhaps, it may be as well to consider how the alkalies act, although, probably, from what has been advanced already, the whole subject has been anticipated. The alkalies have been supposed to act in one of two ways:—first, by entering the circulation, entering into combination with the lithic acid, and retaining it in solution. Secondly, the deposition of lithic acid is supposed to depend upon an acidity in the stomach, which being neutralized by the alkali, the separation of the lithic acid ceases. “In the case of the carbonated alkalies,” says Marcet, “this apparent difficulty can be easily explained; for it is obvious that the gaseous acid, possessing but a very weak attraction for the alkaline bases, the alkali of the carbonate may have the power of combining with, and neutralizing in the stomach, any other uncombined acid by which the secretion of lithic matter might be promoted; whilst the carbonic acid, thus disengaged, is expelled from the stomach in its gaseous state*.”

Upon this it may be observed, that acidity of the stomach frequently exists without any deposition of crystallized lithic acid; and that this latter prevails without any acidity of stomach; and that in this latter case the use of alkalies exerts the same control over the lithic acid. Therefore this explanation does not meet every objection. It has been already suggested that the lithic acid is secreted as usual, in combination with ammonia; and it has been already shewn, that when crystallized lithic acid is deposited, that the urine contains a free acid. Now this reacts upon the lithate of ammonia, causing, either immediately or mediately, the precipitation of the lithic acid, by depriving it of its ammonia. Therefore the alkali acts by neutralizing this free acid and preventing its reaction. We know also that the alkaline salts, to be effectual, must be constituted with an organic acid. We know also that these salines are converted into carbonates, and that lithic acid neither acts on nor is acted on by the carbonates; but that the lithic acid is precipitated by the carbonic. Consequently, if the lithic acid were separated in the free

state, the use of the alkaline remedies, as now used, would prove wholly inert. But by the view that the free acid secreted by the kidneys acts by decomposing the lithate of ammonia, we can readily comprehend how the carbonated alkalies may prevent this, because the free acid will expel the carbonic, and saturate itself with its base. It may here perhaps be urged, that even so, the liberated carbonic acid ought to precipitate the lithic acid from the ammonia; but we may observe, that under these circumstances the urine does not appear to contain carbonic* acid, as I have frequently examined the subject; therefore it is probable that the carbonic acid, being volatile, escapes at the moment of its liberation, or suffers decomposition, or is in some other way disposed of. Evidently, however, upon the principle of the lithic acid being generated in excess in the free state, the alkaline salts which exert the greatest influence being converted into carbonates, and these and the lithic acid exerting no reaction whatever upon each other, could have no control upon the appearance or quantity of lithic acid. It may be still farther observed, that urine, under these circumstances, at the beginning especially, contains lithic acid in tolerable abundance. Thus, if you add an acid to the urine rendered neutral by the exhibition of alkalies, as above, it will after a time deposit lithic acid; thus shewing that lithic acid, in some soluble combination, still exists.

So far as we have been considering, the object is to prevent the effects of this diathesis, and, if possible, to eradicate every trace of it from the system during early age, where a tendency to it is hereditary, or that it has become habitual. When children are the subjects, it cannot be too strongly impressed upon the minds of practitioners how necessary it is to attend to this subject at the very first moment. Care and attention on the part of the practitioner at the commencement, in many such instances, will prevent the formation of stone in the bladder—indeed we may say stone can be almost certainly prevented; but if the case be neglected or improperly treated, this most dreadful result is almost sure to follow. I have lately seen two instances of this sort at the Dispensary. From their history, I could ascertain that the symptoms, such as I have described, had prevailed for a considerable time before, and the cases had been treated in the ordinary way, without any special attention to the urinary organs, except attributing the consequences of the urinary irritation—namely, wetting the bed, &c.—

* This is to be understood in the free state; it may contain the alkaline carbonate in solution.

to laziness and dirty habits and propensities. On sounding the bladder, in both cases, calcoli were discovered very readily; and these patients were subsequently operated on in some of the hospitals: the parents, negligent at first, on discovering the danger, immediately took the children to the hospital. Parents, therefore, are bound to watch carefully over children circumstanced as just described; and, indeed, this care is essential till they have arrived at the age of puberty, after which the disposition to this affection will be much less, and where it has existed, seems to be greatly diminished. But we shall find, that about the age of forty another change takes place in the constitution—and which we are next to consider.

OBSERVATIONS ON COMPLICATED SURGICAL INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with the Auxiliary Forces in Portugal and Spain.

(As delivered in his Lectures at Sydenham College School of Medicine.)

[Continued from p. 452.]

IV.—INJURIES OF THE HEAD.—CONCUSSION, COMPRESSION, LESION, AND RAMOLLISSEMENT; THEIR EFFECTS EXAMINED AND COMPARED.

Inflammation during coma.—Complicated case.—Disorganization, partial or general, of brain.—Cases.—Death by lesion of junction without perceptible alteration of structure.—Cases.—Confirmed by effects of concussion in the eye.—Cases.—Partial loss of sensation and motion from lesion of cerebral nerves.—Cases.—Effects of concussion do not cease with comatose symptoms.—Disguising and paralyzing power of concussion—compared with compression.—Cases of extravasation and ramollissement compared—conclusion.—Indications afforded by pupil and pulse, how to be understood in practice.—Exemplified in cases, showing three degrees of concussion.—Gradually subsiding lethargy.—Absence of all reaction.—Case.

AMONG the effects of concussion which I described in my last lecture, you will remember that I gave you an instance of concussion “inducing inflammatory effects without any intervening coma from the blow.” Such cases are far from rare. Another class to which I shall now call your attention gives the

converse of this, and may be thus described:—

In some cases, during the first comatose stage or continuance of coma, particularly if the concussion be complicated by any lesion or lodgement of a foreign body, an exalted action supervenes, and inflammation or irritability becomes developed. The pupil contracts, and the pulse beats sharply.

CASE I.—*Exalted Action. Inflammatory or Irritative Stage during the continuance of Coma.*

Thomas Cole, æt. 30, struck, on the 15th of March, by a musket-ball, which penetrated the scalp, over the centre of the right parietal bone, fracturing and depressing a portion. Brought into hospital comatose, with the pupils contracted to the smallest point; pulse full and bounding. Twenty-four ounces of blood were abstracted. He soon recovered from the coma, and could converse.

R Hyd. Submur. gr. vj. Pulv. Jalapæ, gr. xx. Pulv. Ipecac. gr. iss. Ft. pulv. st. s. Cold applications. Spoon diet.

2d day.—Semi-comatose condition. Pulse remarkably strong, full, and quick. No paralysis. V.S. ad 3xx.

10 o'clock p.m.—Strong febrile symptoms. Great pain in the head.

V.S. ad 3xx.

3d day.—Not so much fever; wanders considerably; does not complain of pain. Bowels have not been acted upon.

Rep. Pulv. Cal. cum Jalapæ.

4th day.—Wanders very much; pulse tolerably quiet and regular; much thirst; bowels freely opened; not so much pain in head; answers questions incoherently at first, but after a short time becomes more collected.

5th day.—Better; pulse quiet; complains of numbness in the left hand and arm (injury on the right side); still a little incoherent; bowels open; tongue pale and clean.

6th day.—Talks incoherently; when asked a question, takes some time to comprehend it, and then answers with difficulty. Memory much impaired; misplaces his words and mistakes them; says he has no pain in his head; pupils rather dilated; tongue drawn a little to the right side. Complains of great numbness of the left

arm, also of hunger. Pulse not above sixty, and soft; bowels open.

(Here is distinctly indicated, by pulse and pupil, diminution of irritation or inflammatory action; also by the hunger, open state of bowels, &c. that the functions of animal life alone were affected; the organic functions unimpeded.)

7th day.—I carefully examined the wound, and made the following note of its appearance and his state generally. The wound made by the entrance of the ball has contracted to a very small opening; the bone is felt denuded, considerably fractured, and presenting irregular surfaces, several portions being evidently depressed. He says to-day he has no numbness of hand, arm, or tongue. Bowels freely opened; tongue clean and moist; pulse presents precisely the same characters as in *Thorn* and *Burne*—it is 64, small, and languid. Slight discharge. In the absence of urgent bad symptoms, it does not seem advisable to perform any operation.

Saline and diaphoretic mixture.

8th and 9th.—Each day expressed himself better. On the 9th, answered clearly and distinctly; expressed a wish for food. Bowels act freely; tongue clean and moist; pulse unvaried.

10th day.—Pulse more laboured, 56, but not hard. Some pain in the head, referred to the forehead. Says he slept well. Tongue slightly coated; pupils natural, perhaps the right in a trifling degree dilated.

Up to the 21st day no variation; pulse gradually rising to 80.

22d and 23d.—Puffiness of scalp in the neighbourhood of the wound; and as matter seemed burrowing, a free incision down to the skull was made the next day, that is, on the 24th, when he had become drowsy, with occasional vomiting.

25th.—Drowsiness much increased; pupils contracted; tongue brown and moist; bowels not very open; utterance thick and difficult; pulse 52, small, soft, and regular.

Cal. and Colocynth pills. Sol. of Sulphate of Magnesia.

26th.—Lethargy; pupils contracted; tongue brown and moist. Passed his motions in bed to-day; last night he got up. Vomiting had ceased the previous day. When roused does not complain of pain in head.

Emp. Lyttæ nuchæ.

27th.—Died.

For a considerable period it is evident that the cerebral system alone was impaired in its power and functions, the injury acting upon the ganglionic only secondarily, by withdrawing one of its sources of power: hence the lowered circulation and remarkable slowness of pulsation. In the later stages, as the power of the cerebral system became affected, the excito-motory became disturbed in a prominent degree—first evinced by the combined act of vomiting, and ultimately by relaxation of the sphincter ani. To the last day before death, notwithstanding the deep lethargy and prostration of power in the excito-motory system, the pupils maintained their contracted state, marking the existence of internal irritation.

Post-mortem.—The dura mater was injected in the meningeal arteries a little more on the right than the left side. Some slight traces of inflammation in the pia mater. Both skull and dura mater torn through, and portions of bone forced into the substance of the posterior part of the right hemisphere. On removing a thin slice of the cerebrum the ball fell out, jagged and flattened on one side; it was situated about half an inch from the surface of the brain. The structure of the brain was ulcerated and destroyed nearly perpendicularly downwards to the roof of the right lateral ventricle. The whole of the right was exceedingly softened; the left firm and natural. No obvious traces of inflammation in the structure generally. Right lateral ventricle filled with turbid fluid, and the whole surface somewhat discoloured, and apparently implicated in the disease. The whole of the dura mater, at the base, was of a bright purple colour. Right cerebellum slightly softened.

And in these facts I think we see an explanation of the apparent contradiction between the pulse and pupils on the 25th day. There seems to have been fluid enough to cause pressure; and it is more than probable its gradual increase was denoted by the gradual drowsiness, deepening into lethargy and paralysis. But while this was slowly forming, not having the same universal, pervading, and potent influence as concussion on the whole fibre of the brain, the inflammatory process of ulceration and *quasi* inflammation of

dura mater, at the base of the brain, was manifested in the contracted pupils.

Wherever lethargy and a contracted pupil are concomitant, and supervene together, it may be tolerably safely predicated, that with inflammation there is also effusion or extravasation, unless there be any considerable depression of bone, or lodgement of foreign body. In this complicated case the four agents were present.

We pass on to another class of effects to be referred to concussion.

Little loss of consciousness or coma at first, but quickly succeeded by disorganization of the brain, partial or general.

The following case I select, as being one of the shortest:—

Case of partial Disorganization following Concussion.

John Medley was struck on the 1st of October, 1836, by a musket-ball, which entered the back of the head at the left side, coursed below the integuments, and was cut out over the parotid gland of right side. The constitutional or sensorial disturbance very slight, and at eight in the evening he was in an easy sleep.

On the 2d day he was drowsy, and rather inclined to wander; pulse was feeble, and very slow.

V.S. ad 3xvj. Cold applications to the head.

3d.—Moribund; and the 4th he died.

Post-mortem.—The ball was found to have struck the bone below the occipital protuberance, to have driven in a splinter on the dura mater, then passed on externally, and lodged under and to the inside of the mastoid muscle. The dura mater was slightly torn. The brain for some distance about the wound was dark, sloughy, and disorganized; all the vessels were injected, and the ventricles full of serum. The ball had not fractured the skull where it pierced the scalp, but obliquely in its passage.

I am the more inclined to attribute this disorganizing effect to concussion, and neither to contusion nor inflammation, since I have observed disorganization or softening of brain will give, on the other hand, all the symptoms of concussion. Take the following as an example:—

A gentleman was under my care

some months ago, aged about 50, having suffered, during the two previous years, from fits of an epileptic character, but differing from true epilepsy in many points. His chief symptoms were tenderness and frequently occurring intense pain at the vertex of the head; pain at the pyloric orifice of the stomach. The pain felt chiefly when he took a false step, or after eating a meal; and so strongly and equally marked were these symptoms, that it was difficult to say whether the head symptoms arose from some morbid state of the stomach or the symptoms of the stomach from the head; and the case was rendered still more embarrassing by the fact, that cupping at back of neck apparently relieved both on one occasion, and on another, leeches applied to the stomach produced a similar effect.

I was called to him suddenly, early in the morning, when one of his attacks had come on, but instead of shortly recovering with memory impaired for a few minutes or hours, he was seized with violent vomiting, and remained totally insensible.

On arriving, I found the pupils a little dilated, the breathing embarrassed, the extremities and skin generally cold. In two or three hours the breathing became more laboured, and ultimately stertorous; the pulse slow, laboured, and feeble.

Dr. James Johnson, who had previously seen him many times with me, in consultation, saw him at my request; and it seemed to both, that effusion or extravasation had probably taken place. There was a glimmer of returning consciousness towards evening: a high febrile action was ushered in by a hot skin and flushed face. This was soon followed by prostration, relaxation of the sphincter ani, and on the next day by death.

The disease was found, on examination, to be extensive softening, amounting to disorganization of the brain in a considerable portion of one hemisphere.

There was one very curious fact connected with this case—viz. as he gradually regained consciousness after each fit, he always complained of an intolerable stench in the nostrils. Whether such a sensation could be produced in a retrograde course along the sentient nerves, by disorganization or disease of the cerebral fibres in which the olfactory nerves terminate, I am not prepared to

decide; but I see no other or obvious explanation for the well-marked circumstance.

The converse of this effect of concussion—disorganization—is also to be found in these cases. Thus it will even cause death by rendering the brain unfit for its functions, without obvious alteration of structure, of which I consider the following case an example.

Case of Concussion, producing Death by Lesion of Function, and not perceptibly of Structure.

John King, on the 16th March, 1837, was struck in the face by a musket-ball, which entered below the insertion of the orbicularis tendon on the right side, passing backwards and downwards through the antrum of Highmore. The orbital portion of superior maxillary bone, styloid process of temporal, and the occipital bone, corresponding to the right lobe of the cerebellum, were all fractured, and the ball was found lodged in the fleshy parts between the mastoid process and occiput. He was admitted into hospital in a semi-comatose state, with laboured and stertorous breathing.

On the second day, the pulse was very small and thready; coma and stertor had increased. He threw his hand, in quick succession, from the parts of generation to the region of the cerebellum, moaning piteously; he used the right hand only, there being apparently paralysis of the left, indicating the probable site of injury to be the right portion of the cerebellum. In the afternoon he died.

Post-mortem.—The course of the ball has been described. The dura mater was found uninjured, but a small coagulum of blood was effused between the arachnoid and pia mater, at the right lobe of cerebellum. *Both cerebrum and cerebellum appeared perfectly healthy.* There is neither sufficient in the fracture here nor the trifling extravasation of blood to account for death, the brain presenting no obvious alteration of structure. The concussion must have been very violent, and if not by some effect on the power and function of the brain not obvious in any alteration of structure, how was death induced?

These and thus various have appeared to me the effects of concussion, and as all violence to the head implies it, so may they be more or less distinctly traced in all such injuries. Having

classified and described in what these effects consist, I am anxious to turn to the state of the pulse and the pupils in reference to them; but first it is desirable to draw your attention to some peculiar effects on the eye from concussion. You will find that in a singular manner they confirm, by analogy, two of the principal effects of concussion, for these are still more clearly demonstrated within the coats of the eye than in the cerebrum—viz. *disorganization in some cases, and in others total loss of function, without perceptible trace of altered structure*—effects which I believe to take place in the brain, and have endeavoured to demonstrate. The following cases shew these in a striking degree, at the same time that they bring under notice some other effects complicating injuries of the head:—

Case of Disorganization in the Eye, from Concussion, probably with violence to Nerves of Nutrition.

Thomas Barber, on the 5th of May, 1836, was wounded in the face; a musket-shot entering the lower eyelid, without injuring the external structure of the eye, passed downwards into the mouth, and was swallowed.

Both pupils became dilated, and acute ophthalmia, with purulent discharge, came on. About the 12th day, coagulum was observed in the lower part of the anterior chamber, and also in the posterior, before the lens in the eye of the wounded side.

He was discharged about the end of the second month, the iris assuming an irregular pointed form, fixed. On looking into the back of the eye, the lens seemed to be absorbed, and the whole eye presented a clear greenish hue. Some weakness of the other eye had been induced.

In a parallel case, where death ensued, the vitreous humour and aqueous seemed converted into coagula, and the lens was softened.

Ophthalmia seems invariably to follow any injury to the ophthalmic branch of the 5th, which sends filaments to the conjunctiva, while the long root of the ciliary ganglion from the nasal branch supplies the interior of the eye with sensibility. We know that when the superior cervical ganglion has been destroyed, inflammation of the eye follows; and from the filaments of this ganglion ac-

companying the nasal and ophthalmic branches, the nutrition of the eye would seem to depend. I infer, therefore, that either by concussion or more directly by the contact of the ball, there was injury to these nerves.

CASE II.—This is not interesting only as a collateral evidence of the power of concussion to induce loss of power or function without injury to fibre, but as showing also a circumscribed loss of sensation in consequence of a lesion of nerve.

John M'Naughton.—June 5, 1836. A musket-ball entered the right malar bone, immediately below the edge of the orbit and close to the os unguis, and, passing under these last bones, traversed the face, and came out over the zygomatic process about the centre.

Complained immediately of severe pain round the forehead, which was relieved by his applying a tight bandage.

2d day.—Integuments of right eye swollen and discoloured; complains of severe pain in it. Has a slightly comatose appearance. Bowels have not acted; pulse slow and irregular.

Hirudines xij. oculi.

3d.—Some headache; has passed a tolerable night; integuments less swollen; pain in the right temple.

6th day.—Slough separated from below the right eye.

At the end of the month the entrance of the ball had healed up; the exit, which was like a clean incised wound, had been healed some time before. The vision of the right eye was partially destroyed; the iris had lost none of its power, nor does the eye present any appearance of disease. He was subject to drowsiness on walking about, if on foot for any time. On passing a line from one wound to the other, the ball would seem to have passed immediately across and under the right eye.

There was loss of sensation over part of the face, extending from the lower margin of the eye to the angle of the mouth, including the upper gums and one side of tongue, which had gradually become more circumscribed than it was at first, indicating very distinctly lesion of the second division of the trigemini or fifth pair of nerves. The superior maxillary given off, or rather passing to the gasserian ganglion; and, from the parts implicated, the lesion was probably at,

or very near to, its passage across the spheno-palatine fissure. The pulse was very remarkable—50, and irregular in its beat. He could not open his mouth to above half its natural extent. No bone exfoliated.

The following is a very nearly similar case, as regards the original injury, and one of the effects—loss of sensation:—

John Sullivan was wounded on the 5th of May. A musket-ball entered at the root of the nasal bone on the left side, between the inner canthus of eye and the nose; traversed the face deep, and presented behind and a little below the right ear, where it was cut out. The ball took a deeper course than in the preceding case, and thus saved the eye. He complained, however, of weakness of sight in the left eye; but as he had chronic ophthalmia, it might arise from that cause. The dotted line of the diagram shews the extent of loss of sensation, which also include the whole of the right side of the tongue, with some loss of motion affecting his speech, and making him speak as though he had a cleft palate. He was discharged to duty at the end of the second month. Here, evidently, there not only was injury to the second division of the fifth, but some branches of the third or motor division distributed to the tongue and muscles of mastication.

Several other very similar cases it is unnecessary to detail. In all these violent shocks or concussions, by the crushing track of balls across their axis or near them, impaired vision, more or less complete and permanent, is the result.

A gentleman consulted me last year, where a similar effect had resulted from the wheel of a gig passing over his face, crushing the bones of the nose and injuring the forehead. At that time, no appearance of disease could be seen, but lately some opacity of the lens is perceptible.

Let us continue our comparison of the various effects of concussion with those of other injuries.

To successfully distinguish between compression and concussion when both have taken place, is not always possible; and I think the endeavour has often led to error. It has led to the practice of considering, that if after a comatose state, from concussion, or even without that effect having occurred, if some hours or days after, a state of stupor, &c. come

on, the surgeon in such a case had undoubtedly to deal with compression, and that only. It will be seen by the facts I have already brought forward, that such can rarely if ever be the case; that the effects of concussion do not cease with even the first stupor, but that there are manifold effects assuming many forms, which follow as natural sequences. It is exceedingly rare that some one or other of these do not ensue; and if compression be one of them, it is not compression only that baffles our skill or taxes our diagnostic powers, but compression added to concussion, from which in truth it proceeds. I have endeavoured to show that this very compression may exist by the blood within the vessels, and only by the altered fibre of the brain, induced by concussion. Nay, if lesion, disorganization, and ulceration ensue, we still are among the sequelæ of concussion, when that has existed in the first instance; and if to concussion they add some features or symptoms, which yet remain to be seen, still they are enveloped, pervaded, as it were, by the general characteristics, and controlled by the injurious influences of concussion. I have yet to show that concussion, by its disorganizing effects, will control the outward manifestations of inflammation, and maintain the action of the heart at its own lowered standard. It will paralyze and rigidly fix the iris, in despite of inflamed membranes and brain, the natural effect of which is greatly to increase the irritability of the retina, and endue the iris with morbid contractility. It will permit the development of inflammation within the skull, and yet control the manifestation of any increased action throughout the system; where, then, are the unerring guides to be sought for on the supervention of inflammation, lesion, or extravasation? Not in the pulse, not in the iris, neither in the skin; all these it will control at periods, when it has hitherto been deemed to have ceased all action. Without concussion or a blow, compression may often be truly predicated; lesion I doubt if ever, and not always compression; for I have also shown that disorganization and softening will produce symptoms undistinguishable from concussion and compression. Here are two cases—one of compression by extravasation; the other of softening by disease—how are they to be distinguished?

To avoid as much as possible the multiplication of cases, recal the case already given of the gentleman who died of softening of the brain, and compare it with this of compression by extravasation.

Case of Compression and Lesion by extensive Extravasation, caused by the shock of a mental emotion to contrast with a case of Ramollissement, and another of Concussion.

George Frederick, æt. 30, a negro, while in bed at night was alarmed by a man committing suicide in a neighbouring room opening into the one in which he slept. He cried out that he "saw the flash and heard the report!" and did not speak afterwards. This was soon after midnight. Next morning he was found in a state of insensibility: *there was no stertor*; foaming at the mouth; pulse scarcely affected, so little that it was not thought necessary to bleed him by the surgeon who first saw him. Next morning little alteration; he was bled, but the blood flowed sluggishly, and in small quantity. There was no distension of the bladder. He died about thirty-six hours after the firing of the pistol, which seemed to have frightened him.

Examined about 50 hours after death.—The brain was firm; some indurated portions of a darker colour than natural were observed in the posterior right lobe of the cerebrum. There was extensive extravasation of blood, which seemed to have been the cause of insensibility and death. The coagulum was chiefly in the right hemisphere, and probably four ounces or more. It had torn up the brain so as to appear upon the surface; but the chief seat of it was in the medullary portion of the right hemisphere, which had been torn up. Some portion of the coagulum was in the right lateral ventricle. The vessel or vessels pouring out the blood were not ascertained; probably those of the velum, or of the choroid plexus. Some coagulum had passed under the tentorium; none in the left lateral or in the fourth ventricle.

In what do these two cases differ in their symptoms in the first stage? Death was brought on in both in about 36 hours. There was vomiting, and subsequent arterial reaction for a short period in the first; but it is impossible to erect these into the distinguishing

marks to judge between extravasation and ramollissement, and in what do either differ from some cases of concussion with no extravasation or lesion, or only very trifling. In these cases, it must be confessed there is nothing distinctive to mark these two very different forms of injury, from the case I have already given of John King, where extravasation did indeed exist, but in a most trifling degree—where there was no alteration of structure—where the cause was a violent and fatal concussion—for the right arm thrown to the occiput is an exceptional symptom that cannot be erected into a type.

Careful observation, continued through a series of years, of a large number of cases, has convinced me that where concussion exists, it may and often does envelope with its own pulsing mantle all other injuries obscuring or warping their symptomatic manifestations; and that extravasation and lesion without concussion do not always present characters distinguishable from each other or from it. And I cannot but consider it most important to the proper understanding and treatment of these injuries that this conclusion should be established; it leads us to view with becoming caution the symptoms which have so long been held certain signs of compression, extravasation, &c., particularly when we know concussion to have existed, and by thus probing the real depth of our knowledge we avoid a blind reliance in false or uncertain signs which, if believed, are calculated to lead to equally erroneous diagnosis and practice. There are symptoms by which we can determine the kind of injury in a majority of cases, but not in all.

Although concussion possesses the power I have attributed to it, and is occasionally developed to the fullest extent, yet in a very great number of cases other actions or concomitant injuries may be detected, and their manifestation even be sufficiently distinct for the diseases from which they spring, to be tolerably confidently and successfully grappled with. Being once fully convinced of the pervading power of concussion, both in its first energy and subsequently on to its decline, we are less liable to be deceived, and better prepared to detect that which points to other actions and causes.

We will now proceed to trace these,

and unravel them, as it were, from the changing characters of concussion, and in so doing endeavour to show how the indications given by the pupil and the pulse are to be understood by searching for the controlling influences, which, when first the study of their injuries is commenced, seem to baffle all inquiry, and by their contradiction involve the inquirer in confusion inextricable.

The usual, and therefore apparently the natural effects of concussion on the other nervous centres, is to weaken their action, and hence the circulation and the respiration are lowered, and the action of the heart is depressed, giving a slow and laboured, or sluggish pulse, rarely intermitting; the pulse resembles much in character the breathing; it drags its slow length along—not hard, for there is no increase of force, on the contrary, it is laboured, as if there was a want of stimulus, or *vis à tergo*. Observe a patient comatose in the first stage of concussion; compare the general character of the respiration and the pulse, and you will be struck by the similarity.

The pupil is dilated; generally fixed; insensible to stimulus of light.

In observing the variations from these, endeavour to trace them to their causes, and so obtain indications of the true state of the injury, and the actions going on in the brain. After long and anxious study at the bed-side, if I have not solved all doubts, discovered certain and sure guides in the varying indications—and it would be strange presumption were I to fancy I had—at least have I solved many doubts that beset me when I commenced. I have obtained some indications both for diagnosis and treatment. I failed in gleaning from writers on the subject, and on this ground I hope to communicate information calculated to be useful in your practice.

The usual progress of a case of slight or moderate concussion you have well exemplified in the following case, which I select for the purpose of placing distinctly before you the usual features before I endeavour to put you in possession of the complications and varieties as regards the iris and the pulse.

Case of slight Concussion going through the usual stages.

John Clewes, æt. 22, of usual good

health, stout, middle-sized, and muscular, of fair complexion, and sanguine temperament, was struck, on the 1st of October, with a splinter from a shell, about the size of a bullet, which entered at or rather a little below the internal angle of the right eye, and passed out through the meatus auditoris externus, where a piece of the cartilage of the ear presented itself. The cheek was much swollen on his admission into hospital, and there was slight hæmorrhage from the wound.

Pulse slow, heavy, and compressed; sickness of stomach; severe pain of the head; drowsiness, *complete loss of vision of the right eye*, although it has not apparently been injured.

Half-past 8 P.M.—No sickness of stomach; still appears a little confused, but says that he feels much better. Pulse rather quick, but not strong.

2d day.—Has passed a good night; system tranquil; no confusion of head, and little pain. Pulse moderate.

Pulv. Jalapæ gr. xxv.; lemonade; spoon diet; cold lotion.

3d day.—Complains of great pain in the head.

V. S. ad 3xx. Rep. Pulv.

4th day.—Improving. Pulse strong and full; bowels confined.

V. S. ad 3xvi.; Cap. Ol. Croton. gtt. ij. st.

5th day.—Eye closed by the swelling, which extends to the ear; no headache; pulse natural.

6th day.—No unfavourable symptom; he sleeps soundly and easily.

To the 28th day, although cheek enormously swollen, and a piece of bone, including the foramen orbitale inferius, came away, no one unfavourable symptom or indication of disease from the head.

29th day.—Renewal of pain in the head, with dizziness.

Emp. Lyttæ nuchæ. Cap. Pulv. Jalapæ, gr. xx.; Pulv. Ipecac. gr. ij. st. sumend.

Next day relieved, and succeeding day no pain of head.

Feb. 10th.—The 5th month he was invalided home; he had completely lost the sense of vision in the right eye, although no change in structure could be

discovered; sense of hearing in right ear also destroyed. He was subject to occasional headaches and vertigo; his memory, he stated, was impaired. The iris is in a state of semi-dilatation, and not sensible to light.

A more distinctly or finely marked case, shewing point by point the most common and usual course of a case of concussion (independent of the complication of the eye), without serious consequences or deviations, I could not possibly select.

It shews first the comatose symptoms in mild degree; the sickness and pain of head; the peculiar character of the pulse; next the quick subsidence of the lethargic symptoms, and the consequent change in pulse.

The intervening period of freedom from all symptoms, generally from the second to the third day, occasionally to the fourth. The recurring head symptoms, indicating the supervention of irritable or inflammatory stage, diminished secretions, and increased pulse.

The almost equally sudden relief of these by free depletions, and renewed secretions from skin and bowels.

After this the recurring attacks of similar character to be similarly dealt with, and easily checked.

Finally, the peculiar action I have ascribed to concussion in the brain—destruction of function without perceptible alteration of structure, as exemplified in the eye.

The permanently irritable fibre, leading on every application of stimulus to headache, vertigo, &c., which I have also pointed out as the almost invariable consequence of concussion.

In the progress of these cases there is an astonishing similarity; and I could easily detail from my notes twenty so identical, that, but for the name or some unimportant change of irrelevant circumstances, it would be difficult to distinguish them.

You will observe that, in the natural course of concussion, the cases pass through three well-marked stages:—

1. Coma, depressed or paralysed action, which may be confined to cerebral system, or implicate in various degrees the excito-motory and the sympathetic.

2. Exalted action, more or less extended in a similar manner, and varying in degree in each; attended almost in-

variably with suppressed or diminished secretions.

3. Stage marked by irritability of cerebral fibre existing in some for days, and often for life.

ON A NEW AND SUCCESSFUL
METHOD OF TREATING PRO-
LAPSUS UTERI.

By BENJAMIN PHILLIPS, F.R.S.

Surgeon to the St. Marylebone Infirmary, and
Lecturer on Surgery at the Westminster
Hospital School.

[*For the Medical Gazette.*]

THERE can, I apprehend, be no question, that a large proportion of the cases of prolapsus of the uterus are occasioned by the absence of that support which, in the healthy condition, it derives from the vagina.

In consequence of increased capacity, produced by frequent child-bearing, or a laxity in the parietes of that organ, the uterus experiences little resistance in descending a certain distance within it; and there can, I think, be no doubt, that where either of these conditions exists, either before or after the capacity to bear children, the remedy should be sought by endeavouring to restore the tone, or lessen the capacity of this canal.

The following case is related for the purpose of laying before the profession the application of a new method, successfully employed, in the treatment of this infirmity.

The principle upon which this mode of treatment is founded is not new, except as regards this disease; it has been employed with great success in the treatment of many fistulous and other openings, which have resisted ordinary modes of treatment. But although frequently employed, it does not appear that the principle upon which its success depends is generally known; and I believe that this knowledge is all that is necessary to make its employment, in an extensive class of cases, very generally successful.

In the winter of 1837, a woman, aged 46, was admitted into the Marylebone Infirmary, suffering from prolapsus of the uterus. She had given birth to many children, and had experienced a

slight inconvenience from a trifling displacement of the uterus after the birth of her fifth child; this displacement occasioned her from time to time much uneasiness between each succeeding pregnancy, but had not become a pressing evil until about four years ago. As a means of remedying the evil, pessaries of various shapes had been used; but whatever the shape or size of the instrument employed, she was unable to support for more than a few hours the irritation which they produced.

Her occupation obliging her to be much of the day in the erect position, the prolapsus increased, the uterus projected slightly beyond the vulva, and its further progress was restrained by a bandage.

I found the uterus just pointing into the vulva, the os tincæ directed forwards, but then she had been in a recumbent position for twenty-four hours previously. The tissue of the organ exhibited a perfectly healthy appearance, and it was very easily reduced. The vagina was also in a healthy condition, and there was only a very slightly increased mucous secretion from the parietes.

Finding that reduction was so easily accomplished, and that no structural change was apparent, I was induced to hope that the horizontal position, persevered in for a few weeks, together with the support which might be given to the organ by means of fine sponge introduced into the vagina, would be sufficient to remedy the inconvenience from which the patient suffered.

The bowels were carefully regulated; the sponge was introduced, impregnated with decoction of oak bark and sulphate of zinc, and was borne without discomfort; and the same astringent solution was injected into the vagina three times a day. For six weeks this treatment was persisted in, at first I had hoped with benefit; but in this I was disappointed, and at the end of that time I was compelled to abandon this course of treatment, as the patient's condition was not sensibly better than when it was commenced.

Pessaries of various kinds were now used, in the hope that some particular shape might be found which the patient could bear without much discomfort; but that hope was disappointed.

I now determined to employ some

agent which would destroy a portion of the mucous membrane of the vagina, and produce a suppurating surface, in the hope that the cicatrix succeeding to it would occasion a contraction of the vagina sufficient to constitute a mechanical obstacle to the further descent of the uterus.

I introduced into the vagina Weiss's three-pronged speculum, and, without giving the patient much pain, I was enabled to separate the prongs to their fullest extent. Between each of the prongs the mucous surface of the vagina was exposed to the extent in width of half an inch; upon two of the surfaces so exposed, lunar caustic was liberally applied, and it occasioned very little pain. Before the speculum was withdrawn, the vagina was carefully washed out with tepid water, so as to prevent the caustic from affecting any other portion of the surface.

Liberally as the caustic had been applied, its effects did not appear to have extended beyond the epithelium, and when the eschars were detached, no appearance of a granular surface was presented. Six weeks did I wait in the hope that the irritation at the point might have excited some contraction, but still the uterus descended.

I then resorted to another caustic, from which more energetic effects might be expected: with the same precautions as were used in applying the nitrate, I used the fuming nitric acid, brushing it over a larger surface by means of a camel-hair pencil. The pain it occasioned was greater than that which followed the use of the nitrate, but still it was not severe nor long-continued. The inflammatory action was much more decided; the whole thickness of the mucous tissue sloughed, and a fair granulating surface, yielding a considerable purulent secretion, was established.

For some time the uterus manifested little tendency to descend, but when the patient got up and walked about, at the end of a month, the infirmity returned, though not with the same facility as before. Another month passed; still her condition was not very sensibly ameliorated. She became dissatisfied, and said, that unless any thing else could be done for her, she would go out.

I proposed to endeavour, by means of suture, to bring the sides of the vagina into contact, previously destroying the opposed mucous surfaces. She consent-

ed to have the trial made, but afterwards declined, and was discharged.

From the period of her leaving the Infirmary until a few weeks ago, I lost sight of her. It now appears, that from the period of her discharge, the disposition to displacement of the uterus gradually lessened, and for eight months has entirely ceased. Upon examination, it was found that the capacity of the vagina was very materially lessened; that from having been, when I first saw her, unusually capacious, it is now reduced to the size of that of a woman who has not borne children.

In a second, and in many respects a similar case, in which I employed the acid, I had reason to expect a similar success; but I have lost sight of the patient, and I cannot therefore speak with any certainty as to the result of this treatment in her case.

The success of this treatment depends upon our power to cause the production of a fibrous tissue of a peculiar character: well developed, this tissue presents a dull white colour, rarely presenting any shade of yellow or red, neither resembling the muscular structure of mammalia nor birds; it has neither the glistening appearance of aponeurosis, nor the satin-like character of tendons, but it has all the density of tendinous structures:—yet the fibres are not so closely compressed, nor so regularly disposed. In its colour and its elasticity, it bears no resemblance to the yellow ligamentary tissues. It has much more density than the fibrous tunic of the arterial parietes, and does not yield like it to perpendicular pressure. Its appearance is not unlike that of the muscular structure of batrachian reptiles, and its consistency may be compared to the strongest articular ligaments. It is endowed with a retractile power independent of volition, and exercised in an almost insensible but constant manner, which may be increased by the prolongation of inflammation, and which has no other limit than that which may be opposed to it by a mechanical resistance as strong as itself. It was believed by Delpach, that for its production suppurative action was absolutely necessary; that wherever a suppurating surface exists there will it be developed; and that where a wound heals without granulating, there it is not found. The impression existing on my mind is a little different: I think it

may be developed, under the influence of chronic inflammation, without suppuration; and I believe that certain contractions of the rectum support this opinion. To develop it with most certainty, is to produce a suppurating surface; but all substances capable of exciting suppurative action do not produce this tissue in equal quantity, equal density, or of equal force.

There is no cause so energetic in producing this tissue as the action of caloric upon the living body; thus we find it most abundant, and causing the greatest deformity, in certain cases of burn; and there we see the power which it exerts in producing changes of relation the most remarkable; changes against which we vainly struggle, in a large number of cases. This effect is rarely better shewn than in those cases where a burn has affected the neck, and where this tissue brings down the chin towards the sternum.

But although caloric seems to be the agent most capable of exciting the development of this tissue, there are other agents not wanting in power, and among these the mineral acids hold the first place. As illustration of this, I may refer to cases where these acids have been swallowed. If they have had contact with the lips, and have not destroyed life, the tendency to contraction of the oral orifice is irresistible, unless the whole of this fibrous structure so developed, can be excised. A similar contractile tendency will be produced in the œsophagus, causing stricture of that organ.

Besides caloric and the mineral acids, other caustic substances, fluid as well as solid, blisters, &c. are capable of exciting the development of this tissue; in fact, all substances which can produce a loss of surface, and excite a suppurative reparatory action, produce a similar result. It does not seem to be rapidly developed, and its density would appear to depend, not alone upon the agent employed, but upon the duration of the suppurative action. And it may be increased by repeatedly irritating the suppurating surface. If we apply lunar caustic upon such a surface daily, we shall render this structure much stronger and more energetic in bringing the edges together, than if the surface were left to itself.

Again, I repeat that I am not seeking to introduce an agent which is new;

I only take credit, if any belong to it, for having successfully applied a very manageable agent to the treatment of a very frequently unmanageable infirmity; and I trust that I shall direct attention to a principle susceptible of very extensive employment in the cure of many diseases to which humanity is subject.

ON THE
EMPLOYMENT OF MERCURY
IN IRITIS.

By RICHARD MIDDLEMORE,
Surgeon to the Birmingham Eye Infirmary.

[For the Medical Gazette.]

A FEW days ago a friend called upon me to inform me that I have incorrectly stated, in my work on Diseases of the Eye*, that Dr. Farre was the first to suggest the administration of mercury as a means of arresting inflammation of the iris and deep-seated textures of the eye, and of removing some of its effects; and he further apprised me that Mr. Carmichael, of Dublin, has very properly (?) given to Mr. Saunders the credit of originating that practice, which I have stated to have been first suggested by Dr. Farre. As it is probable other members of the profession may also be led into error, by the perusal of Mr. Carmichael's statement, I beg permission to place the facts of the case before your readers. Mr. Carmichael, in his published speech, is represented to have said—"May I be permitted to ask, from whom did physicians learn the great utility of mercury in inflamed organs? From surgeons. The utility of it (in this country at least) was first practically established by the late John Cunningham Saunders, a surgeon, in the treatment of "inflammation of the iris†." On perusing Mr. Saunders's account of "inflammation of the iris"‡, I find the following measures recommended for its cure:—1, Blood-letting; 2, cathartics; 3, tartar emetic; 4, leeches; 5, lead-collirium; 6, belladonna; but no allusion whatever to mercury. At page 66, of the same chapter, he says—

* Volume i. page 18.

† Supplement to the *Dublin Medical Press* for June 5, 1839.

‡ A Treatise on some practical points relating to the Diseases of the Eye. By the late John Cunningham Saunders. London, 1816. Page 65.

"But this state (that is, *inflammation*) of the iris sometimes arises from syphilis. Then the general plan of treatment here proposed (that is, blood-letting, &c.) must be changed for the specific remedy, and mercury must be rigorously exhibited." And further, when relating Case 1, at page 68, in which "there were evident marks of inflammation of the iris," "having," says Mr. Saunders, "treated the patient much according to the plan* inculcated in this essay, for the space of a fortnight, but without any success, I was induced to investigate the case with the most particular attention. I found, on examination, a painful and contracted state of the elbow, but no enlargement of the bones or thickening of the ligaments. This symptom, in conjunction with the state of the eye, determined me to treat the case as syphilis." I now proceed to quote a few of the prefatory observations of Dr. Farre, the editor of the work of Mr. Saunders, and here I would state that I know of scarcely any remarks on the treatment of diseases of the eye which contain more useful information — information remarkable alike for perspicuity and originality, and for the comprehensiveness and importance of the principles it unfolds. "The certainty," says Dr. Farre, "with which the mercurial action arrested the deposition of coagulable lymph in *syphilitic* inflammation of the iris, led me to give this remedy a fair trial in *simple* inflammation of the iris, in which the disorganizing process by the adhesive inflammation is precisely the same, however it may differ from the former in its exciting cause. The result of the trial has perfectly satisfied me that the mercurial action *alone*, when properly kept up, is sufficient to subdue the ophthalmia iridis in its most acute stage†." From the preceding quotations, and from an attentive perusal of the entire work of Mr. Saunders, I feel justified in making the following statements:—1. Mr. Saunders did not recommend mercury for the cure of simple iritis, and that medicine is not once mentioned by him for the cure of the simple form of iritis, in that chapter of

his work expressly devoted to the description and treatment of iritis. 2. In syphilitic inflammation of the iris, Mr. Saunders, it is true, employed mercury; but not (as, indeed, it is stated in effect by himself) for the cure of the *inflammatory*, but the *syphilitic* portion of the disease. 3. On the other hand, Dr. Farre practically ascertained, and clearly pointed out, the utility of mercury in iritis and other forms of inflammation of the internal membranes of the eye; and by a clear and somewhat elaborate chain of reasoning, justified the propriety of his practice. Perhaps, however, a fair mode of putting the case would be pretty much as follows:—Mr. Saunders administered mercury for the cure of one of the secondary symptoms of syphilis affecting the eye; whilst Dr. Farre not merely suggested, but urgently recommended, the use of mercury in inflammation of the iris generally, which practice he was, I believe, the *first* to adopt, and the success of which he was the *first* to demonstrate and record.

I hope to be excused for this, I fear tedious, vindication of the accuracy of my published statement in reference to the credit of suggesting a most important improvement in the treatment of ophthalmic diseases, and trust I have done so in a manner which has manifested the most respectful feeling towards Mr. Carmichael, whose claims to a far more important and lasting reward than the "double honorarium" no one is more willing to admit than myself. At the same time I beg permission to suggest, that to recite the services of physicians and surgeons with a view of representing the superiority of the one over the other, is not the best mode of calming existing disquietudes, and of promoting that union and harmony it is so desirable to create and maintain. For my own part I am truly thankful to the improvers of medical science, whether they be physicians or surgeons, and feel gratefully indebted not only to Harvey, but to Wiseman also—not merely to Cullen and Baillie, but likewise to Hunter and Abernethy, and a host of distinguished cultivators of medical science of the present day, who, like the illustrious men whose names I have just recorded, have voluntarily renounced in some

* The outlines of this plan have been already mentioned in the order stated by Mr. Saunders in his work.

† Preface to the second edition, London, 1816, p. xxxviii.

degree the emoluments of productive practice, in order that they might obtain that leisure which was necessary to enable them to arrange and explain their views, and record their experience, for the benefit of the present age, and the advantage of succeeding generations.

ON THE STETHOSCOPE AND EAR.

To the Editor of the Medical Gazette.

SIR,

COMPARATIVE anatomy may ultimately tend to illustrate my subject, but the knowledge of a certain number of principles or laws in acoustics is necessary, to enable us to benefit by this species of reasoning.

Anticipating that the following observations will be favoured with a place in your GAZETTE, and referring to my first and second papers in your numbers of the 15th December and 9th February,

I am, sir,
Your obliged servant,
W. SHAND.

Aberdeen, June 1st, 1839,

On again renewing my observations on the stethoscope and the human ear, I shall advert to certain experiments made with the stethoscope. This instrument I find is formed in a variety of ways, and of different woods: like all other hard bodies, as conductors of sound, it must produce very different effects; and yet I cannot but think, that when the operator finds any instrument to have the desired effect, he should not change it for another, for very obvious reasons.

Some are made round, with the same diameter throughout, and of equal bore when complete, but in several distinct pieces, fitted into each other, and a brass tube in the centre, so as to produce a counteraction in the wood, and a metallic sound. They are frequently made of mahogany or rosewood, without any attention to the length or direction of the fibre. It might be supposed that the object of the maker was beauty, and not utility, and I suppose it is considered that the sound is to pass through the opening, and not the wood; but nature must be coerced

yet farther to produce this effect. Every medical man with whom I have conversed, admits that this is not an efficient instrument. They also allow generally that the most simple and plain stethoscope, with a conical or trumpet-formed (not semispherical) end, is found to answer best, and when there is no break or interference with the fibre. Few practitioners use more than the ear division of this description of stethoscope, which is usually about seven inches in length, but it is doubtful whether this is sufficient.

After the sound is collected in the expanded end, it passes by the fibres, and must be ruled in the longitudinal action as in a single string, the length of the wave being determined by the length of the string in both cases; and as the different sounds are regulated in duration by the length of the wave, this should be attended to and the instrument should be of a certain length, probably nine or ten inches, without any break in the fibre, because this must shorten the waves and sounds.

I tried the sonorous power of several stethoscopes of pine, the fibre being long, and the wood free from knot, by applying to the larger end a tuning fork in a state of vibration, the other end being in contact with the ear. There was a circular cap of hard wood upon the ear end, about an eighth of an inch thick, and equal to the width of the pinna.

On using the instrument in this manner, I was very sensible of the vibratory action in the ear, when the two bodies were in contact. On placing cloth in the opening of the stethoscope, and also cotton, I was not sensible of any difference as to the intensity of sound, with or without the material in the aerial passage, nor was sound damped in any sensible degree, when cotton was placed in the concha. I then used a small instrument of mahogany, of straight long fibre, about an inch in diameter at one end, and tapering from the middle to a quarter of an inch at the other end; this was nine inches in length, with a bore in the larger extremity, four inches deep to encourage vibration.

The small end of this instrument was applied to the antihelix, and the tuning fork in a vibrating state to the hollow end, when it communicated sound more loud than might have been expected

from so small a body. I next covered the pointed end with woollen cloth for half its length, to prevent sound escaping from the external surface, leaving the fibres of the wood open at the end where it was brought in connection with the antihelix, and placed cotton in the concha to damp sound at the entrance of the meatus externus, but I experienced no diminution of sound from these means.

These experiments are easily made, and I must regard their results as evidence of the transit of predominant and intelligent sounds, not only by the fibre of the wood, but by the solids and aqueous fluids of the external and internal ear.

ON THE HUMAN EAR.

Previous to pursuing my observations on the physical properties of the ear, it is proper to refer to the general principles that are laid down in the second page of my first essay, and to make a few preliminary remarks on external bodies, because the operations of sound in these may be more easily understood.

An analysis of the organ of hearing must illustrate the laws of sound; but a knowledge of external objects, as connected with acoustics, should pave the way, as the latter are more perceptible, of greater magnitude, effects are more intense, and are exhibited in greater variety; and the ear, like the atmosphere, must conduct without change of character in original sounds. I should also observe that bodies in contact are so much, and so instantaneously influenced by each other, that it is necessary simultaneously to consider them, collectedly and abstractly. Sound, like heat, may be said to enter into all bodies, therefore, as in reference to heat, some may be termed conductors, and others non-conductors, with regard to sound. When the effects of the strings of a violin are considered, those of the body of the instrument must also be considered in connection with the strings, and the influence of the atmosphere on the whole, in order to form an accurate and comprehensive idea of the means by which the various harmonizing sounds are produced and conveyed to the ear.

Sounds produced in the atmosphere by the tuning fork only are very limited; but when it is brought in contact with another body, new vibrations and sounds

are produced in that body and other sonorous bodies, if in connection with it; and similar effects extend to their every atom, until the counteracting influence of friction shall bring them to rest. A refined illustration of these principles of action is exemplified when the voice of a singer is directed towards the strings of an open piano, the proper strings are found predominantly to respond to each other and every minute change of the voice.

This may be effected chiefly by a similar degree of tension in the chordæ vocales, the lips of the larynx, and the strings of the piano, but, perhaps, also in a certain degree according to the diameter, and the peculiar composition of the different strings.

There is one material point obvious in this case that the atmosphere conducts without altering the character of sound (otherwise than by varying its intensity), a property which seems to attach to all fluids more than to solids.

If it be an acknowledged axiom, that any body in motion coming in contact with another body that is at rest, the still body arrests the moving body, then a wall does not increase sound by preventing its spread in one direction, nor does water facilitate the passage, or add to the intensity, of sound on this principle merely, or by the smoothness of its surface, but by tremulous action, and in degree in conformity to its expansion and general arrangement of its particles. All still water conducts sound more rapidly and to greater distance than the atmosphere. These effects are most apparent within the tropics, and are particularly exemplified in the locality of the Cobra; therefore, there is reason to conclude that water in all situations, at a similar temperature, is a powerful conductor, although its influence may differ materially by diversities in general arrangement, and from other causes. If the surface of the water be agitated, this must retard and confuse sound, as is the case from the same cause in all other bodies.

When there is little wind the sound of a bell is heard loud, and to a considerable distance. These effects are increased by a light current of air towards the listener; but if the wind be strong in any direction, the derangement of the vibrating particles in the atmosphere lessens and confuses sound.

I have been thus particular in regard to water as a conducting medium, because it has been considered to possess but a very limited degree of conducting influence, and I am not aware that in the organ of hearing this power has been attributed to it—at least, the predominance is given to the aerial over the aqueous fluids, the fibrous tendons, gristle, and bone; and yet all these are to be found more potent and rapid conductors than the atmosphere, apart from each other, and I am not aware why their influence should be less in this situation, where they are adjusted by the unerring hand of the Creator, forming a mechanism that is intended only for conveying the phenomenon of sound to the sensorium. Contrasting the arrangement in this case with external bodies, I must conclude, that in all cases there is more transit of sound through the aqueous fluids and solids than by the aerial passages, were there not other reasons than have yet been explained for belief in this fact; nor is any thing found that can arrest tremulous action and sound in these; whilst transit by the external surface of the auricle, the auditory passage, and the tympanum, is impracticable, without encountering many physical impediments, calculated to damp and derange sound. Sound is unquestionably intended to be transmitted by the atmosphere and the ear to the acoustic nerve, without change in its nature, from the point of its production or formation.

Magendie makes the following remarks in opposing Boerhaave's attempt to prove that all the sonorous vibrations which fall upon the anterior, or rather external, surface of the pinna are concentrated in the auditory passage:—"The auricle collects the sonorous radiations, and directs them towards the meatus externus, in proportion as it is large, elastic, prominent from the head, and directed forwards.

"Boerhaave supposed he had proved by calculation, that all the sonorous radiations or pulsations which fall upon the external surface of the pinna are ultimately directed to the auditory passage. This assertion is evidently erroneous, at least for those pinnae in which the antihelix is more projecting than the helix. How could those rays arrive at the concha, which fall upon the anterior surface of the antihelix?"

"It is much more probable that the pinna itself, in consequence of its great elasticity, which may be slightly modified by its internal muscles, is capable of entering into vibration when influenced by sonorous undulations impressed on the air. In fact, experience teaches that according as a membrane is or is not parallel to the surface of the bodies which vibrate near it, its oscillations are more or less distinct. Parallelism constitutes the most favourable case."

This distinguished physiologist had evidently predetermined that the transit of predominant intelligent sounds must be by the aerial cavities of the meatus externus and tympanum, also that they are collected on the external surface of the pinna; whilst he admits it to be much more probable that the elastic properties of the body, the tension, longitudinal form, and direction of the fibrous lamina and muscular arrangement, may induce a degree of vibration through them, than that the tremulous waves of the atmosphere, falling on the back part of the antihelix, could by possibility reach the auditory canal. Now when it is considered that the part of the pinna above the concha is frequently formed into projecting curvatures and deep recesses, having no inclination towards the auditory passage, and it is also admitted that sounds which reach the surface are nothing more than the sudden impingement of atmospheric fluid, which recoils from all such bodies at an angle of reflection equal to that of incidence, it cannot in this case reach the meatus, any more than in that which acts between the helix and antihelix, when the latter rises above the former; in fact, in many instances there is no conformity of inclination towards the concha in any part, from the extremity of the pinna. The first and chief objects in nature appear to be to carry the sonorous atmospheric wave over the meatus, and to extend its sphere of action on the solids without admission to the membrane of the tympanum until its sonorous power be exhausted, and it becomes a limited operation of simple pressure, and nature has at the same time adopted means otherwise to damp sound in the membrana tympani, as I trust may hereafter be satisfactorily proved.

MEDICAL GAZETTE.

Saturday, June 29, 1839.

"*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ lueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*"

CICERO.

MEDICAL CONGRESS AT
DUBLIN.

MR. CARMICHAEL is of opinion, that if the physicians and surgeons of Ireland would unite in one college, it would be well for the profession and the nation. "We should then be able to repress quackery—to protect our interests—to repel aggression—to regulate our own body, so that those dissensions which might occasionally arise amongst individuals of the same profession shall not obtrude themselves upon the public, making us, as hitherto, a stalking horse of laughter in every town and village, and consequently degrading us in the estimation of the public at large. We should be able to do all this," &c.

Indeed! Only just grant Mr. Carmichael his One-faculty Act, and you will create a heaven upon earth. No quackswithout—no irreconcilable feuds within! Hippocrates will no longer cure jaundice at 7s. 6d. a case, nor Sosander produce enteritis at threepence halfpenny per box of pills. Truly did Plato say that hopes are the dreams of waking men. Mr. Carmichael sleeps most sweetly.

But, instead of considering the fancied benefits that would result from a forced fusion of the two higher branches of the profession in Ireland, let us rather discuss some of the real grievances that might be remedied by a wholesome and cordial union—a United Service Club of medical and surgical practitioners. The great point which such an association should impress upon parliament and the public, is, that the miserably low pay given upon all occasions to medical

officers is not only unjust to them, but to the commonwealth. If a commissioner is wanted to examine into anything, no matter what, though little is required but a gentlemanly bearing—and what Mr. Carmichael calls a vague perception that he is to do something for his money—the salary is commonly 1000*l.* a year; if an assistant-surgeon is wanted for the army or navy, the pay is about one-tenth of this amount, though the list of qualifications demanded is so terrific that an Abernethy or a Cline might retire in dismay from the examination. Now if it is for the interest of the state, or, not to use so cold a phrase, if justice and humanity alike demand that our soldiers and sailors should be skilfully tended in their hour of sickness, it is clear that double the present pay would still be an inadequate recompense to their surgeons. It once happened, says a credible writer, that a singer being taken ill, whose salary was 20*l.* a night, his place was supplied by a very inferior person. The pit hissed; on which the performer, no way abashed, cried out, "Gentlemen, are you so unreasonable as to expect me to give you a twenty-pound voice for fifteen shillings?"

At the Dublin meeting, Dr. Kidd, of Armagh, mentioned an instance where an intelligent member of the College of Surgeons was called upon by the coroner to make a post-mortem examination: he was rewarded by an order for two guineas, but this was subsequently cut down to half that sum at the special sessions. The same practitioner examined a soldier, by direction of the War-Office, to see if he was fit for service, and the fee offered him was HALF-A-CROWN! The system of tenders for the office of surgeon to Poor-law Unions, is justly complained of in this country; but we are happy to find, from the speech of Dr. Phelan, one of the Poor-law Commissioners for Ireland, at

the Dublin meeting, that it is not to be adopted there. The medical officers, he says, are to receive "certain reasonable fixed salaries;"—how much that may be, does not yet appear. "Equity," says Selden, "is a roguish thing;" and the "reasonable" of a Poor-law Commissioner may turn out to have as much reason in it as our Union Bastiles have of kindness or justice.

As the call of the Dublin meeting appears to be responded to from every part of Ireland, it is to be hoped that a minimum salary may be fixed by the common consent of the profession, than which nothing less could be accepted, without degradation. It is impossible to conceive that any Poor-law Union should be so small that the medical officer could deserve less than 100*l.* a year; or if his attendance should be confined to the workhouse alone, the same sum would be a very trifling reward for a daily visit. Less than a daily visit is injustice to the patients, unless there is a sound practitioner residing in the house.

One point remains to be touched upon. Dr. Bewley, of Moate, in his speech at the meeting, said, "*We enjoy (unjustly perhaps) a monopoly of the county infirmaries.*" This is a curious fact; to be surgeon to a county infirmary in Ireland, you must be a member of the Irish College of Surgeons; the Lincoln's-Inn diploma will not do. We recollect, that in the panic of 1826, a country woman having changed her local bank notes for gold, was met by a wag, who persuaded her that the sovereign bank had broken, and that it would be best to get her notes back again, which she accordingly did. Our Irish brethren play the part of the wag in the panic: the diplomas coined in Lincoln's-Inn are current from London to Calcutta, from Jamaica to Ceylon; but they have contrived to persuade good, simple Parliament, that they are

not fine enough for Killskeara and Ballylochlin. The sovereign bank is distrusted there, and none but local notes will pass. "Oh!" but our brethren will cry from the other side of St. George's Channel, "you mistake the application of the story; we coin the real sovereigns, and the rest of the empire is content with paltry counters: if Worcestershire legs are mangled, that is no reason why we should not protect Cork ones." Be it so; but at any rate let the legislature get out of the present ridiculous dilemma. If English surgeons are not fit to treat fractures and imposthumes, let their education be improved; if they are fit, do not exclude them from the county infirmaries of Ireland.

When Colbert asked the French merchants what he should do for them, their answer was, *Laissez nous faire*—Let us alone; for they had made sufficient advance in political economy to know that trade flourishes most when unoppressed by protecting duties and other varieties of forced encouragement. Now, talent is a kind of commodity, and thrives best when allowed to be exported without passports and permits.

A century ago, the metropolitan counties petitioned against the turnpike act, because, said they, the more distant shires will now be able to compete with us, and send their produce to London. The same motives still operate, though not always so frankly avowed; and as "the whirligig of time brings about its revenges" it is now the remote provinces which exclude the produce of London. Let us trust that the day is not far distant when commerce may throw off its remaining shackles, and surgeons properly qualified may practise in any part of the British empire.

We have been thus diffuse in our criticism on the meeting at Dublin, as

it has evidently some vivaciousness in its composition, and has many men of note among its members—how unlike that strange association which still lingers on here, under the presidency of a Dr. Webster!

MEDICAL LIBEL.

FIELD v. AUSTEN.

AN action for damages in a case of libel took place in the Court of Common Pleas, on the 21st and 22d of this month. The plaintiff, Mr. C. V. Field, has practised physic in the parish of Rotherhithe for seventeen years; the defendant, Mr. Austen, is medical officer to the Board of Guardians, in the same parish. It appears, that last year a complaint was made to the Poor-Law Commissioners that a poor woman, named Daly, on being taken in labour, had not received proper attention from Mr. Austen. A letter was sent to the Commissioners, complaining of the defendant's neglect; it was signed H. Flagan, but no such person was known to Mrs. Daly, or her friends, nor did they ever express a wish that such a letter should be written. The letter was ill written and ill spelt; but Mr. Austen appears to have thought that this was merely a blind, and that it really came from Mr. Field. The charge fell to the ground; on which Mr. Austen sent a circular, containing the gravest accusations against Mr. Field, to each member of the board of guardians, and also to Mr. Field himself. In this he not only asserted that Mr. Field was the author of the unsubstantiated charge concerning Daly, but that he had performed a murderous operation on a Mrs. Mason, and that this was not a solitary instance of his malpractice. "Of this character I should say that he was shunned and avoided by every medical man, as a dangerous, ignorant, and presuming fool,

and cowardly poltroon. This animal answers to the name of Charles Ventris Field, and he lives in Paradise Row."

Dr. Blundell, who was called for the plaintiff, deposed that he had known him professionally for fourteen or fifteen years; that he "had conferred with him in several obstetric cases, and had not found him more deficient in knowledge than gentlemen generally in that rank of the profession." On his cross-examination, he said that in midwifery he had always reprobated the use of instruments; that his motto was, *arte non vi*; and that instruments were only to be used when there was less danger in employing than in abstaining from them. He had very probably used these terms, "Wild beasts are caged, and yet the accoucheur, with all his instruments of destruction about him, is let loose upon the world."

"Mr. Justice Vaughan.—You would scarcely go so far as to say *labor omnia vincit*?" (Laughter.)

"Dr. Blundell.—Almost, my lord."

Mrs. Mason was a patient in the 72d year of her age, who was tapped by the plaintiff for ovarian dropsy, and died soon afterwards, the colon having been punctured by the trocar.

Mrs. Jane Smith deposed to having been delivered by Mr. Field, in 1826, when she felt as if she was being torn to pieces. She could not see whether he used instruments, but the nurse said so: "there was a cut over the right eye of the child, as if done by scissors; afterwards I could not stand up for a month, and then not for five minutes at a time. I could not do any thing, or pursue my ordinary domestic employments for three or four years."

The other cases alleged against the plaintiff were not so strong. A Mrs. Clockworthy was supposed to have been delivered with instruments; there

were large incisions on the head and neck of the child, which died in a few hours. But this was a lingering labour, the patient did well, "expressed herself exceedingly grateful to Mr. Field," and would have sent for him again, had she not removed to too great a distance.

In another instance it would seem that the lever was used, and the child's cheek, forehead, and ear, were cut. The child, now 13 years old, was in court, and seemed in good health. "No marks of any wounds were perceptible," says the reporter, "at least at a little distance."

Lastly, in the case of Mrs. Jefferd, the wife of a lighterman, where instruments were used, the child was cut on the neck, and bled till it died. Mrs. Jefferd had two children before Mr. Field attended her, and they both died in the birth.

Jefferd, the husband, in his examination in chief, represented Mr. Field to have said, that he did not care about killing a hundred such things—and there the phrase ends; whereas, in the cross-examination it runs, "he said he would kill a hundred such things as that to save the woman"—an important difference!

The jury retired for three-quarters of an hour, and then returned a verdict for the plaintiff. Damages, 100*l*.

This is a very brief abstract of a trial which occupies nearly four columns in the *Times* of June 24; but even our compendium may be sufficient to shew its importance. It is a specimen of the never-ending attempts made by society to settle the vexed question of libel. If we allow each man to tell every painful truth of each other man, the accused will avenge themselves with the strong hand, and the social bond is at an end; if we say with our English lawyers, "the greater the truth the greater the

libel," the wholesome check of criticism is gone—a check far superior to the formal censures of the law. The verdicts of juries and sentences of criminal courts are, of course, a series of oscillations between these extreme points; and an act of Parliament to amend the law of libel would be merely a limitation of the arc within which the pendulum vibrates. To suppose that any act could exactly define what might and might not be published, would be Utopian indeed. Perhaps, on the whole, the verdict in the instance before us was just; for although the plaintiff does not seem always to have employed obstetrical instruments with the reluctant delay and gentle hand inculcated by the great masters of the art, still but little decidedly unscientific was proved against him in this branch; and the only case where he went quite wrong was Mrs. Mason's. This error may be palliated by his not being an operating surgeon; but we could wish that in London, where so many dedicate themselves to the manual branch of our art, after long years spent in the study of anatomy and surgery, that operations were performed by them alone. But if one great error committed in seventeen years' extensive practice is to justify such a circular as Mr. Austen's, who will be safe?

ROYAL MEDICO-CHIRURGICAL SOCIETY.

June 11th, 1839.

SIR BENJAMIN BRODIE, BART., IN THE CHAIR.

On the Structure of the Corpus Luteum. By ROBERT LEE, M.D., F.R.S.

THE author commences with a short description of the mature Graafian vesicle in the human ovarium, which he represents as a small spherical pellucid sac, containing the ovum, the granule, and the fluid with which it is surrounded. The vesicle itself he describes as always consisting of

two membranous layers or coats, closely adhering together, the external surface being loosely united to the proper substance of the ovarium by soft cellular tissue, blood-vessels, and nerves.

When impregnation takes place, the coats of the Graafian vesicle and peritoneum covering it burst, the contents escape, and around it a corpus luteum is gradually formed. The author states that the observations of De Graaf, Haller, and others, have proved that the corpus luteum is always formed in that ovarium from which the impregnated ovum has escaped; but it has not been positively determined by them whether the corpus luteum is produced by a thickening of the inner layer of the vesicle, as Professor Baer has supposed, or between the coats, as Dr. Montgomery believes, and if corpora lutea are not sometimes formed in the ovaria of women who have never been pregnant.

The author then proceeds to describe the appearances which he observed in the ovarium of a woman who died in St. George's Hospital, at the end of the second month of pregnancy, which have induced him to conclude that the corpus luteum is formed around both layers of the Graafian vesicle, and not between its coats, or by a thickening of the inner membrane. In the preparation of the ovarium the Graafian vesicle, like a small cyst, consisting of two distinct layers separated from one another, were clearly seen. A drawing of the recent corpus luteum, which had a deep orange colour, was likewise exhibited.

In two specimens of Fallopian tube conception, which were placed upon the table, the Graafian vesicle was likewise seen, surrounded by the corpus luteum. The same fact, the author adds, is still more evident in the ovarium of the gravid uterus of ten weeks, described and figured in the 17th volume of the *Medico-Chirurgical Transactions*.

In several of the preparations in the Hunterian Museum, at the College of Surgeons, which the author has recently examined, with Mr. Owen, he states that the Graafian vesicle is also seen inclosed within the corpus luteum, and forming its central cavity.

The author concludes this part of the paper by recommending additional observations to be made upon the subject, when opportunities, which are not very frequent, present themselves, in order that the correctness of the view which he has given of the structure of the corpus luteum may be rendered perfectly conclusive. All observations upon the subject, to be decisive, he remarks, should be made soon after impreg-

nation and the date of conception, and all other circumstances should be clearly stated.

The author next proceeds to describe the changes which the corpus luteum undergoes in the latter months of pregnancy, and after delivery; and observes, that it is frequently almost wholly absorbed about the end of the third month subsequent to parturition. Various preparations were exhibited to illustrate these appearances.

In the ovaria of women who have never been pregnant, yellow oval-shaped bodies, he observes, are frequently found, which it is difficult to distinguish from true corpora lutea resulting from impregnations. The greater number of these are produced by blood extravasated within the Graafian vesicles; and he thinks they can generally be distinguished from true corpora lutea by this circumstance, that in the latter the corpus luteum surrounds the Graafian vesicles, but in false corpora lutea the yellow substance is usually contained within the Graafian vesicle. A thickening of the coats of the Graafian vesicle, and the changes it undergoes during menstruation, the author also conceives, might readily be mistaken for true corpora lutea. Various preparations and drawings were also exhibited, to illustrate these statements; and Dr. Lee closes the paper with the following remark, that from all the observations hitherto made on the corpus luteum, we may infer that it is never found but as a consequence of impregnation; that the yellow oval-shaped substances found in the ovaria of women who have not been pregnant, may be distinguished from true corpora lutea by the smallness of their size and irregularity of their shape, the greater depth at which they are situated in the ovarium, the absence of the white membranous appearance of the centre, and by the fawn or yellow-coloured substance being inclosed within the cavity, and not formed around the exterior surface of the Graafian vesicle.

A Statistical Account of 120 Cases of Carcinoma Uteri. By JOHN C. W. LEVER, Esq. Communicated by Dr. CLENDINNING.

As the value of the paper of Mr. Lever consists almost entirely in the tables which it contains, it would be impossible to do it justice in an abstract.

The Case of a Girl who voided from the Urethra a number of Entozootic Worms not hitherto described; with an Account of the Animals. By T. B. CURLING, Assistant-Surgeon to the London Hospital.

The patient is 5 years of age, and is not suffering, as far as the author could ascer-

tain, from any disease of the bladder or kidneys. She first passed some of the entozoa in question on the 26th May last, and continues to do so occasionally to the present time; which enabled the author to exhibit some of them alive to the Fellows present, by the aid of the microscope. When first voided, they float separately in the urine; but in a short time they coalesce and coil themselves up together in a ball, at the bottom of the vessel. If allowed to remain in the urine, they live for two or three days. They are of two sizes—the larger being more numerous than the smaller.

Having discovered, by reference to Rudolphi's Synopsis, and other works on the subject, that the entozoon in question has not been hitherto described, the author enters into a minute description of its characters, and illustrates his description by magnified representations of the male and female, as seen under the microscope. From this description, which our limits do not permit us to give at length, those who are conversant with the structure of the entozoa will recognize a true nematoid structure. These worms differ, however, from the known genera of this class, in possessing several peculiarities of structure; especially a well-marked annulated body, an anal aperture of a labiated form, and a tegument armed throughout with spines. Referring it, therefore, to the order Nematoidea of Rudolphi, he thus describes its characters:—

GENUS DACHYLUS.

Corpus teres elasticum, annulatum et utrinque attenuatum, caput obtusum, os orbiculare, anus trilabiatus.

Dactylus Aculeatus.

Capite obtuso, toto corpore aculeorum serie quadruplici armato, caudâ obtusâ et annulatâ. Habitat in Hominis vesicâ urinariâ.

Remarks on the Acute Form of Anasarcous Tumor of the Scrotum. By R. LISTON, Esq. Surgeon to the North London Hospital.

The object of the author in this paper, is to direct attention to the diagnosis of cases of infiltration of the scrotum with serous fluid, which is often as rapid in its origin, and as calamitous in its consequences, as the effusion of urine itself. Six cases, occurring in the author's public practice, are related, with the view of enabling the surgeon to form a correct opinion of the nature of the mischief, and of directing his proceedings properly and satisfactorily.

CLINICAL LECTURE

ON

OSTEITIS OF THE UPPER THIRD OF THE FEMUR, SIMULATING HIP-JOINT DISEASE,

Delivered, during the Session of 1838-1839, in St. Vincent's Hospital,

By J. M. FERRALL, Esq. M.R.I.A.

First Surgeon to the Hospital.

Anatomical characters — Walther's case — Causes — Scrofula, Lues, Scurvy — Local injury — Treatment — Local depletion — Cautions — Mercury — Hydriodate of potass — Sir B. Brodie's opinion.

GENTLEMEN,—I have described the symptoms of this obscure disease, and pointed out to you the marks by which you can generally distinguish it from morbus coxæ, with which it is liable to be confounded. In continuing the subject of its anatomical characters, I wish to draw your attention to a plate in the treatise on Spina Ventosa, by Ludovici Augustin, of Halle, and taken from the museum of Walther. It represents an enormous enlargement of the upper end of the femur, beginning about its middle, and extending upwards so high as to engage the neck of the bone, close even to the head. The head of the bone, however, projects beyond this huge growth, and has all the characters of perfect health. In this case very little motion could have been enjoyed by the limb during life, as the bony growth protrudes in every direction, so as necessarily to meet the pelvis. The tumor is larger, but less solid than the specimen in Sandifort's museum, and appears to consist of a large irregular cavern, surrounded by walls of great thickness. These parietes are evidently a new growth, and present the appearance which you see in those specimens of necrosis. The surface of the bone appears to be perforated by innumerable apertures, and the substance of the mass has the same peculiar effect as if the bone could, like glass in a state of fusion, have been moulded on the surface in shapes of the greatest irregularity.

This case is given as a specimen of spina ventosa. It is impossible to be quite certain, from its appearance, as to the nature of its contents. It may have been, as implied by the name given to it, a large abscess in the bone; or it might have contained the sequestrum of the upper portion of the femur, if this part had undergone the usual changes of necrosis. It might possibly be conjectured that it was an instance of osteo-sarcoma, and that this

large cell contained the gelatinous or other deposits met with in this disease. It does not, in my opinion, correspond with the usual characters of osteo-sarcoma, for the cell is single, and its parietes remarkably thick in appearance, and not broken up or even weakened in any portion of its surface. Whatever may have been its exact nature, it is probable that, like the disease we are considering, it presented during life many of the symptoms which are supposed to be peculiar to disease of the hip-joint.

Causes.—The causes of this disease are obscure. There is no constitutional peculiarity which, as far as my experience goes, seems exclusively to create a predisposition to this affection, although the concurrence of phthisis in the fatal cases would, at first view, appear to connect it with the scrofulous diathesis. You are not, however, to conclude that a disorder is of a strumous character because another complaint of a tubercular nature is developed during its progress. The injury to the general health, and derangement of the nutritive functions incident to a state of long-continued suffering and fever, are of themselves sufficient to account for the supervention of consumptive symptoms. How often do you see, even the short course of an idiopathic fever followed by the rapid development of tubercles in the lungs of persons who had been previously in rude health, and had never exhibited any tendency to pulmonary disease.

The occurrence of suppuration is also to be considered when estimating the agency of this or any acute disease in the production of tubercle; the consideration, however, of this view, would lead us too far from the immediate object of our inquiry.

We may conclude, therefore, that no proof of the scrofulous origin of this disease is afforded by the occurrence of phthisis in the cases which proved fatal. In confirmation of this opinion I may remind you of the cases in which the constitution has sustained the violence of the attack, and the chest has preserved its integrity, through all the stages of the disease. Certain cases, to which I shall allude hereafter, have also displayed a vigour not usual in strumous subjects, by bearing the very active treatment which succeeded in checking the complaint in its early stage. As to the darts and scorbutic virus to which our continental brethren attribute the occasional occurrence of hyperostosis and exostosis, I can only say, that we have no evidence of their agency in this class of complaints, nor is it very manifest upon what grounds the opinion rests. I do not assert that venereal taint

cannot display itself in the spongy extremities of bones; but I have never witnessed its occurrence. With regard to the cancerous diathesis, we shall presently see that, although not concerned in the production of acute disease in the upper end of the femur, it is occasionally present in more chronic alterations of this part.

The proximate or local cause is scarcely less difficult of detection. I have told you that a patient may retire to rest apparently in health, and towards morning be disturbed by the pain and other symptoms. It has no doubt happened in two instances, that he had used immoderate exercise the day before; and if we were disposed to indulge in conjecture, we might suppose that excessive muscular exertion of the lower limbs, being accompanied necessarily by an increased activity of the vascular system of the parts, had led to a more persistent hyperæmia and its consequences. It would not be so easy, however, to explain why one limb should suffer more than the other; or one part of the limb, or the bone, rather than any of the joints. I was not able to trace the occurrence of local injury, by fall or bruise, in any case which came under my notice, although such an accident might well be supposed capable of determining the situation of the mischief.

There is another mode in which it is possible that muscular efforts might give rise to this affection. If the action of the strong muscles which connect the upper portion of the thigh-bone with the pelvis should have been unusually violent, it is not unreasonable to believe that an unaccustomed degree of tension and stretching of their tendinous insertions might be followed by increased action in the periosteum and corresponding portions of the bone. I was consulted in November last by the parents of a boy, 14 years old, who suffered from the effects of over-exercise in his first trials of gymnastics. He was feverish, and complained of acute pain in both arms, neither of which he could raise to his head. I found the muscles morbidly sensible to the touch; but the parts to which he referred all his suffering, and which were so exquisitely tender that pressure made him scream, were the spaces into which the apex of the deltoid muscle of each arm was inserted. There was, in these situations, a really perceptible degree of deep-seated swelling, which disappeared under the application of leeches and other means of that kind. In this case, there could be no doubt of the existence of inflammation in the tendinous insertion of the muscles, and probably of the periosteum to which they were attached; and there could be as little ques-

tion as to its cause. It would be difficult to verify the origin of periostitis of the upper portion of the femur in an injury of this kind; but its possibility is apparent from the foregoing considerations.

Treatment.—If no other evil resulted from confounding the complaint under consideration with hip-joint disease than the confinement to the position so necessary in the latter case, it would be sufficient to confer a great degree of importance on the inquiry. To “take away the function of the joint” is, in the emphatic language of Sir Benjamin Brodie, the first principle in the management of morbus coxæ, and one without which no other remedy can avail. But the same acute observer remarks in another place, that “the health of the patient suffers, even before abscesses are formed, from the want of exercise as well as from pain and want of rest.” This is so true, that the ruin of the constitution, which so often results from the immovable position of the limb, is only compensated for by the knowledge, founded on experience, that no treatment will be successful as long as the diseased surfaces are allowed to rub and irritate each other.

In osteitis of the upper portion of the femur, there does not, for obvious reasons, exist a necessity for preserving the immobility of the joint. The movements of the limb may be left at the discretion of the patient; for in the early stage, when rest, on principles applicable to all inflamed parts, is serviceable, voluntary motion is painful, and therefore not attempted; and the passive movements communicated to the part by himself or others, and so inseparable from the ordinary attentions to cleanliness and comfort, are neither painful nor injurious.

At a later period, when the inflammation has abated, and when the constitution may be expected to feel confinement, there is no objection to his being moved from his bed to a sofa, or from one room to another, every day, or even being carried into the open air, as a moderate support by cushions placed under the limb will maintain the position most agreeable to the patient.

If you are consulted within a few days from the commencement of the attack, and acute pain with fever are present, you should not hesitate to employ free local depletion. I never saw a case in which I was tempted to direct general blood-letting; the symptoms were rather those of severe constitutional irritation, than of the kind of fever which indicates the use of the lancet. I do not deny that a case may occur, in which the vigour of the patient may give to his fever such a character as to re-

quire this valuable measure, antecedent to other treatment. I merely give you the result of my own experience since I first observed this disease. Local bleeding will always be proper and necessary in the early stage, but even here you must be guided by circumstances, and keep in recollection that children are more easily depressed by loss of blood than adults, especially if it is allowed to drain away for any considerable length of time, even though a large quantity may not have been withdrawn. I recommend you, therefore, to place a cupping-glass over the leech-bites, and remove as much blood as you think prudent, with as little delay as possible, and then carefully close the wounds. Generally speaking, you will find it easier to secure the leech-bites and prevent subsequent hæmorrhage, when a cupping-glass has been applied, than when they are treated in the ordinary way. The plan has this advantage also, that the patient is less fatigued and irritated by this shorter process, which may be accomplished in twenty or thirty minutes altogether. Should the symptoms require a repetition of the leeching, it should be conducted in the same expeditious manner; the pain, local tenderness, and fever, being your guides. As to the situation most advisable for the depletion, it must, of course, depend very much on the degree of tenderness on pressure. The pain is often referred by the patient to parts below the seat of the actual mischief: if you wish, therefore, to make a selection, you must do so by a careful manual examination of the parts.

As happens in all forms of inflammation, you will meet with cases where warm applications are more soothing to the patient; and then the ordinary anodyne fomentations, containing poppy, hemlock, or belladonna, according to circumstances, will be required. I have found an evaporating lotion, containing some anodyne tincture, very generally applicable in these cases; and I think I have observed that cooling lotions are more available in young persons, for the management of deep-seated inflammation than in adults. It may be, that heat is more quickly generated on the surface of their integuments, and that deep-seated congestion therefore obtains, if I may say so, a more speedy outlet by evaporation. With respect to position, discover, if possible, one in which he is comparatively at ease, and maintain it by proper support. He will often desire a change of posture, without being able to procure it for himself; but you may place the limb in any way most agreeable to him, and you should, from time to time, have it altered when he becomes fatigued.

The constitutional treatment best suited to the early stage, will, after moderate aperients, be a mild mercurial plan, conducted so as to affect the system in three or four days.

I need not now repeat the maxim I have so open impressed upon you, when speaking of this powerful agent—namely, that if, for sake of speed, you commence a mercurial course, on a plan capable of giving rise to gastro-intestinal irritation, and that this state unhappily occurs, you are foiled by your own zeal, and retarded by the very anxiety to obtain a hasty result. This interruption to the use of mercury is not the only evil, for you will find that a degree of debility and irritability of the system is induced, which is very unfavourable to the removal of the effects of inflammation. Commence your mercurial course, therefore, with this conviction, that the plan is most speedy which allows you to go on without interruption to the development of its constitutional effects, to a degree suited, in your judgment, to the exigencies of the case. The high doses of mercury which you have seen used in acute visceral inflammation are not applicable here. The quantity of opium necessary to guard the bowels cannot be given with safety to young subjects; and salivation, when it does occur, is generally accompanied by more swelling and inflammation of the tongue and cheeks than is safe at this early age.

The minute doses of calomel, as the twelfth of a grain, recommended by Dr. Law, to be given every hour, will often produce their effects with a few grains of the medicine, and I add, with pleasure, my testimony to his own as to the safety of this mode of exhibiting it. There is, however, a difficulty in managing the regularity of the doses at such short intervals; and, whether from this cause, or that the medicine in a state of such minute division is lost in the primæ viæ, I cannot say; but you will remember being sometimes disappointed, while waiting from day to day for some sign of mercurialization, at a time when the symptoms for which it was administered were in steady progress. On the whole, the mode I recommend in the present case is the conjunction of the external employment of mercury, with its internal exhibition in small doses of a mild preparation. Suppose, then, that you have depleted locally, as far as you think the patient will bear, you may direct ten grains of mercurial ointment to be rubbed over the abdomen every sixth hour, and if you desire an early effect, place a few grains of the re-

medy on each axilla. Extending the surface creates a mercurial atmosphere about the patient, independent of the stimulation of the absorbents where it is applied. I have tried mercurial friction over the groin and upper portion of the thigh; but, however cautiously performed, it was complained of as increasing pain.

Should you deem it expedient to resort to the internal exhibition of mercury at the same time, you should combine it with other medicines calculated to lessen the fever. With this view, two grains of the hydrargyrus cum cretâ, with two grains of James's powder and half a grain or a grain of Dover's powder, may be given every fourth hour. The hydrargyrus cum cretâ is a valuable preparation if successfully made; but, with the best management, its metallic basis is often perceptible if examined with a lens. I therefore frequently direct one grain of blue pill with three grains of prepared chalk to be rubbed together with the other medicines, and made into pills of a convenient size. Another mode I sometimes combine the mercury with chalk is, to have the pill containing the blue pill, James's powder, &c., washed down with half an ounce or an ounce of the *mistura cretæ*. Should the patient be unable to swallow a pill, you may order the blue pill to be made into a draught with a little mucilage and water, or with the chalk mixture. If the *pilula hydrargyri* be prepared as directed by the Edinburgh College, with starch instead of liquorice powder, it will be in every way more likely to agree.

Counter-irritation is often of great service, and is followed by a diminution of pain. When blisters have been applied, you should have a warm poultice laid over the blistered part, with a view to detach the cuticle; and afterwards dress the surface with a very much diluted mercurial ointment.

Under this treatment, if an early opportunity is afforded you, the first stage may be sometimes so effectually antagonized, that the pain may cease, the local tenderness and swelling be lessened, and the disease receive a check. You are not, however, to promise that this formidable complaint will yield with certainty to the mercurial plan, and hence another reason for conducting it with caution. You must, at least, secure your patient against ill consequences from your remedies, if you cannot ensure their success. When the complaint has been only partially arrested, other means remain to be used; but a few days' repose should be given to the constitution; the mercurial irritation should be allowed to subside; and light

nourishment allowed. During this period your local treatment may be persevered in, and varied according to circumstances. You may then direct the hydriodate of potass—a remedy from which you have witnessed such signal benefit in various diseases of the bones and their coverings. You are aware that I do not employ this medicine now in high doses, unless more moderate ones have entirely failed. Two or three grains thrice a day will often produce as much benefit as the medicine is capable of affording; and the risk of occasioning those obscure constitutional disturbances which sometimes follow its use is avoided. I am indebted for this fact to Sir Benjamin Brodie, who, in one of those conversations which I shall always remember with pleasure, mentioned his experience on this point. We occasionally, however, meet with instances in which full doses of the hydriodate of potass succeed when milder ones have failed.

Should you not have an opportunity of treating this disease before the second week, it rarely happens that its progress can be stayed; the management in that case will be nearly such as would be required in acute necrosis. When abscesses are formed, the matter must be evacuated, poultices and soothing applications employed, nourishment allowed, and change of air if possible procured.

We shall next consider the chronic form of the complaint, and the diseases to which it bears a resemblance.

ON THE ACTION OF VARIOUS SALINE SUBSTANCES

ON THE ANIMAL ECONOMY,

When injected into the Circulating System.

BY JAMES BLAKE, ESQ.

[*For the London Medical Gazette.*]

A MEMOIR on this subject was lately presented to the Institute of France, by Mr. James Blake. The following *resumé* of the experiments contained in this paper was read by the author when he presented it:—

The memoir which I have the honour to submit to the Institute contains the result of a series of researches that have been performed, in order to observe the effects produced on the functions of certain tissues, by the changes that take place in the blood when brought into contact with various inorganic compounds. Experiments have been performed with

the salts of soda, potass, ammonia, baryta, lime, and magnesia—solutions of these salts being injected into the veins or arteries—and the phenomena they have given rise to have in most instances been observed by aid of the hemodynamometer—an instrument of the greatest value in all researches connected with the circulation. Owing to a well-marked difference in the physiological action of these substances, they have been divided into two classes: all those contained in one class destroying the irritability of the heart the instant that blood containing them in any quantity is circulated over its parietes; whilst the substances contained in the other class, without in the least degree affecting the irritability of the heart, prove fatal by arresting the passage of the blood through the lungs, apparently by an influence they exert on the pulmonary capillaries. This division, founded on the physiological action of these substances, has also the advantage of separating them into two groups, the chemical composition of which is equally well marked; the only salts the presence of which in the blood does not appear to affect the irritability of the heart being those of soda, the salts of all the other bases, as far at least as they have been tried, suddenly arresting the action of that organ, when introduced into the blood in any quantity.

But although the presence of the salts of soda in the blood does not render this fluid unfit to maintain the irritability of the heart, yet the phenomena they give rise to when injected into the veins are such as to place them amongst the most rapidly fatal poisons. If a solution of one of these substances is injected into the jugular vein of a dog, the supply of blood to the left side of the heart is cut off in about six seconds, although its contraction still continue; at the same time the blood accumulates in the right side of the heart and venous system, to such an extent as to cause a degree of pressure to be exerted on the parietes of these veins, which has been found to be equal to a column of mercury of two inches. This pressure being felt equally on the surface of the ventricles of the brain as in other parts of the venous system, must produce a degree of compression on the brain sufficient to fully account for the sudden death of the animal, which generally takes place in from thirty to forty seconds after the introduction of the salt into the veins. After death, the heart still retains its irritability; and so perfect is the obstruction afforded by the pulmonary capillaries to the passage of these substances, that in some instances not a trace of them could be discovered in the left cavities of the

heart. Should the quantity introduced into the veins not be sufficient to totally arrest the passage of the blood through the lungs, the action of these substances on the pulmonary capillaries is shewn by the increased secretion that takes place in the air passages, and which is such as to quickly fill the bronchial tubes, thus causing the death of the animal by asphyxia. The presence of these substances in any quantity in the blood, also affords a powerful obstacle to the passage of this fluid through the systemic capillaries; a pressure equal to a column of mercury of fourteen inches being often attained in the arterial system a few seconds after their introduction into the arteries, and which is evidently owing to the passage of the blood through the systemic capillaries being arrested.

The phenomena that follow the injection of a solution of any of the substances into the veins, contained in the other class, are widely different from those above described. The most striking method of observing their action is by injecting them into the veins of an animal, the thorax of which has been opened, artificial respiration being had recourse to. In these circumstances, the action of the heart is *seen* to be suddenly arrested in from 7 to 10 seconds after the introduction of the injection. So completely is the irritability of this organ destroyed, that no contractions of it can be produced a few seconds after death, even by the application of the galvanic stimulus, if the dose of the poison has been at all large. General death does not follow so rapidly in these instances as when the passage of the blood through the lungs is arrested, the respiration and sensibility continuing sometimes after the pulsations of the heart have ceased. The injection of solutions of these salts into the arterial system is followed by phenomena analogous to those that are produced by the introduction of the salts of soda, the blood containing them requiring a force equal to a column of mercury of fourteen inches before it can pass through the systemic capillaries.

This fact, viewed in connection with the facility with which these substances traverse the capillaries in the lungs, is interesting, as proving that certain changes may take place in the blood which may affect the capillaries of one organ without apparently producing any influence on those of other organs. The injection of these substances into the arteries also affords a satisfactory proof that their action on the heart is entirely due to the blood containing them being circulated over its parietes, for when injected into the veins the pulsations of the heart are arrested in

from seven to ten seconds; whilst from twenty-five to thirty-five seconds elapse, when these substances are introduced into the arteries, &c. before that organ is affected, although in this case the poison is directly circulated through the brain. Any attempt to connect these phenomena with the changes that these substances produce in the composition of the circulating fluid, is, in the present state of organic chemistry, but a hopeless task. That they depend on certain definite changes produced in the composition of the blood cannot for a moment be doubted, when we consider the intimate connection that exists between the chemical composition of these substances and their physiological action. A series of experiments, undertaken with a view of elucidating this point, led to results which, if possible, tend to render it more obscure; for I find, that on mixing these salts with the blood, when drawn from the body, the changes which this fluid undergoes, as far at least as a superficial analysis will enable us to detect them, are intimately dependent on the acid contained in the salt; whilst the changes produced by these substances in the blood, and on which their physiological actions depend, are as strikingly owing to the base of the salt, and are but slightly modified by the combination of this base with even the most powerful acids.

MM. Magendie, Breschet, and Flourens, were appointed commissioners, in order to examine the memoir.

OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.
By DR. VENABLES.

At the age of forty, as we have just observed, another change takes place in the constitution, and the lithic acid begins to be secreted in greater abundance. This, too, is the age at which persons inheriting a disposition to gout, begin to suffer from the lurking seeds of that disease. At this period, Dr. Prout says, "the lithic acid may not inaptly be considered as a sort of *materies morbi*—that is to say, the cause of irritation in the constitution, whatever it may be, seems to be transferred to the kidneys, which are thus induced to secrete an extraordinary quantity of lithic acid, and by this means to give great relief to the system at large. Upon this principle it is," he continues, "that the good effects ascribed to certain remedies of the active diuretic kind, may be probably explained; such remedies appearing to possess the power, when given in certain favourable conditions of the system, of exciting the kidneys to secrete large quantities of lithic acid, and in this way, by bringing about a sort of artificial crisis, to produce great temporary relief*."

In confirmation of these views, I may bring to your recollection the irritable state of system in certain febrile states, and also

that arising from certain organic diseases, that a remission is attended with a discharge of a large proportion of lithic acid, or some modification of it—the purpuric, for instance; and if we can succeed in effecting, artificially, the same deposit, we seldom or never fail of affording relief. In the specimens which you see here, and which have been passed by children in whom the urgent symptoms of scarlatina, measles, &c. have remitted, there is a considerable deposit of the lithate and purpurate of ammonia. Henry also mentions cases in which a remedy, composed chiefly of tincture of opium and turpentine, brought away several ounces of lithic acid in the course of a day or two. He supposed the lithic acid, in this case, to have been lodged in the kidneys, and that the increase of urine merely washed this away, as it were, mechanically; but Dr. Prout thinks, that although this might have been the case in part, yet he says he cannot help thinking that by far the greater part of it was actually secreted under the influence of the medicine: and that this is generally the case, I think, cannot admit of doubt; for it is not in general pure or insoluble lithic acid, but, for the most part, some of the soluble compounds of the lithic acid—lithate of ammonia, for instance—which, under such circumstances, appears in such large quantity. In some, however, it consists of the lithate of ammonia with a mixture of lithic acid; these may be separated either by raising the temperature or adding a little hydrochlorate of ammonia, which render the lithate of ammonia more soluble, while, at the same time, the more insoluble lithic acid will remain, and may be recognized by its specific characters. I here show three specimens of urine passed by a person who inherits a disposition to gout, and who, if I understand his history, has already suffered some warning attacks of the disease. You see that lithate of am-

monia in abundance has separated from some; but from one, even although hydrochloric acid has been added, scarcely any appreciable portion of lithic acid has separated. Now the question is, whether in this case the health, which is generally worse under these circumstances, is caused by the lithic acid not being separated. We offered some observations upon this subject before, and therefore we must refer to that part. I here present you with the matter passed, or rather thrown off occasionally, from the joints of a gouty patient under my care at the Dispensary. When lithic acid disappears in the urine, this salt (the lithate of soda) generally makes its appearance in the joints; and if there were not this outlet, in all probability something worse—as apoplexy, inflammation of the brain, or something similar, would happen. It has been observed, that persons suffering from this state of system frequently die suddenly; therefore the management in this is both important and delicate.

With respect to the means of relief, opium, not only from its sedative effects, but from its property of increasing, as it is said, the secretion of lithic acid, is a very valuable remedy. It calms and tranquillizes the system; and whether it be that this tranquillity favours the evacuation of the lithic acid, or that the quantity of this principle is actually increased under its use, certain it is that the lithic acid appears more abundantly in the urine. With respect to the preparation, some prefer the opium itself, and others the tincture. I myself have been long in the habit of giving the salts of morphia—as the sulphate or muriate—of either of which from half a grain to a grain may be given every night, or every other night, according to the necessities of the case and the urgency of the symptoms*.

At the same time the diuretics should be continued, for the purpose of increasing the quantity of urine, and bringing

away the lithic acid. The diuretics may vary according to circumstances. Turpentine, as already mentioned, of which from ten to twenty or thirty minims may be given twice or thrice a day, which the dose as a diuretic should not exceed*, as it will then act as a purgative. In some cases the hydrochloric acid may be substituted for the turpentine; and they may be conjoined with the opiate, or the opiate taken at night, and the diuretics in the day. However, it should always be borne in mind, that the acids are dangerous remedies in the lithic acid diathesis; and if this acid shews any tendency to concreate, the hydrochloric acid should be immediately discontinued, and an alkali—potass, for instance—substituted in its place.

As vehicles we use some of the old remedies used by the ancients, and still popular as diuretics, as the decoctions or infusions of the wild carrot, of the *Alchemilla arvensis* (the parsley breakstone), or *pyrola* (winter-green). There are also many other diuretics mentioned by the ancients, some of which are articles of food; such are parsley, mint, nasturtium, capers, asparagus, parsnips, carrot, horse-radish, onion, &c. An infusion of some of the more active of these may be given during the day; and if they have no other advantage, patients will often take these infusions as medicated, when they would not take fluids merely as diluents; and yet the dilution of the urine greatly favours the expulsion of the lithic acid from the system.

In many cases of this kind I have found colchicum a very valuable and powerful auxiliary; and, indeed, I should add a portion of it to the diuretic draught, or perhaps what is preferable, the extract of colchicum may be used to form the pill-mass for the exhibition of the morphia. But it must not be forgotten that, in many of these cases, there is a tendency to congestions and other affections of the head, which opium increases; but I believe morphia is much less disposed to such effects, and, consequently, so far less liable to objection.

While this plan is pursuing we must narrowly watch the state of the system, and whenever there appears to be any excitement, or tendency to inflammation, no

* Some form the salts of morphia into pills by means of soap, which is not only unscientific, but prejudicial to the influence of the remedy. The alkali of the soap deprives the morphia of its acid, and so far renders it much less soluble. If a poisonous dose of a salt of morphia were swallowed, I should not hesitate, if in want of any other antidote, to administer a solution of soap; by which the morphia would be separated, precipitated, and rendered insoluble, till, perhaps, it could be evacuated from the stomach. It is, too, upon this principle that the acetate is less suited for internal use; it parts with a portion of its acid, and thus becomes less soluble, and consequently less efficacious. Hence, too, the utility of adding a small quantity of acetic acid to keep the acetate in permanent solution. Therefore it is better, if the form of pills be desirable, to form the sulphate or hydrochlorate of morphia into pills by means of extract of liquorice, mucilage, or some such matter, which will exert no peculiar chemical action upon the salt.

* There are many who make the diuretic effects of English gin an excuse for an extensive and pernicious indulgence in its use. That it has a diuretic effect there can be no doubt, and that this effect arises from the turpentine and stimulating and essential oils with which it is manufactured, there is no doubt. But as turpentine is diuretic only in small doses, in larger passing off by the bowels, it is evident that excess in the use of gin will disappoint the expectations, and will also prove otherwise injurious.

matter what the locality, it must be combated by venesection, and the interposition of mercurials and antimonials; and this is especially necessary when there is a strong tendency to active inflammation of the kidney, or when a renal calculus, too large to pass along the ureter, is suspected. In such cases the exhibition of the diuretics, &c. as calculated to do much mischief, must be suspended, and recourse had to the means just mentioned; nor, in the opinion of Dr. Prout, does the employment of the foregoing plan appear to suit any other form than that of the crystallized lithic acid; and he considers it objectionable, even in such forms, if in very young or in very old subjects. "Hence," he observes, "as this class of remedies does not appear to exert any beneficial action in any case, in removing the tendency to gravel, but are calculated to answer a particular and temporary purpose only, the moment this has been effected they should be no longer employed; but the means above recommended, as adapted to prevent a tendency to the affection, be resorted to."

Indeed, this is the most dangerous as well as the most difficult form to manage which the lithic acid assumes, because we have two ulterior consequences to combat; first, if the secretion of lithic acid be suddenly checked or interrupted, the severest constitutional symptoms follow. Nor does it matter whether this check have been effected by appropriate remedies or not, the effects will be the same—coma, apoplexy, or fatal congestion of blood, or hæmorrhage from the lungs. On the other hand, we have to fear the formation of stone in the bladder, to which there is generally found a great tendency under such circumstances. Indeed, this is one of those very intricate conditions for the management of which no special rules can be laid down; but if you observe cases of this sort narrowly, and watch their progress, you will find that the facts have been by no means misrepresented; and I have in a few instances seen persons die under such circumstances, and whose deaths were referred to causes very distant from the real ones.

The symptoms of calculus in the kidney have been already detailed, and the passage of this, or at least the elements of it in large quantities, has been termed a fit of the gravel. A fit of the gravel consists in the secretion of an unusually large portion of lithic acid by the kidney, and this is preceded by fever, inflammatory action, and the constitutional derangement already mentioned. Here our treatment must be more active; bleeding, cupping the loins, or leeching, will be necessary,

especially if the symptoms are at all acute. Calomel and antimonial powder, to which, if there be but little nausea, the small portion of potassio-tartrate of antimony, already mentioned, may be added. At the same time, but more especially if there be much nausea or vomiting, we should administer opium, hyoscyamus, &c., and this plan should always be persevered in till we obtain some relief, nor should the diuretics be previously administered.

Immediately after the bleeding, or before any purgatives can have produced their effects, the patient may be put into a warm bath; or, if this is not practicable, warm fomentations should be applied to the loins. He may then have recourse to the purgatives before mentioned, namely, tartrate of potass or the Rochelle salts; and it is here, too, that the addition of colchicum will be found so very beneficial. After venesection and the warm bath, colchicum and opium exert a wonderful control over the inflammatory or spasmodic actions of the kidney and urinary organs in general, and therefore seldom fail to induce a flow of urine. The greatest caution is necessary at this period, and stimulating diuretics should be most carefully avoided, as the very worst consequences have resulted from their use. Not very long since I was called to a Dispensary patient, who, I was informed, had been suffering from lumbago, for which he could obtain no relief, and was advised by somebody to take purg, or some such sort stuff, in the quantity of half a pint, three times a day. He had a mixture which consisted principally of gin and hydrochloric acid, with some spirits of turpentine, of which he took a wine glass full night and morning. He continued this for a week, when he was attacked with most dreadful pain in the loins, extreme irritation of the urinary organs, and a constant desire without the ability to pass a single drop of urine. When the efforts were very strong and forcible, a few drops of blood came. He had as great a desire to evacuate the bowels, but no stool passed. He had vomited in the beginning, but now was affected with severe nausea. He had had one or two severe attacks of rheumatism, as he described it, but which appeared to me to be gout. Under these circumstances he became a Dispensary patient, and I was called to him. By bleeding, the use of the warm bath, morphia and colchicum in large and frequent doses, and the use of tartrate of potass, a flow of urine succeeded. The quantity was increased by the use of diluents; and sinapisms, with a view of exciting gout, were applied to the joints of the great toes. On the fifth day after I saw him, he passed at one micturition very nearly two quarts of urine, in which the three small

lithic calculi, which I here show you, were passed. This patient, in the course of a fortnight, recovered from his urgent symptoms, and gradually gave up coming to the Dispensary, and I lost sight of him. The case, however, is instructive, as shewing what injury may be done by an ignorant interference in conditions of this sort.

If the attack, therefore, be attended to in time, and properly treated, we shall be almost certain of preventing the formation of a calculus in the kidney, or if formed and small, it will be brought away without those distressing symptoms which, under opposite circumstances, attend the descent of a calculus through the ureter, or its impaction in this canal. When the urgent symptoms have been relieved, the strictest regimen must be adopted, and a seton in the loins often proves beneficial. If the patient will not submit to this, sinapisms to the loins should be occasionally applied, and in the intervals a large pitch or galbanum plaster should be worn.

Oxalate of lime, or mulberry diathesis.—Oxalate of lime is found forming the nucleus of calculi, and also giving a coating to lithic nuclei; but to determine that the urine is in a state or condition to deposit oxalate of lime is not quite so easy. This is owing to the circumstance that oxalate of lime never appears alone in the urine, in the amorphous form. It sometimes appears mixed with the lithic amorphous sediments, but even this is very rare; and when it does so occur, it forms comparatively but a very small proportion of the sediment. Oxalate of lime is still more rare in the crystallized form of sediment. Dr. Prout states, that he saw but one instance, but as he merely received the gravel for examination, he declares himself unacquainted with the particulars*. Mr. Brande mentions the particulars of a case in which an oxalate of lime calculus was afterwards extracted. "The patient was 62 years of age, and about five years previously had suffered a slight attack of the symptoms of a stone passing from the kidney to the bladder. He had voided no sand, and his urine always appeared clear. During the last two years, the symptoms of stone in the bladder attained such violence as to render the operation necessary, and a very perfectly formed mulberry calculus, about the size of a nutmeg, with a distinct oxalate of lime nucleus, was removed†."

But renal calculi, consisting of oxalate of lime, are by no means very uncommon. Dr. Prout, in his work upon Urinary Diseases, gives the particulars of twelve cases,

for the detail of which I must refer you to the work itself. The history of these cases, Dr. Prout thinks, warrants the following conclusions:—

1st. That the disease occurs in both sexes, may exist before puberty, and at all ages between that and 40 or 50, when it is most frequent; but that it does not occur after 60, and hence probably is not a disease of old age.

2d. It is not incompatible with gout, but, on the contrary, is often associated with it; and both it and the lithic acid are frequently connected with a tendency to cutaneous disease.

3d. It occurs in sound constitutions, and in persons ordinarily enjoying good health; rarely occurs a second time, unless at long intervals, during which the intermediate health is good*.

4th. The urine is acid, and apparently but slightly deranged in this form of calculus, and very free from all sort of sediment or gravel.

5th. That as renal calculi of the oxalate of lime often subsequently attain considerable size in the bladder, it may be inferred that the formation of this compound is connected with a distinct diathesis, excluding the presence of other diatheses, and that it is not an accidental occurrence, happening, in common with many others, to the urine.

6th. From the dissection of calculi, it appears that the oxalate of lime diathesis is preceded and followed by the lithic acid diathesis—a circumstance which seems to be peculiar to these two forms of deposit, and which, when taken in conjunction with the other circumstances, appears to shew that they are of the same general nature; or in other words, that the oxalic acid merely takes place, as it were, of the lithic, and by combining with the lime naturally existing in the urine, forms the cretion in question.

7th. That the diathesis being of a similar nature, the principles of treatment adapted for counteracting the original tendency to it must be also similar—that is to say, of an antiphlogistic character; great attention being at the same time paid to the digestive functions†.

Such were the inferences first formed by Dr. Prout, and subsequent experience fully confirmed these views. As far as my own limited experience goes, it coincides very much with the above; but there are

* Dr. Marcet makes the same remarks:—"It appears," says he, "that persons who have voided this species of concretion are much less liable to a return of the complaint than those subject to the lithic acid calculus."—(Marcet on Calculi, 2d edit. p. 85.) Similar observations are made by Mr. W. Brande (Phil. Trans. 1808, p. 238).

* On the Urinary Organs, p. 153.

† Journal of the Royal Institution, vol. viii. p. 213.

many obstacles in the way of acquiring knowledge upon this subject. First, the subjects, generally speaking, enjoy good health, or at least are not conscious of any disease, and therefore opportunities for observation occur only at particular periods.

In the second place, a great proportion of the persons so afflicted at these periods resort to the hospitals, where the operation is performed, and the medical and chemical particulars of the case either are wholly neglected, or, if recorded, such record is mostly confined to the private journals of the establishment, and consequently are not available for general purposes.

Diagnosis.—This, perhaps, is the most important, and perhaps at the same time the most difficult, part of the inquiry. Dr. Prout laments this circumstance:—"With respect," he says, "to the means of determining when this diathesis is going on in the system, I am sorry that I can give but little positive information. The absence of urinary sediment, &c. is of a negative character, and leads to no inference where other circumstances are wanting, as is most generally the case. But if there be pain," he continues, "in the region of the kidney, and other symptoms of gravel, without any appearance of sediment, and if the urine be acid, and of the yellow tint* above alluded to, the stomach deranged, and an inflammatory diathesis, either general or local (*i. e.* about the urinary organs), be present; and if all these are associated with suppressed gout, or tendency to cutaneous disease, the existence of this form of the disease may be suspected, and means immediately taken to counteract it."

If sediments existed in the urine, we may presume that they would consist principally of oxalate of lime, and possibly oxalate of magnesia. If either of these be boiled with a solution of carbonate of potass† for a considerable time,

* Dr. Prout states, that he has observed the urine in this diathesis to present a peculiar *yellow* tint, different from that usually present when the lithic acid prevails, which is usually more inclining to red. He professes himself, however, incapable of deciding whether this appearance be characteristic or not. He also avows the difficulty of conveying a clear and perfect notion or conception of this quality by verbal description. For my own part I should have depicted it as a citron tint, or a yellowish green, in which, however, the yellow greatly predominated. So much for our capabilities of defining the more simple or abstract notions.

† On Diabetes, &c. pp. 160, 161.

‡ Caustic potass would answer the purpose as well, if not better; but Gay-Lussac has announced the singular fact, that oxalic acid is produced by the action of potass at the boiling temperature upon animal matter. Consequently, if we used caustic potass, oxalic acid might be produced by the action of the alkali upon the organic or animal matter, always intermixed with calculous matter. Carbonate of

by the long boiling an interchange of principles is effected, and carbonate of lime, which is insoluble, and a soluble oxalate of potass, result. In this flask I present you with the results of a portion of this mulberry calculus thus treated. If we pour off the fluid, on testing it with chloride of calcium, sulphate of copper, and nitrate of silver, the characteristic precipitates—as you see—are obtained. But unfortunately there are no sediments to assist us. Then the question is, is there any certain means of diagnosis? So far as I know, the qualities of the urine are equivocal. Dr. Prout thus describes his ninth case:—"It occurred in a captain of the navy, about 60 years of age, of a gouty family, though he had never had gout himself, and in general enjoyed good health, was active and temperate. Within the last fourteen years he had passed four calculi from the bladder; the two first of these were lithic acid; the last, composed of a congeries of pale-coloured crystals of oxalate of lime, was passed about three years before I saw him, which was in March 1822. At that time he had every symptom of a small calculus in the bladder; the urine was of a pale citrine colour, and of specific gravity 1019·8, acid, but yielded a copious precipitate of the mixed phosphates on the addition of ammonia, and of oxalate of lime on the addition of oxalate of ammonia. This gentleman had never seen gravel in his urine*."

Here there is nothing very characteristic; the principal points are, the urine was acid, of a peculiar colour, not usual in the lithic acid diathesis, and abounded in the earthy salts†. But let us suppose that the pain in the loins, and the other presumptive symptoms already noticed, exist, and these associated with the condition of urine just now mentioned, we should not only be justified in suspecting the oxalic diathesis, but bound to investigate chemically the urine, for the purpose of discovering and identifying oxalic acid.

If the urine contain oxalic acid at all, evidently it must be in the free state, or combined with a base. We can scarcely admit it to be in the free state, because as the urine appears to abound in earthy

potass, however, is wholly free from any such source of error, and consequently from all objection.

* On Diabetes, &c., p. 156.

† Dr. Prout does not notice the circumstance, that oxalate of lime might have precipitated with the insoluble phosphates; and an inconsiderate investigator might thus lose the evidence of which he was in search; for the intermixture of oxalate of lime would not hinder the fusion, while it is evident that the oxalic acid would be destroyed during the heating, and thus no evidence of its existence would be left.

salts, of course it would precipitate as an insoluble oxalate, as you will observe to happen on adding a solution of oxalic acid to urine containing any of the earthy phosphates; and as I myself have ascertained occasionally, on adding oxalic acid to the urine of persons suffering from the oxalic diathesis. Neither can we suppose it to exist in combination with the alkalies, for oxalate of potass and superphosphate of lime are incompatible salts, and therefore could not coexist in the same solvent. Therefore we must conclude, if it exist at all, that it must exist in combination with lime, and that the oxalate of lime is held in solution by some mineral acid, as the hydrochloric, but more probably the nitric; for oxalate of lime, as we have already seen, is readily dissolved by nitric acid. If such be the case, the difficulty will be to separate the earthy oxalate from the phosphates; but I believe it may be in some degree effected as follows:—We neutralize the dissolving acid by potass or its carbonate; a mixture of oxalate and phosphate of lime precipitates, as you may observe by treating this artificial solution of these salts in nitric acid, as above; you see a precipitate subsides. We next pour off the supernatant fluid, and wash the precipitate with distilled water. If I now add a little acetic acid, it dissolves the phosphate, but—as you see—leaves the oxalate of lime untouched; and this may be recognized by the characters already enumerated. I have had but one or two opportunities of putting this method to the test of experiment in urinary cases. In those in which I tried it, I have not found it satisfactory, perhaps from the non-existence of oxalic acid, except upon one occasion, and that was a case of rickets, or mollities ossium, of an inveterate description, and a general serofulous diathesis. I saw it asserted that the lime of the bones passed off in the urine as a superoxalate of lime. Although this appeared highly improbable, yet the urine in such cases often appears turbid, almost like whey, and seems to have a whitish powder floating or suspended in it. This, I have ascertained, consists of carbonate of lime, sometimes suspended, sometimes dissolved by excess of carbonic acid, and in this last case the urine becomes turbid or wheyish on being heated. This is owing to the expulsion of the excess of carbonic acid, the insolubility of the resulting carbonate of lime. In the case of mollities, however, oxalate of lime was distinctly traced, by the method above mentioned; and it seemed to have been held in solution by some strong acid.

OBSERVATIONS

ON

COMPLICATED SURGICAL INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with the Auxiliary Forces in Portugal and Spain.

(As delivered in his Lectures at Sydenham College School of Medicine.)

[Continued from p. 494.]

V.—INJURIES OF THE HEAD.—ON THE INFLUENCES REGULATING, AND THE INDICATIONS AFFORDED BY, THE IRIS, THE PULSE, AND RESPIRATION.

Cases of concussion.—*Mode of distinguishing concussion in certain cases from compression.*—*Different views of many surgical writers of repute from those here given.*—*Intermittent pulse is not an indication of compression, neither of concussion; case.*—*Case of lesion, with cerebral inflammation, fixed and dilated pupil.*—*Compression producing coma and no dilatation of pupil; case.*—*Causes of compression classed.*

As regards the breathing and pupil, perhaps this case of concussion in the next stage of severity, added to the one given as a type at the conclusion of last lecture, will leave nothing to explain further on the usual course and symptoms.

James Clark, æt. 17, short, thin, of previous good health, lymphatic temperament, on the same day was struck by a musket-shot on the top of the head, glancing through the scalp, and abrading the pericranium.

Admitted, 1st day, comatose; pulse and respiration labouring.

V.S. ad 3xvj. Pulv. Jal. gr. xxv.

2d day.—More conscious; may be roused to answer a question, but when not spoken to returns to a semi-comatose state. Pulse and respiration more free and equal, although the former is becoming full, quick, and hard.

V.S. ad 3xx. Rep. Pulv.

3d day.—Is still in a half comatose state; has difficulty in answering a simple question; pupils widely dilated, and contract imperfectly on exposure to the light; bowels obstinately constipated.

Emp. nuchæ ampl. nuchâ. V.S. ad 3xvj. Ol. Tiglii, gtt. ij. st. s.

4th day.—Rather more sensible than yesterday, but the head symptoms seem more defined; cannot answer coherently, moans piteously, and talks of his headache.

C. C. ad nuchâ. V.S. ad 3xvj.

Pulse full, sharp, and quick.

5th day.—Answers rationally; pulse softer, less sharp in its beat, but still of excited character.

V.S. ad 3xij. C. C. nuchâ.

6th day.—Bowels open; aspect much improved, but still complains of headache.

7th day.—Much relieved; free from pain.

29th day.—Convalescent, but complains that he always has dizziness of head when he walks. No permanent pain; bowels act freely.

Cal. gr. iij. Pulv. Ipecac. gr. ij. st. s.

In this case the shock was more severe, coma more complete, no vomiting, and the pulse and respiration corresponding.

With returning consciousness rising pulse, announcing reaction, and the inflammatory or irritative stage; suppressed secretions from liver and bowels; dilated pupils, with slight contractile power. The retina still impaired; generally it recovers itself with the other cerebral functions.

The greater obstinacy and violence of the reactive or inflammatory stage, is also generally in strict relation to the greater violence of the original shock.

The continued irritability of fibre after recovery; the powerfully beneficial effect of depletions, proportioned to the violent and unyielding character of the inflammatory stage (demonstrated by the pulse and diminished pain), and of the re-established evacuations and action of the liver, are also well exemplified.

In some cases we neither find the pulse thus change its character, nor, indeed, the irritative stage supervene perceptibly. The lethargy lasts longer, and seems to fling its palsyng power over the whole system, preventing or concealing this reaction; or the same lethargic state and pulse come on a second time. The following is an example of this last form, and may be

taken as an indication of continued pressure:—

John Burn, æt. 23. On the 15th of March, 1837, was struck by a musket-ball over the anterior and superior part of the left os parietale, fracturing the bone. There was also depression, partially relieved by an elevator. The patient was admitted in a semi-comatose state; pupils dilated, and in a trifling degree only answerable to the light; pulse weak and faltering.

Cold lotion. Pulv. Purg.

2d day.—Patient describes himself as having passed a good night, but answers with hesitation. Pulse has changed, become full and strong.

V.S. ad 3xvj. Rep. Pulv.

3d.—Better; answers well; complains only of pain in head.

4th.—Giddy and light-headed occasionally, if he lies on the side opposite the wound; no pain in head; pulse quiet.

5th.—Neither pain, giddiness, nor lightness; pulse 60—64, sluggish, languid, small in volume. Next two days doing well in all other respects; pulse the same.

9th.—Pulse 48, rather thready; pupils more dilated than natural, left more than right.

10th.—Pulse 52.

11th.—Pulse 60; tongue perfectly clean and moist; bowels acting freely. Not finally relieved of pain till the 22d, when pulse became nearly natural.

Fourth month discharged; giddiness when exposed to sun only.

The case of Philip Thorne, already given, may serve to shew the absence of reaction and gradually diminishing lethargy to time of cure.

This continued labouring and slowness of pulse, either without any intervening stage of exaltation, or with so slight a one as that marked in the first case, I have been led, from my observations on these injuries, to believe the best sign of compression—not necessarily from effused or extravasated blood or matter, as I have shewn, although this may occasionally be the cause, but compression in one form or the other. In the mild and mitigated form occurring in Burn, I doubt the propriety of much bleeding; such depletion as can be effected from the skin and bowels,

was trusted to in that case, and with good success. Moreover, this case is of value, as proving the importance of not unnecessarily meddling with depressions in fracture.

The natural tendency of concussion and compression is to produce, while either the one or the other is the prominent feature of the case, a dilated pupil, the sensibility of the retina being more or less impaired, and a slow and laboured pulse, from a depressed action of the heart, in like manner more or less decided.

These two injuries, or either the one or the other, may be sufficiently strong to paralyse all other actions, or their outward manifestations only, and so gradually relinquish their grasp upon the brain and system, that *their* symptoms, and theirs only, can have been recognised throughout the case of which Burn is a good example.

But more commonly either concussion or compression, particularly when the latter arises from the former, subside, and then the irritation and the inflammation, which are the natural sequences, become developed and manifest. The pupil then becomes morbidly contracted, the retina having exalted sensibility; the pulse, no longer sluggish or feeble, acquires increased volume and velocity, beats sharply against the finger, and often from 100 to 150 per minute. This may in some cases subside, and be followed by the first symptoms of concussion or compression, and so alternate during a period of some months, recurring again and again. In many such cases I have no doubt fluid is compressing, whether from inflammation of serous membrane—the arachnoid—from the deposition of matter—or pressure within the vessels: the two former may always be distinguished from the latter by the sudden relief afforded from the lethargic and other symptoms in the last form of compression, by bleeding. No such relief can be obtained if there be fluid of any kind effused.

The pulse by its frequency and character is our index to the action of the heart, and to the state of the circulation as regards force, quantity, and speed. In all conditions it affords us one of the guides on which we most rely, to determine the nature and degree of deviation from health. It is highly important,

therefore, that the indications of the pulse should not be misinterpreted, while considering the nature and extent of the injuries now under consideration.

On what does the heart's action depend? what are the chief influences which modify its force, or change the rhythm of its contractions? for until satisfied on these points, no surgeon can be competent to draw correct conclusions from the pulse. This is a question into which it is impossible to enter at present; but I call your attention to it, and shall merely add for your guidance, that the pulsations of the heart are chiefly under the influence—1st, of respiration; 2d, of the nervous system, any irritation exciting, not a single contraction, but a succession of periodic contractions; and thus the time and the rhythm are occasionally both changed, or only one.

Whenever the changes in the blood induced by respiration are impeded or interrupted, whether the respiratory movements be mechanically stopped, as by closure of the glottis, or by lesion of the nerves on which the muscular combination depends—whatever the cause, in fine, the result is depression of vital action in all the organs of the body, and in the higher animals speedy annihilation.

Interruption of respiration, then, you will bear in mind, enfeebles the heart's action; and that this is not entirely dependent on the nervous centre of the encephalon was proved by Sir Benjamin Brodie, who beheaded a dog after tying the cervical vessels. By keeping up artificial respiration the heart continued to beat for two hours and a half. The influence of respiration here seems to be more important to the heart's action than that of the nervous system, or of the brain at least.

In cold-blooded animals, however, this law seems reversed; for when frogs can neither breathe by the lungs nor by the skin—as, for instance, when immersed in pure hydrogen—they will live for many hours, the heart acting.

On the other hand, the influence of the nervous system on the heart's action is very great, as may be observed whenever the passions are called into play; sudden joy or grief will for a time paralyse its movement. All passions, which are excited states of the nervous

system, accelerate the pulse, and increase the force, with the exception of certain depressing feelings, such as fear; the action of these on the heart is still to accelerate the contractions, but they enfeeble the pulse.

Bichat devoted much time to determine by what part of the nervous system the heart was chiefly influenced—whether its movements were derived immediately from the cardiac plexus and sympathetic system, or through the medium of these from the spinal marrow and brain; and in taking the pulse as a criterion of the nature or degree of injury to the brain, you see at once how important such an inquiry must be.

The history of acephalous monsters proves that circulation may be carried on without a brain, and even without a spinal cord; but when these have once existed in the higher animals, there can be no doubt, from all the facts and experiments collected to elucidate this subject, that the brain and spinal marrow have a great influence on the motion of the heart, and are capable of accelerating or retarding, invigorating or depressing, its action. It seems equally certain, that the heart's action is not wholly dependent upon these.

The brain and spinal cord, as centres of nervous power upon which the sympathetic seems in a great measure to depend for its continued energy, very certainly when injured or affected, react probably through the medium of the nervous fibrils accompanying the blood-vessels upon the sympathetic, and excite its peculiar motor power. With this view, even though the constant source of the heart's action were considered to be the sympathetic, yet its excitement, and the maintenance of its power, must depend upon the brain and medulla spinalis. You are aware that several cerebral nerves are closely connected with the sympathetic nerve, as also that the par vagum enters essentially into the composition of the cardiac plexus; the influence of the brain, therefore, may thus be even more direct.

The causes of change in the rhythm of the heart's contractions giving various kinds of intermittent pulse have not yet been determined, and there is room for a series of experiments of high practical importance on this subject. It seems probable that such change is the effect of a peculiar irritation—peculiar in cha-

racter rather than violent in degree. I am further confirmed in this view by observations on the pulse in connexion with injuries of the head.

An intermittent pulse, I must maintain, notwithstanding a host of authorities against me—for I am not disposed to close my eyes to the facts which I myself have carefully observed—is not a common symptom; nay, that it is sufficiently uncommon, and very rarely, indeed, exists where the injury is concussion. When it does occur, it is generally where there is compression, with or without other complication. It is only in such a case as the following that I have observed it, and by no means constantly, for many similar ones presented no such symptom or feature.

Case of Lesion of Brain giving an Intermittent Pulse.

William Knight, æt. 15, sanguine temperament. On the 9th of September, 1836, was wounded by a musket-ball, which penetrated the brain at the occiput, entering a little to the left of the occipital process. Shortly after receiving the wound he became lethargic, and was roused with difficulty to answer any question.

Head shaved. Cold lotion. V.S. ad 5xx. Enema.

2d day.—Passed a restless night; at present quiet; pulse 56, slow, labouring, and intermitting every third beat; pupils dilated, insensible to light; breathing natural; skin warm.

5 P.M.—Attacked with convulsive twitchings of the extremities; pulse small and feeble; motions and urine passed involuntarily. Died next morning.

Post-mortem eight hours after death.—On removing the scalp the pericranium was found injected in the neighbourhood of the wound. A fragment of the inner table of the skull was depressed, and resting on the posterior surface of posterior lobe of the cerebrum of left hemisphere. Pus was found extending over the surface of the brain below the membranes. Substance of brain and vessels of pia mater much injected. The ball passed diagonally across the brain, entering at the posterior part of left posterior lobe, and was found near the opposite side, imbedded in the substance of the right

middle lobe. Purulent matter found along the track of the ball, and also at the base of the skull. The whole of the pia mater gave strong traces of inflammation. Viscera of chest and abdomen healthy.

This case not only gives one of the rare examples I have met with, furnishing intermittent pulse, but it also proves that which I have already dwelt upon at some length, viz. that under violent concussion, neither the pupil nor the pulse will give indication of any irritative or inflammatory action. Here is great and extensive inflammation of membranes and substance of brain, yet the pupils continue widely dilated, the retina perfectly insensible to light, and the pulse slow, labouring, and intermittent, unless it be said the intermittence marked the inflammation—an assertion that cannot be maintained. The implication of the excito-motory system towards the close of the second day is also well marked, commencing by twitchings and convulsions of extremities, and ending by relaxation of the sphincters. Compression much more rarely produces this state of the pupils, in spite of irritation and inflammation: lesion more frequently. The following case seems to me an instance where the lesion rather than the concussion produced this effect:—

Case of Lesion producing permanent loss of sensibility in Retina, and a fixed Pupil during Cerebral Inflammation.

John Jennings, wounded on the 25th of July, 1833, at Oporto, struck by a musket-ball on the left side of frontal bone, which fractured the skull and penetrated the brain. I met him scampering back to his post, across the courtyard of the building at that moment attacked. Seeing him bleeding from the head, I stopped him, and felt with my finger the fracture and the ball below. As we were both under a pretty smart fire where we stood, and the roar of musketry and artillery rendering the voice well nigh inaudible, I pointed to a part of the house where I had established one of the English ambulances, telling him to go there.

It appeared, that the moment my back was turned, instead of going to the medical officers, he reloaded his musket, joined his comrades, and fought out the

day. Even the next morning, when in hospital, it appeared he had not a single bad symptom. Pulse natural; little or no pain. He was bled to twenty ounces, and purged.

The next morning (that is, on the third day) there was violent pain in the head. He felt drowsy, and answered in a sluggish and incoherent manner. Pulse full, and rather accelerated; pupils slightly contracted.

(These two features both, in my opinion, mark the distinction, and that his symptoms were those of lesion, compression, and inflammation, the last predominating, rather than concussion.)

I removed several fragments of bone protruding inwards, together with the ball, and with immediate relief. He instantly spoke more clearly, and had a less anxious countenance.

4th day.—Extreme restlessness ever since relieved from his drowsiness by the operation. He has also been sick once. Bowels not acted upon: pulse full and quick; face hot and flushed; vessels distended in the vicinity of wound; answers less readily; pupils dilated; countenance heavy. He has just been bled from a large orifice, to rather more than 20 oz. before a decided impression could be made on the pulse.

Cal. cum Coloc.

6 P.M.—Pulse again full and bounding; face flushed; skin hot; cannot be roused.

Enema. Jalap, Cal. and Rhubarb, st.

10 P.M.—Pulse full and hard. V.S. ad 3xvj. Copious evacuation also from medicine and enema.

Evening of next day he died.

Post-mortem.—The ball had fractured the frontal bone, anterior to the coronal suture and to the left of the longitudinal sinus, making an opening of the size of a shilling, with a fissure running backward. There was detachment of the dura mater from the bone; inflammation of the membranes generally, with excessive turgescence of the vessels; effusion of serum and lymph on the surface of both hemispheres, in the lateral sinuses and at the base of the brain. The arachnoid was thickened and opaque, the dura-mater also thickened, and, at the point of injury, pulpy; the brain, at the same part, black and soft; but in the parts distant from the point where the ball entered, the

brain was firm and natural in appearance.

All these post-mortem evidences of inflammation are distinct, and yet there was, during life, a dilated pupil, with the exception of one short period on the third day before operation; the pulse alone giving true indication of the inflammatory process. In a precisely similar case, both as to injury, duration, and termination (*Apjohn*), there was softening and disorganization of the whole brain, and no urgent symptoms for many days; the pupils remaining natural, and the iris contractile.

When compression seems to be the chief agent, a complete state of coma may be induced, and the pupil remain natural (not dilated), and sensible to light. I do not think this could happen in the lethargy of concussion; and in no such case have I ever observed it. The following is a remarkably clearly-marked case, which is further worthy of note as forming one of the only two cases which have come under my notice, where the site of injury was indicated with precision by the patient's movements. The other (*Knight*) is given, p. 521, as presenting quite as unusual a feature—an intermitting pulse.

Case of Compression supervening on Concussion, presenting Coma from each of these causes; no Dilation of Pupil from second.

—Watson, æt. 50, May 10, 1837, fell down stairs when drunk, a height of about fourteen feet. He pitched upon his head, and was brought into the hospital, about three P.M., insensible.

2d morning after injury. — Recovering, and endeavours to speak. Right pupil not dilated; the left obscured by opacity of cornea. He was bled twice yesterday, 12 oz. each time. Pulse is quiet and regular; tongue moist and coated. Head shaved.

Cold applications. Purgative enema.

3d day.—Understands, but cannot articulate; attempts but cannot protrude the tongue; puts his hand to the left side of his head. Right arm colder than the left; pupils a little contracted, but sensible to the light. Pulse slow; bowels opened once yesterday; convulsive movements of the right arm and of the mouth, with rolling of the eyes.

Emp. Lyttæ nuchæ. Mag. Sulph. cum Ant. Tart. 3tiis horis.

4th.—Can protrude the tongue. Can-

not articulate intelligibly; mouth drawn convulsively to right side; convulsive movements of right arm.

5th.—More severe convulsive fits; deteriorating perceptibly; pulse slow and laboured.

6th.—Complete coma; pupil regular, and contracts on suddenly raising the eyelid. Pulse slow; urine thick, and tinged with blood. In comatose state on to the tenth day, when he died.

Post-mortem.—No fissure or fracture of the cranium was observed. The calvarium removed, the dura mater presented a large deep-coloured patch over the upper surface of the left middle lobe. Under this, and between the dura and pia mater, a large quantity of coagulum was found, amounting to six ounces, depressing the left middle lobe over the greater part of its superior surface, separating it from the dura mater nearly half an inch. Vessels of the pia mater were excessively gorged over the whole surface of the brain. The cerebral substance itself showed an injected state of its vessels, and much more than the natural quantity of serum, of a deep tinge, was found in the lateral ventricles. Compression above and in the ventricles must have been considerable.

The details of this case are unusually interesting; proving, 1st, concussion; 2dly, extravasation on the surface of the left cerebrum. Loss of motion in the tongue and power of articulation would indicate paralysis of the fifth, probably within the skull; at all events the third branch of the fifth was affected, and this is further shown by distortion of the mouth. Had there been, instead, paralysis of the portio dura of the seventh, there would have been no distortion of the mouth when the face was at rest; and thus may the affection of these two nerves always be distinguished.

There was also paralysis and loss of temperature of the right upper extremity, evidently cerebral. The excitatory system was morbidly excited, as was proved by the convulsions on the paralyzed or weakened cerebral side, opposite to the injury. The power of motion remained, but it was beyond the control of the will. The action of the heart, as compression increased, became impaired; the pulse slow and laboured. The pupils remained contractile, even in complete coma, four days before death. The sphincters did not lose their power, although the patient was too comatose to be roused, and you find no

stertorous breathing recorded, confirming all I have said to you, and the general law I have laid down on this point. This case I would describe as one of abolished cerebral functions; exalted excitomotor system, with slightly impaired action of sympathetic, evinced by the impeded circulation.

I have entered thus fully into the analysis of this case, otherwise one of great interest, to shew the process by which the surgeon must seek to unravel the symptoms, referring each to the particular part of the nervous system affected.

Compression is produced in many degrees, and certainly by many distinct causes—in a variety of ways, essentially different. The similarity confined probably to the effects which I believe to be the same, and undistinguishable by any symptoms during life, or general alteration of cerebral structure, when examination is made after death. The difference in the effects and symptoms of compression seems dependent chiefly on the extent of compression, and in some degree on the part compressed. Thus more pressure can be borne, without urgent symptoms, on the superficies of the hemispheres than on the ganglia, by fluid in the ventricles or at the base. The causes of compression connected with violence, may be thus enumerated:—

Compression by fluid on the superior surface at the base or in the interior of the brain; serous effusion; formation of matter; exudation or extravasation of sanguineous fluid.

Compression by coagulum, external to the substance of the brain or within.

Compression by bone or foreign body.

Compression by fungus cerebri pressing a portion of brain through an opening in the skull, of which last kind here is a very beautiful preparation.

PARTICULARS

OF THE

ILLNESS AND DEATH OF THE LATE MR. MORI,

The Violinist.

By E. W. DUFFIN, Surgeon*.

It is about nine years since I was first consulted professionally by Mr. Mori.

* This has also been printed in a separate form, but we have been requested by Mr. Duffin to publish it in the MEDICAL GAZETTE.—ED. GAZ.

At that time he evinced decided symptoms of cerebral disease; and on several occasions I could regard his actions, and the sentiments he expressed, in no other light than as the result of mental aberration. But before attaining so advanced a stage as to give rise to the mental infirmities, peculiarities of habit, and moral impulses he manifested, the disease must have been in progress for a considerable length of time. He was nervous, restless, suspicious, irritable, and impatient of control. He was remarkably zealous and energetic in all his undertakings, and jealous of rivalry to a most incredible extent. On more than one occasion was my aid requested to appease his frantic excitement after witnessing the success of foreign talent—for amongst his own countrymen he had no rival. He was extremely ambitious to arrive at excellence in his profession, and to secure public applause and confidence. Indeed, such was his anxiety to afford general satisfaction, especially on the occasion of his own concerts, that his bodily and mental exertion often produced a degree of nervous excitement that could only be regarded as a species of hallucination; and the public will be surprised to learn that, calm and collected as he used to appear before them—so much so as even to be accused of apathy—the effort to maintain that tranquillity was painful to him in the extreme. On one of these occasions, an hour or two previous to his concert, I was sent for by his family to inquire whether his state of mind was such as to render it prudent to allow of his appearance before the public; but he brooked no control, and always assured us that, when the moment arrived, he could restrain his feelings, conquer his anxieties, and perform his concerto as coolly and collectedly as if nothing had occurred.

It was under a paroxysm such as I have described that he first experienced a singular cerebral attack, which, for a few minutes, deprived him of sight; on the restoration of which he found his memory for music gone, so that for nearly an hour he could neither read the notes nor play from memory. This occurred more than three years ago, and he had subsequently several relapses of the same sort. On three of these occasions his left hand remained slightly paralytic for several weeks, so that he could neither exert sufficient pressure to stop the high notes, nor

move his fingers with sufficient rapidity to execute delicate passages. After one of these attacks he found himself sensibly paralyzed in every part of his right side, more particularly in his hand and arm, so that it was with the utmost difficulty he could command his bow. Another of his seizures produced loss of memory and difficulty of articulation. As these consequences were never of very long continuance, and it was desirable to conceal them as much as possible from the public, I could always succeed in preventing his performance till he had nearly recovered; but usually of late he played too early, and his defects in consequence, both in execution and tone, did not pass unnoticed by close and accurate observers of his performances.

In addition to extreme sensibility in regard to professional reputation, he was excessively desirous of accumulating wealth; and as his disease progressed, in like proportion did he become morbidly sensitive and avaricious: yet he has by no means died so rich as is currently reported; his family will be but indifferently provided for. Had his natural passions and propensities taken a different course, it is more than probable that, influenced as they were by a morbid brain, they would have led him to the commission of some outrageous act of insanity, which might have consigned him to the precincts of an asylum. Many an individual less deranged than he may be said to have been has met such a fate. But so long as they pursued a natural channel they were never viewed in this light; and, had not a post-mortem examination of his body proved how little he was accountable for their morbid manifestation, much unmerited obloquy might have attached to his memory.

This exposition, it is hoped, will go far to reconcile the resentment and solace the injured feelings of those whom his uncourteous and irritable temper may have at times offended. Notwithstanding the morbid passion which the impulse of the moment might excite, Mori had still many redeeming qualities. He was warmly attached to his family, kindly disposed towards his friends, grateful for services rendered, and very forgiving and forgetful of injuries.

The death of his wife, which happened about eighteen months ago in the

same awful and sudden manner, made a great impression on his mind. His grief, though short, was very poignant and sincere, and wrought a great change in his dispositions and moral habits. He became comparatively indifferent to every thing which had before so much excited and interested him. Prior to her decease he was accustomed to practise incessantly; the violin was scarcely ever out of his hand; and whilst conversing with any one who called, either out of compliment or on business, he continued fingering such passages of difficulty as he was desirous of overcoming. He slept little; in fact, watchfulness was one of the most prominent symptoms of his disease. He was extremely restless, and used to walk about from room to room, practising and talking all the time.

Unfortunately, a few months after Mrs. Mori's death, another powerful passion took possession of his breast, for the occurrence and uncontrollable nature of which at such an untimely period he was, perhaps, no more accountable than he was for the resistless influence which appeared to govern all his other sentiments and propensities. He became attached to a lady of high professional attainments; and in this passion all others were absorbed, *even his love of gain*, for he stated to me that he had offered, and was still willing to make, any pecuniary sacrifice to obtain the object of his affections. His disease now began to gain more rapidly upon him. Far be it from me, however, to allege that the progress of his malady necessarily depended upon unrequited affection, though doubtless the influence of this on a diseased brain would contribute to feed it. He ceased to practise, and became comparatively indifferent to his own success or to that of others.

The physical evidences of his complaint had become now more apparent, and the unhealthy aspect of his countenance attracted universal attention. Is it not, then, a most surprising circumstance that, labouring under such a multitude of jarring passions, morbidly heightened by uncontrollable disease in the brain, he should have still retained the influence he had acquired among his professional brethren, as well as the interest he had excited in the mind of the public? He now more frequently applied to me for advice. A variety of

symptoms, in addition to those already enumerated, daily declared themselves. He was affected with a very anomalous and extensive ulceration of the throat, and his digestive organs became greatly deranged. But he never on any occasion complained of uneasiness either in the chest or back, or exhibited any diagnostic indication of the extraordinary aneurism that terminated his existence*. His pulse was always feeble, but regular and healthy in other respects.

These remarks bring my history to about the 3d instant, when he was considerably amended in his general health, but completely upset again by the occurrence of his second concert of this season, on the 5th. On that occasion, I am informed, his strange conduct behind the scenes induced a strong belief in the minds of his brethren that he was the victim of mental infirmity.

Late in the evening of the 12th instant, he called at my house in a state of the utmost agitation, and informed me that a few hours before he had been seized with a sudden pain in his back, which had gradually extended itself along the whole length of the spine; that this pain was very much increased on motion; that it prevented him standing upright; and that it was gradually extending itself across the chest, so as to produce a degree of constriction that materially oppressed his respiration. His hands were cold and tremulous; his pulse was feeble, but regular; and his expression of countenance indicated the greatest anxiety. On applying my ear to his chest, I found the heart beating slowly, softly, extensively, and in a measured manner; the breathing seemed much oppressed, but I did not detect any other morbid phenomenon. Indeed, as will presently be shown, the diagnostic symptoms of the earlier stages of the disorder, which terminated his existence, were masked by the rapid advance it had made before he called upon me. Perceiving that he was very seriously ill, and not liking to trust him to return home alone, as I was at the instant called to a gentleman in the neighbourhood, I requested a professional friend to accompany him in a coach, and I followed in half an hour afterwards. Such remedies were then prescribed for him as appeared to me

most likely to afford immediate relief; and we agreed, as it was by this time late at night, that if not better on the morrow, he should be again visited by some of the professional friends who had been requested on former occasions to meet me in consultation on his case.

On the following day, however, he was so much better that he declined taking any further advice, and in the evening was so far relieved that he got up and walked about his room. At twelve o'clock he retired to rest; and in about half an hour afterwards, his family, who slept in an adjoining chamber, hearing a strange noise, went to him, and found him struggling for breath. In a few minutes he expired.

When Mr. Mori applied to me on the previous evening, I conceived it probable that the pain and uneasiness he complained of in the back, coupled with the collapsed state of the countenance, shivering and tremulous motion of the hands, and presumed state of the brain, might be precursory of typhus or some other fever, more especially as I was aware that he had for several days previously undergone extreme bodily fatigue and mental anxiety; but being desirous to avoid alarming his family by expressing such an opinion hastily, as his manner of complaining resembled in many respects an acute rheumatic seizure, I desired his friends, as the readiest answer to the repeated inquiries that were made respecting him, to say that he was affected with rheumatism in the back and loins; hence the origin of the absurd report which got into circulation, that "he died of lumbago."

Post-mortem Examination.—On the day following his decease, the body was examined, in the presence of Dr. Child, Messrs. Rogers and Balderson, and several personal friends of the family.

On removing the cranium, a considerable quantity of bloody serum escaped from under the dura mater. The sinuses and venous system in general were very much gorged with blood. The dura mater was somewhat thickened in its texture, and more dense than usual. It adhered very firmly to the glands of Pacchioni, which were considerably enlarged, and in a tubercular semi-suppurating condition. The arachnoid membrane was thickened and opaque—the result of chronic inflammation of its texture. A milk-coloured serum, and portions of coagulable lymph,

* It may not be unworthy of remark, that in this respect his case very much resembled that of the late Dr. Barry.

were effused under this coat throughout its whole surface, so abundantly as to separate it from the pia mater to the extent of the sixth of an inch. The pia mater and substance of the brain were softened, and in some parts reduced to a pulaceous consistence. The ventricles were filled with serous effusion; and a considerable quantity of fluid ran out from the spinal canal. The arterial system was ossified to a most remarkable extent in every part of its ramifications. The larger arteries, from being closely *annulated* with bony deposit, were preserved quite patulous in their calibre, and presented the appearance of the trachea of a small bird, conveying the same impression, when pinched betwixt the fingers, as this tube would impart when similarly examined. The investing membranes of the arteries at the base of the brain, and their larger branches, as well as of those of the internal carotids, ramified on the corpus callosum, and on the anterior and middle lobes of the brain, were stretched, so as to allow the vessels to float about, and to be easily raised to a distance of several lines from the surface on which they rested. These elongations were so considerable, that they might not inaptly be compared to the mesenteric elongations of the peritoneal covering of the intestines. The choroid plexus of veins was turgid, varicose, and bleached. These were all the morbid appearances observed in the head.

The right cavity of the chest contained between *six and seven pounds of blood*, which had separated into a bloody serum and loose, grumous, dark-coloured coagulum. This was found to proceed from a rupture of the pleura, opposite the attachment of the tenth rib to the spine, where it is reflected to form the thoracic partition. One tracing this opening, which was large enough to admit my forefinger, we found the cavity of the posterior mediastinum, in its whole length, full of a dark coagulum, which was easily separable from its parietes. The effusion had distended its walls, and forced a way to a considerable extent into the loose cellular membrane under the pleural covering of the posterior surface of the lungs, so as to produce a very extensive ecchymosis of this part. On further examination, this effusion of blood was ascertained to have proceeded from an aneurism of the aorta of a very remarkable description, the dis-

eased and easily separable coats of the blood-vessel admitting of our tracing the formation of the tumor in the most satisfactory manner.

It appeared to have been originally formed by ulceration of the inner coat of the artery, opposite to the body of the eighth dorsal vertebra, and on the right side of the vessel. This opening was irregular in form, but approaching to that of an oval, and large enough to admit a moderate-sized crow-quill. A second ulceration, about the size and shape of a small split bean, which had succeeded in destroying the inner coat of the vessel, was found close to the ulcerated opening just described. The blood, it appears, had first insinuated itself at this point between the serous and muscular coats of the aorta, and afterwards had gradually separated these on the posterior and right lateral surface in *their whole extent*; the sac running upwards, and following the course of the arch, till the artery emerged from the pericardium, and proceeding downwards to within an inch of the bifurcation of the vessel. It presented the appearance of a secondary aorta, of irregular calibre. At its lower fourth it did not much exceed the diameter of the blood-vessel; its central half was nearly double the calibre of the vessel, and the upper fourth was of intermediate capacity. The widest portion was opposite the point of formation of the aneurism, extending from about the fourth to the tenth dorsal vertebra. That it was formed by the mechanical separation of the coats of the artery, was most satisfactorily ascertained, as the vessel was in a very diseased state, and admitted of being torn with the fingers, so as to prolong or enlarge the sac in any direction. The muscular layer was converted into a white tough fibrous substance, that could be easily torn in the direction of its fibres, and which, when peeled off from the cellular coat, presented the appearance of a piece of spinal medullary matter macerated in an alcoholic solution of bichlorate of mercury. The serous coat of the artery was studded with large ossific points and tubercles, some of which were as large as a moderate-sized bean, and in a state of semi-suppurated. It was one of these, I make no doubt, that had suppurated and produced the ulcer, which gave rise to the aneurism. That portion of the serous coat which was

denuded of its outer coverings, and formed the common partition between the aneurismal sac and the artery, was greatly thickened, and capable of powerful resistance. The heart was fully three times the ordinary size, and soft in texture. The parietes of the left ventricle were hypertrophied. The coronary arteries resembled those of the brain; they were closely *annulated* with ossific deposit, so as to present the appearance already noticed. They seemed to be detached from their bed, and enveloped in a doubling of serous membrane in the way we have already explained in describing those of the brain; and in like manner was the connecting fold elongated, so as to isolate the vessels, and let them float loose. The lungs, especially those of the right side, which were compressed by the effusion of so large a quantity of blood into the cavity of the pleura, presented a very deep purple colour; and at their posterior surface, as already stated, they were ecchymosed to a very surprising extent. The pulmonary arterial system was in a health condition. The bodies of the vertebræ in the whole length of the spine, more particularly towards the right side, were absorbed in proportion to the duration and degree of pressure to which they had been subject; the sixth, seventh, eighth, and ninth, were most affected, and to a considerable extent,—from which I conclude that the aneurism must have been a length of time in progress. It is only singular that Mr. Mori never at any period complained of symptoms that led his medical attendants (and many from time to time prescribed for him) to apply their ear to his chest. Had they done so, it is more than probable the startling discovery that he laboured under aneurism would have been made.

When he first consulted me, on the 12th instant, the cavity of the posterior mediastinum must have been full of blood, and it was the rupture of the sac into this cavity that occasioned the sudden and subsequent symptoms, resembling, in many respects, an acute rheumatic seizure of the dorsal, lumbar, and intercostal muscles. When I applied my ear to the region of the heart, I found the action of this organ to accord with his pulse, 88, soft, and, as it were, stifled, but I heard no other sound: the fact is, the *bruit de soufflet*, pulsating, and other characteristic pheno-

mena, were then obscured by the immense effusion of blood with which the aneurismal sac was surrounded, and the pressure consequent on the confinement of this within the mediastinal pleura. Indeed, I much doubt whether in a case of this nature the diagnostic phenomena would not at all periods of its progress have been very obscure, complex, and difficult of analysis. No one would have ever imagined that an aneurism would equal in extent the vessel that produced it, especially such an artery as the aorta. The ease and remission of symptoms he experienced on the following day, and which induced him to believe that his complaint was on the decline, were owing to the distended parts having accommodated themselves to the novel circumstances in which they were placed; and the immediate cause of death was the sudden rupture of the mediastinal pleura, so as to admit of a further, and indeed tremendous, effusion of blood into the cavity of the chest, and completely compress the lungs, destroy the balance of the circulation, and thus extinguish life. No other morbid appearances were discovered.

Before closing this memoir, which is replete with novelty and interest both to the physiologist and pathologist, and not less so to the metaphysician, we may be allowed to indulge in a few reflections on the singular facts it presents to consideration. That a man who laboured under such extensive disease in the brain, and who exhibited so many indications of the morbid influence this exerted on the various passions of the mind, should have been capable of displaying so much well-directed energy as Mori always evinced in every thing he undertook, is very remarkable; and the more so when we remember that he was always at issue with his professional brethren, and had their prejudices, opposition, and, in many instances, personal resentment to overcome, before any arrangements could be entered into. Let us remember the admirable manner in which he got up his concerts, the judgment with which the music was selected, and the excellent order which distinguished them, the interest and influence he possessed in controlling an orchestre, and the public approbation and success with which his efforts were always crowned, and we cannot but express our astonishment that such an

individual was himself in reality scarcely accountable for many of his own actions; and let it be borne in mind, moreover, that during a great part of his time he was himself contending with a multitude of conflicting passions, enough, even had his brain been sound, to have induced disease. That being on several occasions seized with paralysis, loss of sight and memory, in consequence of organic disease of the brain, he should again recover the use of the parts and senses affected, is no less remarkable. And when we reflect on the extensive and singular character of the aneurismal sac, and the slender boundary that it placed betwixt life and death for many months, we cannot but shudder at the awful risk he daily ran of being suddenly plunged into eternity in the midst of his most successful undertakings.

VACCINE LYMPH.

To the Editor of the Medical Gazette.

SIR,

As every circumstance connected with the improvement of the practice of vaccination is of importance to our profession and to the public, I trust you will give a place in your journal to the following statement:—

About the middle of February last I received from the National Vaccine Establishment a supply of lymph, in consequence of an application on my part by letter to Dr. Hue, the registrar, in the usual way. About a month afterwards, Dr. Hue wrote to me to request I would report to him the result of this supply. I did so by return of post, informing him that this lymph had proved remarkably active, all the points having taken, and produced in every instance vesicles of unusually large size, with areolæ of greater extent and intensity, and accompanied in most instances with more sympathetic fever than I had been in the habit of witnessing; that I had watched it through eighteen cases, and that two of my neighbours, elderly practitioners in the town, had seen some of the subjects, and declared the vesicles more like the vaccine originally introduced by Dr. Jenner than any they had seen of late years.

Continuing to find successive cases

from the same lymph, exhibiting characters so distinct and peculiar as compared with the vaccine previously in use, I naturally felt desirous of ascertaining from what source the lymph had been derived; and I accordingly wrote to Dr. Hue to ask him if the lymph he had sent me, and concerning which he had afterwards inquired, was Mr. Estlin's, of Bristol. To this inquiry no answer was returned. Not liking to remain in uncertainty upon a point so interesting, I sent a supply of it to Mr. Estlin, with a request that he would be so kind as to try the matter, and let me know what he thought of it. Mr. E. has been so obliging as to comply with my request, and his statement is, that he considers it "excellent lymph," and that "he can hardly say there is any appreciable difference between it and that which he has introduced."

I consider, therefore, that I am now using vaccine lymph recently procured from the cow, and furnished by the National Vaccine Establishment, although not avowed to be so by the Board; and I trust this fact (if so it be) may be taken as evidence that the Board is disposed to reconsider the opinion put forth in their Annual Report, as to the inexpediency of resorting again to the cow, and that they are now disseminating the same active virus as they sent to me throughout the kingdom.

Should, however, any of your readers feel dissatisfied with the virus they receive from the National Vaccine Establishment (to which the profession and the public are entitled to look up for every aid in attempts to perfect the process of vaccination), I shall be happy to furnish them with a supply as promptly as my limited opportunities will admit, on application made to me free of expense.—I am, sir,

Your obedient servant,

N. ADAMS.

Lymington, June 29, 1839.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abrégé."—D'ALEMBERT.

Medical Notes and Reflections. By HENRY HOLLAND, M.D. F.R.S., &c. London, 1839. 8vo. pp. 628.

THE work before us is divided into thirty-five chapters, on the following

subjects:— On medical evidence; on hereditary disease; bleeding in affections of the brain; sudorific medicines; effects of mental attention on bodily organs; on points where a patient may judge for himself; on the connection of certain diseases; on the abuse of purgative medicines; on methods of prescription; on gout, and the use of colchicum; on some supposed diseases of the spine; on the brain as a double organ; on some points in the pathology of the colon; the epidemic influenzas of late years; dreaming, insanity, intoxication, &c.; mercurial medicines; the exercise of respiration; method of inquiry as to contagion; the medical treatment of old age; the use of emetics; the uses of diluents; morbid actions of intermittent kind; diet and disorders of digestion; on diseases commonly occurring but once in life; on the present questions regarding vaccination; the use of opiates; sleep; the influence of weather in relation to disease; time as an element in mental functions; phrenology; on disturbed balance of circulation, and metastasis of disease; the use of digitalis; antimonial medicines; the hypothesis of insect life as a cause of disease? the present state of inquiry into the nervous system.

Without pretending to abridge so large a volume, or to give an analysis of Dr. Holland's opinions on so many subjects, we will just mention a few of the most prominent points.

The following passage, in the chapter on hereditary disease, is very interesting:—

“An instance is known to me of hydrocele occurring in three out of four successive generations, in one family—the omission adding to the singularity of the fact, from its depending on a female being the third in the series, in whose son the complaint re-appeared. I am acquainted with a family in which there are three examples, the father and two children, of inability to distinguish red as a colour. Another example, resembling the last, is known to me, where three brothers, and two or three children of their families, have the inability to distinguish between blue and pink. Instances of this kind as an hereditary defect are far from infrequent. I have known squinting to occur in every one of five children, where both parents had this defect. The repetition of cases

of deaf and dumb children in the same family is well known to those who are concerned in institutions for the relief of this congenital defect. An example has recently occurred to me of that remarkable affection, the *suffusio dimidians*, existing in a father and his daughter; and brought on in each by circumstances singularly alike. In another family I have seen several instances of the peculiar tremor tendinum of the hands and arms, which is sometimes called the shaking palsy; and which here occurred in young persons of sixteen or eighteen, as well as in those more advanced in life. In this case, too, I had proof of the peculiarity having gone through at least three generations. Similarity in the form and setting of the teeth, as well as in the colour of the hair, is often observed between parents and children: and left-handedness, from whatever this proceeds, sometimes takes the character of a family peculiarity. In a family where the father had a singular elongation of the upper eyelid, seven or eight children were born with the same deformity, two or three other children having it not. In like manner I have seen enlarged tonsils occurring in almost every individual of a numerous family, without other cause by which to explain it.

“Enuresis in children, from whatever source arising, occurs sometimes in so many individuals of the same family, as to make it almost certain that it has a common congenital origin. What is not less remarkable, as an instance of similar specialty, emphysema of the lungs has been ascertained to depend in the majority of cases on hereditary influence, independently of any disposition to tubercular pulmonary disease. Another instance, which may be termed special, though belonging to a part of structure diffused over the whole body, is the hæmorrhagic diathesis. Though I do not find in my notes any well-marked examples of its hereditary nature, except where confined to the lungs and connected with phthisical constitution, yet some are recorded so explicit as scarcely to leave the fact in doubt; and remarkable further, from the seeming limitation of these instances to the male sex. Nor is there, indeed, greater difficulty of comprehension here, than where a more limited portion of structure is concerned. The points of question are the same in each case; and the solution, if ever obtained, must be com-

mon to both. I might add to these many similar instances; but they are too familiar to require further recital. It will be remarked, that all are perfectly congruous with, and in no respect more wonderful than the common transmission from parent to offspring of external features, in the peculiarities of which no diseased action is involved.

"There are some examples of abnormal structure or disease, which, though frequently occurring in detached instances, yet are so especially numerous in certain localities, as to give suspicion, in the absence of other sufficient causes, that hereditary tendency is much concerned. Such is the goitre of particular districts, no consistent explanation of which has yet been given, founded on local circumstances of climate or mode of life. The *Plica polonica* is another instance to the same effect. I might apply the same remark, though with greater doubt, to that curious affection, the *Trismus nascentium*, prevalent in particular localities, and these widely different in all physical circumstances. The great frequency of stone in the bladder, in certain districts where there is no obvious peculiarity of air, food, or water, as a probable cause; and the common tendency to lithic acid deposits in the same family, may admit of like explanation. And this is further sanctioned by the certain connection of the calculus with the gouty diathesis."—Pp. 20—22.

In his remarks on bleeding in affections of the brain, Dr. Holland's censures of the custom of indiscriminate venesection in paralysis and other cerebral diseases are very judicious. In delirium tremens, he says, the treatment is seldom mistaken; but in many similar, though less distinct states, the mischief done by large bleedings is sometimes irreparable. The whole of this chapter is worth not only reading but studying.

In the chapter on the "effects of mental attention on bodily organs," there are some curious and useful observations on the effects produced on the bodily organs by the direction of consciousness to them. Thus swallowing is made more difficult by the attention being fixed upon it; and in the same way a sense of weight and oppression may be produced at the stomach; and palpitation of the heart, or hurried or choked respiration, may be brought on in the same manner. Dr. Holland

thinks, with great justice, that the symptoms produced by the infinitesimal doses of the homœopathsists admit of this explanation.

"An example occurs to me at this moment, where the expectation of any strong pressure of the hand instantly creates uneasiness, approaching to pain, in the perinæum; this effect in greater degree invariably following actual pressure."—P. 70, note.

The next chapter, "on points where a patient may judge for himself," is very good; but as we lately discussed it in our leading article*, we shall of course pass over it now.

The same may be said of the seventh chapter, "on the abuse of purgative medicines," which was the subject of editorial comment in an earlier number†.

At the end of his observations "on methods of prescription," our author seems apprehensive that the remarks will be thought either too familiar, or too much *ex cathedrâ*. We do not feel inclined ourselves to make either of these objections; for plain remarks on plain things are much wanted in these days; nor is there any tone in them that reminds us of the professorial chair; though, if there were, would this be blameable in a physician of our author's standing and station? The fault we should find with these observations is, that they are by far too short; the chapter consists of only six pages, and of these but three are strictly devoted to methods of prescription. The same objection may be made to several other chapters: for example, the one "on some supposed diseases of the spine." An essay of six pages on such a subject is too tantalizing.

Epidemic influenza is now so frequent a visitor, that we make no apology for giving at some length the opinions of our author concerning its treatment:—

"A question, however, may be raised regarding the influenza, whether the disorder does not admit of being stopped in the outset; and common opinion, founded on cases where the symptoms speedily subside after their first appearance, leans towards this belief. The proof, however, is ambiguous, seeing the variations which may arise from dif-

* MED. GAZ. May 25, 1839.

† Ibid. April 20, 1839.

ferent states of the virus or temperament of the patient; and the frequency of such cases occurring under different remedies, or where none whatsoever have been employed. If I were from my own observation to name any remedy, having some pretension to the effect, it would be an active emetic in the earliest stage of the symptoms; but, for the reason just given, I am far from thinking this an assured fact.

"Whether so or not, vomiting is, I believe, the best means we can employ at the commencement of the disease, as well as under different conditions of its progress. That it should have been so insufficiently used, in the treatment of the influenza in this country, must be attributed to the same causes which have made the employment of emetics comparatively so infrequent in modern practice. In clearing the mucous lining both of the air passages and stomach from the secretions which load them, no remedy is of equal avail; and none safer in its application, or more immediately attesting the good that has been obtained.

"The employment of purgatives in influenza is probably best regulated by the principles which direct their use in the exanthematous fevers. Frequent and violent action of this kind I believe to be useless, or positively injurious, in the disorder; having no specific influence as a remedy, and tending to increase irritation and depress the general powers. This is probably equally true when the pneumonic symptoms are most severe, and where the virus affects chiefly the membranes of the alimentary canal. The cough which is so peculiarly characteristic of the disorder, whether proceeding from either or both these sources, is often manifestly increased by the irritation thus given; while the bowels, under excess of this practice, readily become tympanitic, and more fretful and disordered in their actions.

"These comments of course do not apply to a better regulated use of the remedy. The proper use of purgatives in influenza seems to be to clear the bowels thoroughly in the outset; and subsequently, by such as are simple and least irritating, to prevent accumulation or disordered secretions. Nor does this view exclude the employment of mercurials to correct and maintain these secretions in healthy state. How-

ever it may be at the beginning, the liver usually gets gorged, and its functions disturbed, in the progress of the malady; and this is true even in many of those slighter cases, where the patient, though for weeks perhaps under the influence of a morbid cause, is never actually withdrawn from his ordinary occupations. To relieve this state, mercurials are the speediest remedy; and often more effectual, generally less irritating, when uncombined with other cathartics. So employed, with the intervention of stronger doses occasionally, calomel and blue pill act most beneficially, not simply in relieving present symptoms, but in preventing many of the most distressing sequelæ of the disease. And this is an effect which, in my experience, is by no means equally produced by mere purgatives frequently or harshly employed.

"I have never known any certain benefit from the treatment of influenza by sudorific medicines. Ambiguous in use in other cases, they are still less called for in a disorder of which continued and copious perspiration is one of the most frequent symptoms. If antimonials are of any avail here, it is not, I believe, under this view, or even as a common febrifuge, but solely as one means among others of exciting vomiting, where this is desirable.

"The same opinion may be fairly given as to the whole class of expectorants. I never saw any good obtained from them in the influenza, unless when unintentionally they have acted more or less as emetics. The act of vomiting is in truth the most effectual expectorant in most cases where this action is urgently required.

"It seems necessary to add opium to the list of medicines, from which little certain benefit is to be had in this disorder. The restlessness at night, which is so general a symptom, would seem to require its use; but from some cause or other it is rarely effectual in giving much relief: and, though the cough may for a while be mitigated or suppressed by this remedy, it is doubtful whether the good so obtained is an equivalent to the disadvantages in various ways incurred."—*Pp.* 206-208.

We are rather sorry to find encouragement by such high authority to the habit of giving mercurials on slight occasions, a point which is the opprobrium of British practice; nor do we see

that the spontaneous perspirations which often occur in the disease are any strong objection to the use of antimonials.

Bleeding, he adds, is generally bad; when much doubt exists as to its propriety, blisters may be tried first, and the epigastrium is commonly the best place for their application. Stimulants are often useful, the pulse being generally a faithful guide to their administration. The majority of cases require rather the forbearance of the physician than active remedies.

"The only other remark I have to offer regards the use of bark, or the sulphate of quina, in the influenza. Its value here is unquestionable; derived not simply from its quality as a tonic, but further, and more especially, from its specific power in various intermittent affections. Any inference that might be drawn as to its use, from the tendency in the disorder to these intermittent actions, is fully justified by the actual effects. It relieves them, when fully established, almost as speedily and certainly as the attacks of a common ague; and this whatever the part of the body so affected. This remarkable power over one of the conditions of the disease gives so far a specific character to the remedy, that it may rightly be adopted in prevention of a state which it is capable of curing. It is not easy to define an exact time at which its use should be begun; this must vary in different temperaments, and in different degrees of the disorder. But it is an inference, from the reasons already stated, that quinine may be given safely and beneficially in many cases where there is still hard cough, with pain, oppression, and restlessness; and experience confirms this conclusion. A soft feeble pulse, and moist skin, often concur with these symptoms, and furnish additional authority for the practice. If the cough itself, as frequently happens, tends to intermittent character, the security of the remedy becomes greater, and its effects more speedy."—Pp. 210, 211.

We must content ourselves with half a dozen more short extracts:—

"Hæmatemesis, however large in amount, rarely needs any active control. It expresses more distinctly, perhaps, than any other hæmorrhage, the need of the relief which it actually affords to a part of the circulation; and I believe more injury than good to be

done by the means often used to check it. The same remark will apply to hæmaturia; with some qualification for cases where it originates in calculi, or disease of the kidney."—P. 280.

"The value of emetics in the treatment of *Cynanche tonsillaris*, though understood as matter of medical precept, is not equally regarded in practice. Nor, indeed, as a general fact, do we sufficiently keep in view the close relation between the several parts of the internal fauces, and the membranes of the œsophagus and stomach; and the frequent and singular translations of morbid action which take place along this continuity of surface. Many more exact interpretations of disease might be derived from looking to this connection through the medium of contiguous structure and function, than from that minute nomenclature which is formed upon the mere locality of symptoms; and the indications of treatment would in the same proportion become more exact, as in the use of emetics under the circumstances to which I am now referring.

"The liver, and the whole system of the portal circulation, are singularly under the beneficial influence of this remedy. Congestion, so prone to occur in this part of the body at the commencement of most fevers, as well as in other diseases, is lessened or removed by vomiting,—the passage of bile into the bowels rendered more free,—other secretions promoted or restored,—purging often obtained without further aid,—and a general state of all these viscera induced, peculiarly tending to lessen febrile action, and especially in those cases where it arises directly from gastric disorder.

"In most of the slighter cases of jaundice with which we have to deal, emetics will be found much more capable of speedily restoring the passage of bile into the bowel than any other means; and the instances are numerous (including particularly those fevers of warm climates, which, however variously designated, have all such close relation to the functions of the liver and the circulation through the chylopoietic viscera) where the direct combination of an active emetic and purgative medicine in the outset of disease, with repetition of the same means when needful, has effect in subduing the violence of disorder beyond any other remedy. This com-

bination is not sufficiently employed in ordinary practice, in the many cases where speedy disgorgement is required of the part of the system just referred to."—Pp. 291, 292.

"The ancients, as is well known, employed friction under a more general conception of its use than we do; not merely as a remedy for feebleness or swelling of limbs, but as altering the condition of the whole body. And, without adopting all they have affirmed on this subject, it is certain that its employment, even in our climate, might be beneficially extended in a variety of cases; in none more than those of enfeebled or disordered digestion. So applied, it affords another example of the many important relations subsisting between the external and internal surfaces of the body.

"Of the use of anointing, as practised by the ancients, we know from experience much less. Some explanation of its employment in tropical climates may be found in the protection it gives against the direct effects of solar heat on the skin. There is reason, as well as scope, for making larger trials of it as a curative means, even in disorders of the alimentary canal. The harsh dry skin of the dyspeptic patient might be improved in its texture and functions by rubbing with warm oils, &c., where wholly unaffected by internal remedies given for the same object. In one or two cases, I have had cause to infer that much benefit was obtained by this method; but, like most other external means, it would require more time and perseverance than the temper of the dyspeptic will often concede to such remedies."—P. 366, note.

"To some of my readers the instance may be known of a late physician, eminent for his learning, who underwent the scarlet fever three times; probably from some peculiarity of habit in reference to the disease."—P. 388, note.

"In speaking of the effects of coffee on the nervous system, I may mention a statement I have heard from one or two West Indians, that the aroma of this berry, strongly concentrated and long applied, is capable of producing delirium, or some degree of aberration of mind. This account I first received in a case of a young man, a native of St. Domingo, who arrived in this country in a state approaching to mania, and died soon afterwards. His illness was

attributed by a friend who accompanied him (and who assured me he had known similar cases), to his having slept during the voyage in a cabin half filled with bags of coffee. I have had no means of ascertaining the truth of this opinion, which, in fact, was disproved in the case in question, by cerebral disease actually discovered, and presumably of a date anterior to the voyage.

"The influence of coffee and tea, in relation to sleep, seems to depend upon some similar cause in each case, whatever this may be. Even the peculiar sensation about the præcordia (the effect, it is to be supposed, of the state induced on the coats of the stomach) is very much alike in both cases. This sensation, familiar to persons who are thus affected, often continues for six or eight hours, and bears proportion apparently to the influence of those liquids in preventing sleep. It is certain, and easily to be understood, that all such effects are much more modified (increased, perhaps, as well as lessened) by conjunction with other articles of food, and especially with wine."—Pp. 444, 445, note.

"Dr. Stokes, in his work on Diseases of the Chest, remarks that the previous use of tartar emetic in pneumonia seems to facilitate the further action of mercury in subduing the inflammation. He advises that in typhoid pneumonia the mercurial treatment should be pursued in preference to that by antimonials. What I have seen would lead me to concur in both these points of practice."—P. 554, note.

Our author says in his note, at p. 595, that the German physiologists have availed themselves of the richness of their language in describing the principle of organization, and that "no other modern language could furnish such phrases as '*die bewusstlos wirkende zweckmässige Thätigkeit*,'—'*die nach vernünftigen Gesetzen wirkende organisirende Kraft*,' &c., which we find in the writings of Müller."

Nevertheless, if put to our mettle, we would endeavour to translate these phrases by "the activity which unconsciously works to its end"—and—"the organizing force which works according to rational laws." If this does not satisfy our author, we hope he will at least say of the translator, *magis tamen excidit ausis!*

In conclusion, we thank Dr. Holland

for the useful hints and instructions which so frequently occur in this volume—a volume which could only have proceeded from one who was a reflecting as well as an active practitioner—from one who knew how essential it was to add to his own experience, that of the generations which had preceded him.

MEDICAL GAZETTE.

Saturday, July 6, 1839.

"*Licet omnibus, licet etiam nihl, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*"

CICERO.

THE LATE MEDICAL ELECTIONS.

JUDGING by the numerous places that have been vacant in our hospitals and other institutions during the last month, and the numerous competitors that have started for each, one might imagine the medical profession to be in a very prosperous state. There have been, we believe, no less than sixteen places to dispose of, and upwards of ninety candidates for them*; and in almost every instance the contest has been fought with the energy of an engagement on whose result the whole fame or the life of the combatants depended. But, unfortunately, this anxiety for success is no evidence of the real value of the object pursued; every one would strive for the mastery in any thing, however trifling; on the same principle on which a game of chess has often caused as much individual excitement as a battle of Waterloo. But in this case, we fear that the number of candidates was only the result of the great number of the profes-

sion who are unemployed, or insufficiently remunerated, and that the eagerness of their canvassing was (as far as they are concerned) only an indication of the urgent need which each feels to increase his reputation and his income, by any means, however feeble or remote.

Many of the offices which have lately become vacant are entirely gratuitous, and many more are only remotely profitable through the uncertain reputation which they may bring by placing their possessor on a higher elevation, where he may be more distinctly and more conspicuously seen than he can be in his own consulting-room—an advantage which, however brightly it may shine in the eyes of the hopeful aspirant, is obscure and scarcely perceptible to the possessor.

The most novel feature, however, of the last month, has been the offering up to competition some places with salaries—Examinerships at the London University, with the promise of actual and permanent life annuities, contingent only on the success of the establishment. The thing was so new in medicine, that, as if to show their approbation of such unexpected liberality, sixty candidates, all men of some renown, started for nine places, averaging less than 200*l.* a year each.

If we could feel certain that party had no influence in obtaining this boon from the government, we should hail it as a omen of better days approaching for the profession—days in which it will be placed, in this respect at least, upon a level with the law; when there will be as many paid medical inspectors and examiners as there are now commissioners and revisers—"barristers of five years' standing." Medicine needs these auxiliaries even more than law, because no public measure can possibly afford it so much benefit as the law obtains from every new act of parliament. It was calculated,

| | Places. | Candidates. |
|--|---------|-------------|
| * London Hospital | 1 . . . | 4 |
| St. George's Hospital | 2 . . . | 6 |
| Charing-Cross Hospital | 1 . . . | 4 |
| Children's Infirmary | 1 . . . | 3 |
| St. James's Dispensary | 1 . . . | 2 at least. |
| Argus Life Office | 1 . . . | 15 |
| University Medical Examiners | 9 . . . | 60 |
| | <hr/> | <hr/> |
| | 16 | 94 |

for example, that the passing of the Reform Bill alone, added an annual half million to the general legal expenditure of the public, and the Municipal and Poor-law Bills have probably added not much less to it. Alas! when will some such benignant but productive annual epidemic fall to our profit? What an advantage have they who feed upon the disturbed and unruly tempers of men, and who are paid for keeping up the irritation, and so perpetuating their own profit, over those who subsist by disordered bodies, in soothing which they do but dry up their own emolument.

But for the late elections: the smallness of the stake has been no measure of the ardour of the contest; and in some cases it has been fought with a total disregard of convenience, expenditure, and, we had almost said, of decency. Not a scheme has been omitted, nor an inducement lost sight of, that might bring voters to the poll; and the whole transaction has assumed the characters rather of a borough election, between two mob-orators, than of a calm and judicious decision upon the fairly stated claims of two gentlemen of a scientific profession. This has been especially the case at the London Hospital; and it is impossible not to lament the extravagances into which each of the candidates has there suffered himself to be urged by the other, in their contest. Every feeling has been interested; politics and religion have each been brought forward to obtain their supporters; and personal invective and lavish praise have been publicly advertised and profusely thrown about on both sides. No expense has been spared; that of the advertisements alone amounting, we are told, to from fifteen to twenty guineas each daily, would be sufficient to deter any person of moderate means or prudence from engag-

ing in such a contest, without mentioning the cost of Parliamentary and other agents, feedings, carriages, and numberless sundries, to which none but those who are anxious to be legislators, have hitherto ventured to expose themselves.

We are sure we speak the opinion of every calm looker-on (and probably that of the candidates themselves by this time), when we say that such a transaction as this election is extremely derogatory to the profession to which we all belong. In the raising up of other pleas for support, the professional character has been lowered, and even entirely forgotten, and a precedent has been set up, which, if followed, would compel medical men henceforth to obtain their places, by the same means as they might a borough from a noisy mob, or from an influential patron. We do not know if Governors of Hospitals equally feel any interest in the selection of their medical officers; but if they do, they may be assured that the permitting or taking part in such elections as these, is the most certain mode that they could adopt to insure the exclusion of all who are most fit to serve them; for no man previously possessed of any good reputation would voluntarily enter upon a contest in which there was any prospect of his being exposed to such annoyances as must have resulted from this.

At the London Hospital the merits of the candidates probably scarcely came into consideration; opposite parties and families had long quarrelled on other general topics, and they made the present choice of a physician the pretext for a trial of their strength. This mode of election often happens; the chief Governors of an hospital, not content with the difficulty which they would find in fairly deciding on the merits of candidates, clear themselves of the trouble by

taking the occasion of an election to settle their own old scores, and the candidate, who, by good luck, is made the stalking-horse of the strongest party is sure of his election, without either his friends or his enemies ever troubling him for his qualifications.

In another place—the Charing Cross Hospital, a fault of another kind has existed. In an Address to the Governors, which the unsuccessful candidate has published, he very plainly, and no doubt truly, charges his defeat to the overwhelming influence of the Director, Dr. Golding. This is one of the most extraordinary documents, connected with elections, which it has ever fallen to our lot to peruse, and clearly demonstrates the utter hopelessness of any candidate succeeding who has not the patronage of the Director. This gentleman not only has a vote himself, but his wife and *four children, under fifteen years of age*, enjoy the same privilege; two of the latter having been invested with their rights on the day of election, and while the ballot was proceeding*!! Under the circumstances detailed by Mr. Palmer, the only wonder is that he obtained so many votes; and if his published statement induces the Go-

vernors of Charing Cross Hospital to look into its management, and reform what is amiss, he will have done the institution much service.

At the same time, with all its real or supposed abuses, a monarchy like that which reigns at the Charing Cross is not worse than the republican anarchy which disturbs the London Hospital. The one is at least generally quiet; but it is scarcely possible that any thing but evil should result from the confusion and discordance which arise in the members of headless and conflicting parties on the splitting of every straw, and who totally neglect merit while they are endeavouring to decide their own quarrels.

On the whole, the recent elections, and the various circumstances which have transpired in the course of them, afford but a bad specimen of the mode in which some of our boasted charitable institutions are governed. But the evil affects those engaged more than it does the objects of the charity, who, amidst all the turmoils and uproar of their benefactors, are tranquil and comfortable, often living and feeding in peace on the very quarrels of those whose charity they receive. Probably the very evils of some of these plans are the source of blessings to the patients. We have lately read with much interest a report on the administration of Hospitals in Paris (the direction of which, as most of our readers know, is in the hands of the government); we shall probably consider some of its details on an early occasion, with a view of comparing that system with our own, and of shewing that, though in many respects the English management is open to objection on professional grounds, yet its faults towards the objects of its care are as nothing in comparison with those which are flagrantly prevalent in France.

* The following is an analytical representation of the poll, as collected from Mr. Palmer's remarks:—

| Minority..... | 81 |
| Votes which were disallowed | 3 |

DEATH FROM PUMPING AIR INTO THE EUSTACHIAN TUBE.

AN inquest was held on the 26th and 28th ult., before Mr. Wakley, at the Plough, Museum Street, on the body of Joseph Hall, aged 18. He died, while undergoing an operation, on Saturday, the 22d of June, for the relief of deafness, at the house of Dr. Turnbull, in Russell Square. The operation consisted in pumping air through the nostrils into the Eustachian tube; it was repeated four times on the deceased, and on the tube of the instrument being taken from his nostril the fourth time, he fell back in the chair, and never spoke afterwards. Charles Spadbrow, the witness, had had the operation performed on himself four times at a sitting. It produced a swimming in the head, and a portion of the air appeared to escape by the mouth, and the rest down the throat.

Three medical witnesses were examined: Mr. James Reid, Mr. Savage, and Mr. Liston. Their evidence is given, as follows, in the *Times* of July 1st:—

Mr. James Reid deposed, "that he found a thin layer of blood on the left side of the membrane of the brain, and globules of air under it, and in the small veins of the brain; that the left tympanum, or internal ear, had its lining membrane swollen, of red appearance, and there was a slight effusion of blood in it. From the known plethoric habit of the deceased, and from the fact of his having exerted himself at filling the air-pump before he was operated upon, he should say the cause of his death was apoplexy.

"Mr. Savage, lecturer on anatomy to Westminster Hospital, was next examined, and differed from the last witness, and stated that there was extravasated blood on both sides of the membrane, and that the tympanum of the right ear was affected as well as the left. He did not consider that deceased died of apoplexy, but that the injection of cold air through the Eustachian tubes was the primary cause of deceased's death. He knew that the instrument used by Dr. Turnbull would be affected by this opinion, but he did not think the operator in the case at all to blame, as he could not be aware of the nervous susceptibility of the patient.

"Mr. Liston, surgeon to University

College Hospital, stated that he was present at the post-mortem examination, at the request of the coroner, and the probability was that the deceased died in a continued fainting fit. He could not easily disconnect the forcible injection of cold air into the tympanum from the effect that followed it. In the region of the tympanum were a number of small nerves connected with the most important one of the body, which, receiving an impression, would cause spasms, or other fatal affections of the heart. Nothing precisely satisfactory could be come to, on account of the decomposed state of the body."

The verdict was, "Accidental death," with a caution to Dr. Turnbull never again to intrust the instrument in unprofessional hands; Mr. Lyon, his assistant, who operated on Hall, not being, we suppose, a medical practitioner.

This case is so exceedingly interesting, that we hope the medical witnesses will publish their opinions in a more trustworthy form. If we understand the evidence, it is clear that Hall's death was the direct effect of the operation. Somebody who professes to cure deafness by catheterizing the Eustachian tube has taken this opportunity of praising himself up to the skies; but we would suggest to him in a quiet, friendly way, that as good wine needs no bush, so a really good operation needs no puffing; that Dr. Kramer, of Berlin, does not owe his reputation to advertisements; and that a man who trusts to these fleeting harbingers of fame is evidently destitute of the *fiduciam magnarum rerum*—the true stamp of genius and reputation.

To the Editor of the Medical Gazette.

SIR,

Two deaths having taken place within a few days, the consequence of operations performed upon the ear, I beg leave to offer a word or two to those paying attention to diseases of the ear.

Firstly.—Under no circumstance ought the tube from the air-condenser to be accurately fitted to the catheter, one extremity of which is placed in the orifice of the Eustachian tube; but, as has been forcibly pointed out by the reviewer in the current number of the British and Foreign Medical Review, p. 95, the "nozzle of the tube of the air-press should be held during the operation so loosely in the dilated end of the catheter that there may

be room for air to regurgitate." By adopting this plan, although I have operated on my own ears many dozens of times, and upon patients many hundreds, I have never even produced emphysema, or any pain in the ear.

Secondly.—The condensed air must not be allowed to rush into the cavity of the tympanum in the form of "charges," but in a gentle and continued stream. Any one thinking of the peculiar and powerful effect produced in the ear, and over the whole of the head, during, and for some moments after, the distension of the cavity of the tympanum by a forcible expiration with closed nostrils, can well imagine the result of a "charge" from a powerful air compressor.

Thirdly.—No one ought to undertake the performance of the operation who has not attained considerable dexterity and tact by the passage of instruments on the dead subject.—I am, sir,

Your obedient servant,
J. T.

July 2, 1833.

CLINICAL LECTURES

ON

OSTEITIS OF THE UPPER THIRD OF THE
FEMUR, SIMULATING HIP-JOINT DIS-
EASE,

*Delivered, during the Session of 1839, in
St. Vincent's Hospital,*

By J. M. FERRALL, ESQ. M.R.I.A.
First Surgeon to the Hospital.

*Chronic or mild form of osteitis.—Diagnosis.—
Other diseases: Osteo-sarcoma; cancer;
and fungoid disease.—Analogous changes in
lower third of femur.—Osteitis and periostitis
confined to trochanter.—Treatment, general
and local.*

GENTLEMEN,—The chronic form of this disease, like that to which I have already directed your attention, is liable to be mistaken for morbus coxæ, and therefore deserves your serious consideration; but, as the mode by which they are to be distinguished is, in many respects, similar to that which we have applied to the study of the acute species, it will be unnecessary to consider the symptoms in detail.

The term chronic, as employed in describing the diseases of the osseous system, is not sufficiently precise. A case may be slow in its progress, and yet be accompanied by local and constitutional disturbance, of a nature which, in any other disease, would be thought sufficiently urgent to be termed acute. The situation of the morbid action will greatly influence

the character of the phenomena in this respect. Inflammation of the periosteum or surface of a bone, if intense, will pass through its stages with comparative rapidity, and hypertrophy, suppuration, or death of the bone, will be speedily manifested by their accustomed signs. But the same degree of inflammatory action, commencing in the cellular tissue of the central portions of the bone, will display its effects more tardily, though perhaps not less severely as regards the suffering of the individual or the effects on his general frame. Both may be attacks of acute inflammation, the difference in their course being attributable to its situation alone. On the other hand, a case may present itself of so mild a character, that, even in superficial parts of the bone, the steps of the morbid process are slow and productive of little suffering, except as they interfere with the free use of the limb. A better division, perhaps, would be into the severe and the mild forms of the disease; for severe cases may be either rapid or slow in their progress, while the mild cases are uniformly slow.

The mild, or, in the language of the schools, the chronic form of osteitis, is developed in a manner so gradual and insidious, as in a great measure to elude observation in its early stage; at least I suppose this to be generally the case, for I have not seen any instance of the complaint which could not be traced to a period considerably anterior to the time of application for relief. The pain, generally occurring at night, has been so rarely felt, and has been so slight, as to interfere little with the natural rest. The lameness, after some time, becomes greater in proportion to the pain than in the ordinary forms of hip-joint disease, resembling, in this respect, the history of scrofulous enlargement of the ends of bones, so well described by Sir B. Brodie. It is not easy to rely upon the answers elicited from patients by leading questions; but as far as we can do so, it appears that the pain is referred to the bone itself in the early period, and afterwards, when some degree of enlargement of the part and thickening of its periosteum is perceptible, the uneasiness is complained of in one or other of the distant points already named. When matters are in this state, the marks I have already mentioned are those which will generally enable you to diagnose the complaint.

But suppose the diagnosis to be satisfactorily established, may you now venture to pronounce it a case of simple osteitis, or periostitis, of the upper third of the femur?—certainly not. There yet remains a question, which, in the acute form, needs no consideration—namely, the discrimina-

tion of this affection from malignant diseases in the same situation. This distinction is the more difficult because the same absence of constitutional disturbance, as well as local distress, may belong to both in the beginning. In Sir A. Cooper's valuable essay on Exostosis, we find cases of fungoid as well as simple cartilaginous exostosis, in which there was no pain in the commencement, nor until the swelling was discovered. I have myself seen more than one case of osteo-sarcoma of the thigh-bone, where the weight and bulk of the tumor, although of considerable size, were for a long time the principal inconvenience. On the other hand, Baron Boyer states that osteo-sarcoma is always announced by deep-seated pains, and that at length swelling takes place. Notwithstanding his authority, I think you may, from what I have already stated, conclude that many cases occur in which the early stage is unaccompanied by pain. Your diagnosis, therefore, should be guarded, even though the patient's health may be good, and he may suffer little beyond the lameness, which is always present when this portion of the femur is affected.

The upper-third of the femur may be the seat of the various forms of malignant disease to which the osseous system is liable—osteosarcoma, cancer, and encephaloid disease. Sir B. Brodie gives a case of large tumor at the hip, in which, on examination after death, the joint proved to be healthy, and the disease was osteosarcoma growing from the periosteum of the upper end of the femur. There is a preparation in the pathological museum of the Royal College of Surgeons, presenting a well-marked specimen of cancer, in the form of a large tumor occupying three or four inches of the upper end of the thigh-bone. The centre of this mass exhibits a transverse fracture which occurred without any local injury, and from some slight movement of the patient. It is an instance of what is termed spontaneous fracture of a cancerous bone. Mr. Cusack, who presented the preparation to the College, was so obliging as to inform me that the patient, a woman rather beyond the middle age, had had a cancerous breast amputated several months before, and that the disease had returned, involving the lung of the same side. She was in this hopeless state when the thigh-bone unexpectedly gave way. In the eighth and tenth volumes of the *Medico-Chirurgical Transactions* you will find ingenious essays, by Mr. Howship, on the minute structure of diseased bones, which will repay you for the perusal. In the latter volume he gives a case from Petit:—"An old woman, with cancer of her breast, was seized with a tumor in her left thigh; the bone was swelled quite

round. It was after a time accompanied by sharp shooting pains. The bone broke in turning in bed. Another formed in her arm and clavicle, both of which broke in the same way." On this case Mr. Howship remarks, "Now, although in the above account the disease is termed exostosis, its history seems to be clearly that of spina ventosa."

I cannot help expressing my surprise that a gentleman who has so successfully studied the pathology of bone should consider the history of this case as "clearly that of spina ventosa." This is the more extraordinary, since Mr. Howship describes spina ventosa to be an expansion of the osseous tissue, the cells of which contain only the natural secretions of the part in the early stage, thus clearly separating it from malignant diseases, in which the presence of a new deposit is the essential change. The leading features of Petit's case—cancer of the breast—tumor of the femur—shooting pains—spontaneous fracture—other tumors on the arm and clavicle, and spontaneous fracture of both—cannot fail to suggest the history of carcinoma.

In the third fasciculus of the article "Carcinoma," in Dr. Carswell's splendid work on the elementary forms of disease, you see a fine plate of fungoid disease of the upper third of the femur. The tumor engages the bone internally as well as outside, and presents the lardaceous tissue in the medullary canal; the cartilaginous and osseous growth outside, close to the bone; and further forward, towards the soft parts, the brain-like structure. Dr. Carswell includes the different forms of encephaloid and schirrous growths under the general term carcinoma—an opinion in which you are aware I entirely coincide, as I have on several occasions demonstrated to you the coexistence of these varieties in one and the same tumor. He gives another plate of spontaneous fracture through the upper third of the thigh-bone, which had undergone the cancerous degeneration. In his learned article on the "Pathology of Bone," in the *Cyclopædia of Anatomy*, Mr. Porter seems to doubt that the osseous tissue is ever affected originally by cancer. If further proof were required, the series of preparations exhibited by Mr. Smith to the Pathological Society of Dublin*, and shewing the cancerous deposit in the interior of almost all the bones in the body of the same individual, would be sufficient to set this matter at rest.

You can easily understand that, in distinguishing these different diseases of the bones from each other, when situated near

* Dublin Journal, March 1839.

the hip-joint, as well as any of them from affections of the joint itself, more difficulty will be experienced than is likely to occur in the neighbourhood of other joints more exposed to view. The knee joint, one would suppose, could present little obscurity to a careful observer; and yet, I can assure you, that much embarrassment may exist in practice even here. Some years ago I saw, in consultation with Dr. Colles, a young lady affected with true fungoid disease of the lower third of the femur, which for some time had simulated white swelling, until the ham became more than usually full, and a fungous growth was palpable in that space. The limb was amputated, but the disease returned in the stump, and she sank exhausted by protracted suffering and repeated hæmorrhages from the fungous surface. There was an encephaloid tumour in the groin, about the size of a small egg. A section of the bone, which I now show you, displays the medullary canal filled for some distance upwards with lardaceous substance—the shell of the bone softened in several places, and converted into a structure like softened cartilage, and in two or three spots altogether removed by the protrusion outwards of the growth, which assumes more of the fungoid character as it approaches the surface. Not long after this occurrence I saw a young woman labouring under what was considered to be fungoid disease of the lower end of the femur, but which eventually proved to be osteitis, ending in necrosis, with the usual process of reparation. Dr. Colles also saw and took a good deal of interest in this case. If such difficulty is experienced when the two bones composing the articulation are superficial, and easily compared with each other, and with those of the opposite limb, you need not be surprised that mistakes with regard to the deep seated and obscure disease which I have described should have hitherto occurred.

As instances of periostitis of the lower third of the femur, you will remember my directing your attention to the cases of Mary Campbell and Eliza Nocher, in Mary's ward, and Margaret Kelly, in Joseph's ward. In the two former the disease yielded in a great degree to mercury, followed by iodine frictions, leaving, however, some thickening of the bone or its coverings. In Margaret Kelly's case supuration took place, the abscess was freely opened, and she left the hospital when it had perfectly healed. She has since, as you know, returned after a lapse of three months, with another large collection of matter on the outside of the limb, and has again returned home, the part being perfectly healed. On neither occasion could

the probe reach the bone, on account of the circuitous route which the matter took to reach the surface; and as both openings healed, it is still doubtful whether the solid swelling which remains is formed by the necrotic process or periosteal exostosis.

Inflammation, generally the result of local injury, may attack the great trochanter alone, and give rise to many of the symptoms of morbus coxæ. The lameness is, however, not so great, nor is there the same disposition to adopt the flexed position. The pain is more localized, in general; but I have known the pain complained of much lower down the outside of the thigh. The trochanter in these cases is enlarged, its periosteum being also very much thickened, and its condition finally becomes either that of chronic exostosis or necrosis, with partial separation of the bony prominence. An instance of the latter you saw not long ago, in an out-patient, a young peasant, who fell in wrestling. The case looked very like hip-disease at first, for the nates were flattened, and the limb was much wasted, but the joint was found on examination to be perfectly free from disease. There had been an exfoliation in this case, but the fistulous opening was then healed.

About three years ago a case of this kind, in its early stage, was treated in Patrick's ward. The part had been bruised against a wall by riding a restive horse. Under the external use of tincture of iodine, after leeching and cold applications, the swelling nearly disappeared, and no trace of lameness remained. In the progress of such cases a question may arise, whether we should interfere to remove a portion of loose or carious bone. If we do so, by simply dilating the fistulous opening, and seizing the fragment with the forceps, we should do so in order to shorten the period of lameness. But if a more extensive incision be required, I cannot advise you to incur the responsibility, unless the patient shares it freely with you by wishing for the operation. Le Dran gives a case of a young man on whom this operation was performed in order to remove a portion of the great trochanter, which was found to be carious. The event was unfortunate, for erysipelas, fever, and rigors, were the consequence, and the patient died on the seventh day.

The treatment of the chronic or mild form of osteitis of the upper third of the femur, will, in many respects, be the same as that required by the acute form, at a period when the violence of the symptoms has abated, but where there is still reason to suppose that a certain degree of increased action continues. Local blood-

letting, according to the constitution and vigour of the patient, should be practised, and evaporating lotions or fomentations according to their effects constantly employed. I have known the hip-bath of great service after leeching in these cases, and, when moderate adroitness is to be found in the attendants, I have never seen any objection to its use on grounds of disturbance to the limb. Passive motion, as I said before, is not complained of; no movement is communicated which calls for resistance on the part of the muscles situated about or attached to the affected part.

If mercury be prescribed in the mild form, it must be on principles quite different from those which apply to the acute case. It should be to improve the secretions, or, at most, to produce that mild impression on the system, so conducive to the removal of chronic inflammation, and which, for want of better, has obtained the name of its alterative action. For this purpose you may give two grains of blue pill with two of prepared chalk, every night, and in the morning a few grains of rhubarb, or an infusion of the root with gentian or cascarrilla, and small doses of sulphate of magnesia or potass, as the case may suggest. This plan may be continued for some days, until the secretions, alvine and renal, are satisfactory, and the tongue nearly natural in appearance.

It will now be advisable to adopt means calculated to promote absorption, and lessen the bulk of the swelling. We possess in the different preparations of iodine, remedies peculiarly adapted for our purpose, and signally useful in affections of the fibrous and osseous tissues. The combinations of iodine and mercury, as you have seen them employed, are sometimes very active; but you should remember that the mercurial action too often predominates. On the whole, the hydriodate of potass or iodide of potassium is the preparation which I can most safely recommend you to employ. I have already remarked upon the mode of exhibiting this medicine.

The local application of iodine deserves a high place in our confidence in treating the mild forms of osteitis and periostitis. If counter-irritation be desirable, you can direct a blister to produce vesication; and having removed the cuticle, dress the surface with the iodide of lead ointment of the strength used in the hospital, two scruples or a drachm to an ounce of spermaceti ointment. When the parts will bear friction, iodine can, in this way, be made a very efficient agent, and for this purpose fresh lard is a better medium than spermaceti ointment. I find the skin bears the ointment composed of iodide of

potassium and iodide of lead with lard very well; the addition of a little tincture of opium is occasionally useful. You have witnessed many examples of the efficacy of this application in dispersing thickenings of the tissues already named. Mr. Cæsar Hawkins relates two cases of fibrous tumor growing from the lower end of the femur, in which leeching and iodine ointment succeeded in checking the progress of the complaint. I need not remind you that the efficacy of your remedies will be increased by those attentions to the general health, in which careful diet, air, and passive exercise, are included. You can accomplish nothing, in slow diseases, without due regard to these important matters.

I have now, gentlemen, described the acute and mild forms of osteitis of the upper third of the femur, and alluded briefly to periostitis of that part, as well as of the great trochanter. I have also related the modes of investigating these diseases, with a view to distinguish them from disease of the hip-joint, which they so closely resemble, and with which I have no doubt they have often been confounded. I have finally glanced at other organic changes in the same situation, lest your attention should be too exclusively directed to a single view of the probable source of swelling of the bone. I shall not fail to avail myself of the opportunities afforded by this valuable hospital, for pursuing the study of these important diseases, and shall willingly share with you the facts and experience supplied by our clinical researches.

PROCEEDINGS

OF THE

PATHOLOGICAL SOCIETY OF DUBLIN.

DR. GRAVES IN THE CHAIR.

1. *Perforating ulcer of the stomach.*—Dr. Hutton exhibited a recent specimen of a large ulcer situated at the lesser curvature of the stomach; it had penetrated the peritoneal covering; the coronary artery ran close along the edge of the aperture. This ulcer was obviously chronic.

The preparation was taken from a body of a young female, to all appearance healthy; seven days previous to her death she received an extensive burn of the face, neck, and shoulder; upon the evening of the sixth day after the receipt of the injury she was seized with vomiting, and on the morning of the seventh day abdominal pain set in, followed by collapse. She died of peritonitis on the next day. (Museum, Richmond Hospital.)

2. *Ileo-cæcal abscess, with perforation of the intestine and groin.*—Mr. Ferrall presented the recent parts in this case. The patient, a young girl, was admitted into the Meath Hospital, with tumor in the right iliac region, about fourteen days after the first attack; suppuration of the tumor had then occurred; the bursting of the abscess was soon indicated by a copious discharge of purulent matter from the bowels; soon after this another tumor formed in the upper part of the thigh, separated from the former by a deep sulcus corresponding to Poupart's ligament, below which an opening occurred, through which pus and ultimately fecal matter was discharged. Mr. Ferrall exhibited the mode of communication between the abscess and opening in the groin; the fistula took a direction at first downwards, and afterwards upwards and inwards, the omentum adhered to the parietes of the abdomen and cæcum; the communication from the abscess into the intestine was by two small openings separated by a slip of mucous membrane, and resembling the appearance often seen in the integuments when an abscess opens by a slough.

An important peculiarity in this case was the mode in which the matter had made its way externally—namely, by perforation of the iliac fascia, and descent on the outside of the femoral vessels.

Mr. Ferrall also shewed, that in this case the communication with the intestine did not, as Dr. Burne supposes, take place through the appendix vermiformis, the appendix being free from disease. The perforation had arisen from the abscess into the intestine, being the third form of the disease formerly described by Mr. Ferrall in the *Edinburgh Journal*. He owed the specimen to the kindness of Dr. Stokes. (Museum, St. Vincent's Hospital.)

3. *Incipient Cirrhosis of the Liver, with Chronic Gastritis and Congestion of the Mucous Membrane of the Intestines.*—Mr. Carmichael exhibited the recent parts in this case. The viscera were those of an habitual drunkard; the liver was but slightly diminished in size; the left lobe presented a more marked type than the right, and had a mammillated appearance, which was scarcely to be detected in the right portion of the organ; the spleen was much enlarged; the mucous membrane of the stomach was thickened and of a slate colour, and that of the small intestines deeply congested; the lungs presented a great number of tubercles in different stages. (Museum, Richmond Hospital.)

This patient died with ascites, for which he had been twice tapped. Mr. Carmichael considered that in this case, and others of the same description, the primary

lesion was inflammation of the gastric mucous membrane, and that the lungs were subsequently tuberculated.

4. *Extensive fracture of the cranium, in consequence of a fall during an epileptic paroxysm.*—Mr. Cusack exhibited a portion of the cranium of an individual, who, in a paroxysm of epilepsy, fell with violence on a stone floor. The skull was extremely thin; the right frontal bone was fractured and depressed, and the internal table extensively separated from the external. About two ounces of blood were effused from the middle meningeal artery, which had been torn across. The arachnoid was vascular, and some effusion existed beneath it. Subsequent to the fall the patient recovered his senses, and remained free from any attack until the next day, when the convulsion returned, and was repeated several times previous to his death. (Museum, Park Street.)

5. *Formation of numerous cysts in the kidneys, with extensive depositions of phosphate of lime.*—Dr. Corrigan presented the kidneys of an individual who had long laboured under symptoms of irritation of the bladder and urethra; he had curvature of the spine of long standing. On dissection the urethra, prostate, and bladder, were found healthy; one kidney was converted into a number of large cysts, while the other presented the same disposition, but with this difference, that the loculi contained great quantities of a substance resembling putty, and composed of phosphate and carbonate of lime, with a slight trace of albumen. In the course of the disease the patient laboured under hæmorrhage from the bladder. (Museum, Digges Street.)—*Dublin Journal of Medical Science.*

CONGENITAL ABSENCE OF THE LIVER.

THIS rare malformation was found, by Dr. Kieselbach, in a human embryo, which was, in all other respects, well formed. The umbilical vein passed through the umbilicus to the part which the liver usually occupies, without dividing; there the portal vein received it, and divided into two branches, one of which passed to the vena cava, but the other divided into innumerable ramifying branches, which terminated blindly. There were no traces of hepatic veins. One cannot, therefore, regard the flocculent division of the branches of the umbilical vein as residue of a liver which had once existed, and at a later period had, from some cause, wasted. The case is probably to be regarded as one of those rare arrests of development

in which one of the most important organs is not formed, but in which a vascular growth occupies its place.—*Froriep's Neue Notizen*, No. 159.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT

OF
CALCULUS,

AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.

By DR. VENABLES.

Pathology.—We have in a former lecture given a tabular view of the composition of the different principles, morbid or natural, which, either by their appearance or increased quantity, produce morbid conditions of the urine. We must now, therefore, refer to that table, and we shall see that oxalic acid consists essentially of two atoms of carbon and three of oxygen. Now sugar is very readily converted into oxalic acid by the action of nitric acid aided by heat. We have already stated that Dr. Prout considered diseases, or at least certain diseases, as arising or intimately connected with an imperfect development of the staminal principles, or from the derangements to which these principles are liable. You may also remember these principles were three—the *saccharine*, the *oleaginous*, and the *albuminous*. Dr. Prout considers the oxalic diathesis as depending on the saccharine principle. The acidifying power of the kidneys appears to be in inordinate activity, and hence the formation of oxalic acid. From this he asserts the formation of oxalate of lime may be traced, and its appearance as urinary calculi. Nor is the mulberry calculus the only form of morbid condition developed under such circumstances. With the production of oxalic acid the

skin becomes affected, and presents morbid appearances of various characters. "One very important class of affections," says Prout, "frequently connected with the formation of oxalic acid, are certain skin diseases; these, from slight scaly crusts down through every intermediate stage to boil, carbuncle, and even malignant forms of disease, as fungus hæmatodes, often accompanying a tendency to saccharine diseases, either in the shape of sugar, or oxalic acid, or more frequently both*." I have already pointed out the connection between certain urinary diseases, as diabetes, excess of urea, &c., and certain affections of the skin, of the leprous and impetiginous characters, and this has also been observed to occur in those disposed to the oxalic diathesis. "When, in particular, the oxalic diathesis prevails, it is rare not to find the skin more or less affected, either in the shape of scaly spots on the anus or legs; or troublesome boils, which, in advanced life, and more inveterate forms of the affection, sometimes assume the shape of carbuncles. I have several times seen impetiginous affections accompanied by a temporary saccharine condition of the urine, and after this has disappeared, succeeded by malignant disease of the bladder, of the kind usually termed fungus hæmatodes. Even in those cases in which there is not actual disease, when oxalic acid is generated in the system to much extent, the skin often assumes a peculiar character difficult to describe, and a livid tint mixed more or less with green or yellow, and the venous blood is often of an unusually dark colour†."

Calculi of oxalate of lime are generally rough and tuberculated, and consequently we can readily understand, how, even by their mechanical action, they produce that pain and irritation, and also the bloody

* Gulstonian Lectures, MED. GAZ., vol. viii. p. 386.

† Ibid.

urine so constantly voided during the formation and growth of mulberry calculi. When large calculi of this description are retained in the kidneys, disorganization of these organs is very apt to be produced; and, as has been observed by Prout, the blood voided with the urine is generally of a very dark or greenish colour. Upon the whole, we may consider the oxalate of lime a somewhat more obscure form of disease, and one the treatment of which it is not easy to base upon strictly rational principles.

Treatment.—The treatment of this diathesis is attended with two very great difficulties:—first, that of determining the existence of the diathesis; secondly, to devise the appropriate remedies. The absence of all urinary sediments obliges us to depend upon evidence at best but equivocal, or at least of little or no service to those who are not practically acquainted with the sensible, mechanical, and chemical properties of the urine, both in health and disease. If, then, we find the urine presenting a specific gravity of about 1.020, having an acidulous reaction, the citrine tint already mentioned, without any characteristics of the lithic acid diathesis, with the prevalence of the associates already enumerated, should we not be justified in looking upon the disease as depending upon the oxalic diathesis? Grant it. Are we acquainted sufficiently with the pathology of this diathesis to see clearly the modes of counteracting it? Much as has been effected, we still are to a great extent in the dark upon this subject. It has been already shewn, and that also on the authority of Prout, that the analogies existing between the lithic acid and the oxalic diathesis, were such as to prove them of the same general nature, and therefore that the principles of treatment should be similar. But this can only be understood as applicable to the general or constitutional treatment, but, in reference to particular methods, would be found highly prejudicial. Thus we may adopt blood-letting (general and local), purgatives, and other antiphlogistics, to subdue and correct any inflammatory tendency. But when we come to consider the conditions of the urine, we find that the analogies in the therapeutics here cease. We found, for instance, that the urine contained a large quantity of earthy salts in solution. Thus, in the instance mentioned by Dr. Prout, ammonia precipitated the mixed or fusible phosphates very copiously, and oxalate of ammonia gave a very copious precipitate of oxalate of lime, and probably of oxalate of magnesia*. In the lithic acid diathesis we

give the alkalies freely, but you must be satisfied that an alkaline or even neutral condition of the urine would be attended with the precipitation of the fusible phosphates, under the circumstances of such a chemical constitution as that which prevails in the oxalate of lime diathesis. Nor would such a condition tend in the least to prevent the separation of oxalate of lime; on the contrary, it would rather favour it. Here is a solution of oxalate of lime effected by means of an acid. Let us suppose, for a moment, this to be the condition of the urine. Observe, the moment we render it neutral, much less alkaline, by means of ammonia, potass, or indeed any alkali, oxalate of lime immediately precipitates. Now this is what would take place in the urine; and still further the fusible phosphates would be precipitated, than which there is a no more terrible or formidable condition, for it seldom prevails long or to any extent without serious destruction of the coats of the bladder. Here, then, is a very marked distinction between the treatment of lithic acid and the oxalic acid diathesis.

We now, therefore, come to inquire, is there any means of rendering the oxalate of lime soluble, and thus preventing its separation from the urine? Some of the acids, as you have already seen, dissolve the oxalate of lime; such are, for instance, the hydrochloric and the nitric. In this tube I have oxalate of lime; if I add some hydrochloric acid—as you see—the first two or three drops do not exert any solvent effect; but if I add a drop or two more—as you see—the oxalate of lime is dissolved. Nor yet is this solution too strongly impregnated with acid to prove injurious to the urinary organs. Nitric acid is a still more powerful and effectual solvent of the oxalate of lime; for you see a single drop dissolves the oxalate of lime, which required five or six of hydrochloric acid. Therefore it would appear that one or other of these acids present a prospect of the greatest success that can attend the use of remedies, but which is preferable I hardly know; but, from my own experience, I should be inclined to prefer the nitric; but what I think still preferable is a combination of the two, the two nitromuriatic, as it is called.

It will be observed, that so far the use of the acid is inferred to be to keep the oxalate of lime in solution, and thus have it expelled with the urine; and that this takes place, I have had one opportunity of verifying. I have already stated that oxalate of lime is not generally discoverable

* I have satisfied myself that oxalate of magnesia is frequently precipitated under such cir-

cumstances. But as they are similarly affected by reagents, and soluble in the same solvents, the circumstance, in a practical point of view, is not of much moment.

in the urine, even when this diathesis is going on; but some years since, a case presented to me, in which there could be little doubt of the oxalate of lime diathesis going on, from the very marked and decided symptoms of this diathesis being present. The patient was at first treated with hydrochloric acid, and afterwards took the nitro-muriatic acid; and during which, I examined the urine two or three times, and discovered traces of oxalate of lime. That is the precipitate by an alkali partially dissolved in acetic acid, leaving a neutral residue insoluble in the acid, but which, on being heated by the blow-pipe, became alkaline, and when moderately heated left a residue which effervesced with an acid. These are characters which distinguish oxalate of lime.

But even this practice requires very close attention and great care; for a perseverance in the use of acids, if carried to too great an extent, will cause the generation and precipitation of lithic acid, and this probably would prove as bad as the evil we wish to avoid. Dr. Prout, indeed, has proposed a principle of treatment founded on this very fact. "Besides," he says, "the principles of treatment above-mentioned, I have lately adopted another principle, very different, indeed, from these, but which I think I have seen of considerable utility in two or three instances. This has been to endeavour to change the diathesis from that of the oxalate of lime to the lithic acid. It struck me, that as these two diatheses never appear to exist at the same time, if the former could be converted into the latter, that a very obscure disease would thus at least be exchanged for one of a more open character. The muriatic acid was chosen for this purpose (though in some instances it is probable the vegetable acids would answer as well*), and its use was continued till the lithic acid began to be deposited plentifully on the cooling of the urine. The muriatic acid is sometimes apt at first to derange the stomach; but notwithstanding this, in the few instances in which I have had an opportunity of adopting this plan, it has been always ultimately followed with very considerable relief to the patient's sufferings, both constitutional and local. Indeed, there are strong grounds for believing, from the analogy between the two diatheses, that an artificial ex-

pulsion of lithic acid from the system, under the above circumstances, is calculated, at a certain period of life, to remove the tendency to the formation of oxalic acid, in the same way and on the same principles, that it was formerly stated to remove the tendency to the secretion of lithic acid*."

The changing the operations of the system so far that lithic, the natural acid, be generated in the place of the oxalic, a morbid and unnatural one, was a very happy idea, and certainly one which has put medicine in possession of a very powerful means of assistance. But it must be borne in mind, that the practice is not wholly without risk, and that it cannot be attempted without care and judgment. First, if a determined lithic acid diathesis be induced, from the peculiar constitution of the urine, the treatment required would be apt to be attended with the precipitation of the fusible phosphates, for even although the lithic acid diathesis may be induced, yet the quantity, indeed unnatural superabundance of the earthy salts, is not materially diminished. Indeed, Dr. Prout himself cautions us as to the adoption of this plan:—"It need scarcely," he says, "be mentioned, that this plan of treatment requires some judgment and care in its management, and that it should hardly in any case be adopted when disorganization or calculus is already supposed to exist in the kidney or bladder, or, perhaps, in very young or very old subjects†."

At the same time that we adopt or modify the plans just now pointed out, the use of sedatives will often prove highly efficacious; and in this case, as in the lithic acid, opium and colchicum will be found of essential service. Opium has been already noticed as promoting the secretion of lithic acid, and colchicum is by many supposed to produce a similar effect. With these means we must attend to the general state of the health, and especially of the digestive functions. Local treatment, such as cupping the loins, sinapisms, issues, and setons on each side of the lumbar vertebræ, and over the region of the kidneys, should not be lost sight of.

Dr. Prout, in the *Gustonian Lectures*, attributes the generation of oxalic acid to the acidification of the saccharine radical. Hence we might infer, from what he states, that oxalic acid would be found in the blood, and he points out several singular coincidences which would seem to justify such an expectation; but I am not aware that free oxalic acid, or even combined, has been found in the blood, by any other than Lecanu. In certain states of

* It may, perhaps, in some measure be questioned how far the vegetable or destructible acids would answer. Certainly, in a vigorous state of the digestive functions, these acids would be decomposed, and their elements differently appropriated than to the generation of lithic acid in the urine. I am not quite certain as to how far the phosphoric acid might be advantageously substituted, but I believe that a solution of chlorine will very often answer the purpose, and effects very salutary changes.

* On Diabetes, &c., pp. 161-162.

† *Ibid.* p. 162.

disease, however, it seems very probable that this, as well as many other morbid principles, would be found to exist in the blood. Consequently the great therapeutical indication would be to prevent this morbid generation; but we are not sufficiently acquainted with the nature or mode of this production to entertain the subject here*.

Cystic oxide diathesis.—You have already been made acquainted with the principal properties of the cystic oxide. Comparatively speaking, opportunities of examining the circumstances connected with this principle occurs so rarely, that but little is known respecting it. I have already stated in general terms the history of this substance. The distinguishing chemical characters at least are very well ascertained; but in a pathological and therapeutical point of view this advances us but a very little way in the history of the disease. I am not aware that any one, with the exception of Dr. Prout, has given any history of the physical properties of the urine. Dr. Wollaston was the first to perceive the peculiar properties of this substance, but he has given us no perfect history of the cases, truly because he had not the opportunity, as he merely had the calculi for analysis without knowing any thing of the history. Dr. Marcet is also in the same predicament; and although he saw something of the cases, yet he had no opportunity of furnishing any thing like a perfect history. I here again present you with a specimen of the cystic oxide that you may again look at its sensible characters.

Dr. Wollaston was the first to describe the characters of cystic oxide. He states, in external appearance they more closely resemble the triple phosphate of ammonia and magnesia, but with this difference, they are more close and compact, nor do they consist of distinct laminae, but appear as one mass,

* I have above stated, that chlorine—and what, perhaps, is equivalent to it, nitro-muriatic acid—is sometimes very beneficial. I have some reason to believe that chlorine, under certain circumstances, decomposes the oxalic acid, abstracting the hydrogen, and setting the oxygen and carbon free. Chlorine will certainly decompose water, more especially if aided by light; for if we examine a solution of chlorine after some time, with the free chlorine, hydrochloric acid will also be found in solution. Oxalic acid cannot exist without being hydrated, and if the chlorine will decompose this water, it will as effectually destroy oxalic acid as the sulphuric which abstracts it. Some experiments which I have but very recently undertaken, but which I have not completed, have induced me to throw out this hint, that others, who have the opportunity, may put the suggestion to the proof. If the above be well founded, chlorine perhaps would not only prove beneficial, by decomposing oxalic acid already formed, but probably would prevent its generation altogether.

confusedly crystallized throughout its substance. It has a yellowish semi-transparency*, and a peculiar glistening lustre, like that of a body having a high refractive density. Urged before the blow-pipe it gives off a peculiar fœtid odour, very different from that exhaled from the lithic acid under the same circumstances, nor at any period resembling the smell of Prussic acid. But perhaps its more distinguishing characters are those already detailed; its solubility, with but few exceptions, in the acids and also in the alkalis. The general symptoms which prevail in this disease are no way peculiar, and therefore require no enumeration.

Diagnosis.—There will be very little difficulty in determining the presence of the cystic oxide diathesis, for no one of the commonest observation can be mistaken upon this point. The properties of the urine are so peculiar and characteristic that, independent of any sediment, they would prove quite sufficient to decide the nature of the case. Of the cases which have been specially noted, we have the following summary. The first calculus, and from which Dr. Wollaston, its discoverer, determined its properties, was taken from a boy five years of age. It was covered with a loose coating of the phosphate of lime. This patient died afterwards, in consequence of another stone of lithic acid having formed. This second calculus appeared as if something more soluble had been removed from its centre†. A second was likewise described by Dr. Wollaston. It was taken from a man, aged 36; but there are no farther particulars of this case. The calculus is preserved in the museum of Guy's Hospital. Dr. Henry next recognised two specimens in his collection, but professed himself unacquainted with the history of either‡.

Dr. Marcet was the next to describe this calculus. The first case which presented was that of a gentleman, about 30 years of age. He was first attacked with symptoms of stone about twelve years before, and was operated on about two years after; and the calculus given to Dr. Marcet for examination very closely resembled, in external appearance, the specimen delineated in figs. 1 and 2 of this plate viii. of his work. On examination it proved to be cystic oxide. This gentleman passed several small calculi by the urethra both before and after the operation, which, on examination, were found to consist of this substance. "But the most remarkable circumstance of his narrative," says

* The specimen in my possession is rather whitish, a dull white.

† Philosophical Transactions, 1810, p. 223.

‡ Med.-Chir. Trans., vol. x. p. 149; Marcet, p. 89, 2d edit.

Marcet, "was, that the evacuation of these stones had invariably been preceded by pain in the left kidney, shooting down the ureters, and, as he thought, following the course of the stone; but he never was subject to pain at the extremity of the penis, or at the neck of the bladder*." After the operation he was not troubled with symptoms of stone, as they were generally voided immediately on their descent from the kidneys to the bladder. This gentleman had been subject to hæmorrhage, which then ceased; but calculous matter, in small quantities, continued to be voided much more frequently than before, even about once a month. He was subject to be bilious or dyspeptic, but was not troubled with acidity. Dr. Marcet considers this, therefore, a distinct instance of the renal origin of this calculus.

The next instance is also described by Dr. Marcet. This gentleman was about 20 years of age, and died in London with symptoms of stone in the kidneys. On opening the body a number of calculi were found in the kidneys, and, upon examination, proved to be pure cystic oxide. One of them had moulded itself in the enlarged infundibulum, in which it was found, so as to afford by its shape a permanent proof of its origin. This calculus is represented in plate viii. fig. 3, of his work. An elder brother of this last patient had also died with symptoms of calculi, and Dr. Marcet obtained the particulars. He was between thirty-six and forty years of age, had occasionally passed small stones from the bladder with more or less inconvenience, and suffered from disease of the prostate. At the time of his death he felt no particular uneasiness in the bladder, nor was there any obvious deficiency of urine. He was suddenly seized with febrile delirium, as if from some great irritating cause, but without particular pain. Under this state his vital powers sunk rapidly, and he died in a few days.

On dissection one of the kidneys was found reduced to the state of a small cyst or bag, without any distinct remains of organic structure by which the kidney could have been recognised, except its being attached to the ureter. The other kidney was enlarged, and contained several cystic oxide calculi, one of which, as in the instance of the brother, assumed the form of the cavity of the kidney from which it was taken. No calculus found in the bladder. The prostate very much enlarged, containing several calculi, one of which, examined by Dr. Marcet, proved of the usual composition—phosphate of lime. A third brother died in Ireland with symp-

tems of calculi, but their nature could not be ascertained.

Mr. Brande mentions two instances. In one the calculus was voided by a labourer; but there are no particulars. In the other, several cystic oxide calculi, varying in size from that of a pin's head to a pea, had been voided at different times, for a period of thirty years, by a gentleman, aged 40. This individual had been subject, from about 6 or 7 years of age, to pain in the loins, not confined to any particular spot, and seldom of any acuteness, so as to prevent his usual occupations, which obliged him to lead rather a sedentary life. His usual state of health was good, his habits very regular, his diet ordinary and plain. He had used soda water, magnesia, and the alkalies, without any advantage. The further history of this case is unknown*.

In the histories which have just been given, two things of some moment appear—1st, that this calculus is always of renal origin, and, contrary to what its name implies, never originates in the bladder; 2d, that most of the specimens are nearly of perfect purity, and very free from any impurity or other intermixture. "I have only further to observe," says Dr. Marcet, "on this substance, that all the specimens I have seen, from five different persons, have been remarkably pure, and free from any other ingredients†. It would appear, therefore, that the cystic oxide diathesis (if I may be allowed the expression) has a more exclusive tendency, in regard to the formation of other kinds of calculi, than the other species of urinary concretions‡." Sometimes, however, these calculi are studded here and there with crystals of the triple phosphate, but receive no distinct coating or stratification of other substances.

Such is a summary of what was known concerning the history of cystic oxide till the publication of Dr. Prout's work. In this no account appears to have been taken of the peculiarities of the urine, from which alone, independently of any other circumstances, the existence of the cystic oxide diathesis may be with certainty pronounced. Opportunities, however, of examining the urine of persons labouring under this disease have presented to both Dr. Prout and myself, and I shall now proceed to lay the particulars before you.

* Journal of Royal Institution, vol. viii. p. 71.

† One of Dr. Wollaston's specimens had a loose coating of phosphate of lime; but this might have been accidental, and does not invalidate the general inference.

OBSERVATIONS

ON

COMPLICATED SURGICAL
INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with
the Auxiliary Forces in Portugal and Spain.*(As delivered in his Lectures at Sydenham
College School of Medicine.)*

[Continued from p. 524.]

—

VI.—INJURIES OF THE HEAD.—GENERAL
CONCLUSIONS ON THEIR SYMPTOMS, EF-
FECTS, AND TREATMENT.*Resumé of the results and facts brought for-
ward in these lectures, and the principles
they establish—1. As connected with the na-
ture of the various injuries.—2. In reference
to their symptoms and effects.—3. As regards
their treatment and ultimate results.*

THE symptoms and effects of lesion are doubtless dependent much upon, 1st, the extent of lesion; secondly, the particular site. I have seen many cases of wonderful recovery from lesion, of which I will relate an instance, stating my conviction, that of all the injuries to the brain, threatening life, that which leads to least disturbance is lesion.

— Woodhouse, a trumpeter, while sounding the advance, received a musket-shot. The ball entered at the right temple, near to the outer angle of the eye, and, passing through the back of the orbit, destroyed the eye; and in its course to the other temple, nearly diagonally, it raised the frontal bone many lines from the transverse suture. It made its exit a little higher on the left side, and, from both wounds, brain passed out for several days. The deformity of the face at and above the transverse suture was considerable, from the displacement. He recovered shortly from the immediate and stunning effects of concussion: the next day, in hospital, I found him rational. He subsequently became delirious. After long treatment he was invalided; the intellect enfeebled, but not destroyed, and the sight of the left eye in the same manner saved, in an impaired state. This was in 1832; and although I have not heard of him lately, I know he was alive and in tolerable health some three years ago.

These have appeared to me the chief varieties to be observed in the symptoms indicative of different degrees or kinds of injury to the head. Fully alive to the danger of deducing general principles from inadequate data, I have carefully studied parallel cases, following out their consequences by post-mortem examinations when they proved fatal, and thus endeavoured to obtain, for myself and others, guides for diagnosis and treatment. Without any preconceived theories or views on the subject, I have already told you I began to observe, scrupulously abstaining from any thing like general conclusions until I had not only observed and treated, but carefully noted and recorded all the symptoms and appearances of these injuries, and their consequences, in a great number of cases.

The general results and facts upon which the views I have endeavoured to convey to you are founded, are given here: the results of ten years' observation, including the whole period of my service in the Peninsula. In Spain, during one year alone, more than a hundred cases came under my notice. The field, therefore, has been extensive; and as the gleaner was not idle, I hope the results will not be altogether without value. Before concluding with a few remarks on the treatment of these injuries, the most complicated and interesting in surgery, I will bring before you, at one glance, the principles laid down in these lectures, and the conclusions on which they are founded, that you may thus the more readily be enabled, at the bed-side, to test, and reject or adopt them, by the results of your own experience hereafter.

1. The most common injury of the head is CONCUSSION; more powerful in its effects, more universally pervading the fibre of the brain and the system generally, than any other. There can be no injury to the head from violence without it: it therefore complicates all; or, more naturally and simply, this may be considered the one great and elementary form of injury, to which any or all the others must, if they exist, be super-added, when violence has been suffered.

2. Compression, ramollissement, lesion of structure, may exist without concussion; yet so generally are they the consequences of a jar or shock, and so constantly do they require to be discovered and treated, not as simple or singly

existing diseases, but as complications of the first great injury, concussion, that the study of them in this form is absolutely necessary to a due appreciation of the effects of injuries of the head. Otherwise we should find, that when we knew the effects of compression simply, we had yet to learn to distinguish them when supervening on concussion.

3. The effects resulting from injuries of the head are of several kinds as well as degrees; and as the most practical mode of classing them, they have been referred to the three nervous systems or centres through the medium of which they are manifested.

a. The cerebral system, and such portion of the spinal as contributes to cerebral sensation, perception, and motion.

b. The excito-motory or true spinal system, including all manifestations of spinal reflex actions; among which are respiration, deglutition, vomiting, convulsions, the action of the sphincters.

c. The great sympathetic—the nervous system of organic life, as it was termed by Bichat, governing secretion and nutrition throughout the body, and probably, in a great measure, circulation through the heart's action.

Lesion of one of these does not necessarily imply, *in primo loco*, injury of any other; although disturbed functions in all generally follow as a secondary consequence. Injuries of the head and spine sometimes, in the first instance, affect chiefly or solely the first; in other instances the second; in others, again, all three.

If one be affected only, and subsequently others, they are generally implicated in the order in which I have placed them. But if the circulation be considered as chiefly referable to the sympathetic, then this will often be the second in order.

In proportion as one or more, or as one or the other, of these nervous centres are chiefly implicated, will the nature of the effects and the character of the symptoms developed be varied.

The functions of the first or cerebral order may be impaired or apparently annihilated, without, for a considerable period, any serious disturbance of the two following. Any one cerebral function may in like manner be affected, exalted, impaired, or annihilated, without much disturbance of any other part of the same system. (See cases, p. 419.)

In some rare cases, this may also

take place when the second order is the seat of injury—as in tetanus and hydrophobia; generally, however, the cerebral and sympathetic are speedily implicated.

The third, when seriously injured, involves the other two, generally promptly and fatally.

The order in which these are implicated in injuries of the head, has no certain reference, and furnishes but an imperfect scale of degree of injury. A wound of the cerebrum, capable in a few days of destroying life, may leave, until all the vital powers are ebbing, the excito-motory and sympathetic systems unaffected. (See case of Maj. G., p. 418.)

When these are involved, however, as a result of cerebral injury, they always imply a grave and dangerous lesion.

4thly. Severity and succession of effects are better guides for diagnosis and treatment in these injuries, than even the accurate knowledge of their exact nature or actual extent, which can rarely be attained. With effects we have to struggle, and they afford valuable diagnostics for the prognosis and the treatment; for by these effects, rather than by the nature of the injury in the majority of cases, must the prognosis be formed. In these cases, it will be found that similar effects succeeding an injury, more generally give similar ultimate results than can be predicated from any similarity of injuries.

5thly. It is important to know that similar kinds and degrees of injury, as far as any material alteration or lesion can define them, give very variable effects (see cases of *Elam*; *Flynn*, p. 448). The one recovered with some permanent irritability of fibre, the other died; proving the impossibility of predicating, *from any knowledge of the original injury*, what form the sequences will assume. Although even the ultimate effects of concussion are various, there is one form much the most common, and that is, permanent irritability of nervous or cerebral fibre. (See cases of *Boase & Wilson*, p. 451, in illustration.)

6thly. It is a great error to consider concussion to have ceased its action and influence on the brain and system generally with returning consciousness, sensation, and voluntary motion. The cessation of coma does not mark the termination of the effects of concussion, neither does that injury in a severe degree always produce coma in the first moments.

A lethargic state, coming on subsequent to the first moments of injury, is very frequent in cases of concussion; supervening probably a few hours after the blow or shock. These have hitherto been held to be instances of extravasation, effusion, &c. Their sudden relief by bleeding proves this to be impossible. If these symptoms arise from compression, as I believe they often do, it is the pressure of fluid within the cerebral vessels, acting on a debilitated fibre, which may have lost its power of resistance. (See case of Philip Thorne, p. 446.)

7. The usual effect of concussion on pupil and pulse is to dilate the one, depress and impede the other. The pulse and the respiration frequently both present the same character.

Dilatation of pupil; drowsiness; laboured pulse; slightly impeded breathing; in milder forms, vomiting—in these consist the chief features of a moderate degree of concussion, not violently affecting either the excito-motory or the ganglionic system; its effects confined chiefly to the head, which does not always happen, even in lighter degrees of injury. (See cases, pp. 446, 493, for three different degrees of concussion.)

Thus concussion, followed beyond its first evidence, presents a group of symptoms and effects in the following order:—

In reference to the cerebral system:—

1. Coma, or depressed action.
2. Febrile, or exalted action.
3. Irritability of cerebral fibre.

To give a clear impression of some of the more important of what may be termed "*Subsequent or secondary effects of concussion*," I will class them in the following order. The most common course of concussion, in various degrees of intensity, has been fully described. These subdivisions may now, therefore, be considered in the light of important deviations from the more usual course, but all distinctly referable to Concussion as a first cause, and unless so classed and considered, calculated to lead to serious errors of diagnosis and practice.

a. From concussion will occasionally result, without any intervening coma, symptoms of irritation or inflammation, attended or not with late developed stupor. (See case of Davis, p. 452.)

b. In some cases the converse of this

may be observed; that is, from the stupor of concussion no reaction is ever manifest, but the patient gradually recovers from a prolonged lethargy, never having given sign of inflammation or irritability of brain. (See case, p. 419.)

c. Again, in other cases, even during the first comatose stage, particularly if the case be complicated by lesion, or the lodgment of a foreign body, an exalted and high inflammatory action supervenes. Either inflammation, or irritation only may become developed, the pupil contracting during the coma, and the pulse beating sharply. (See case of Cole, p. 486.)

d. Even if a shock or concussion give rise but to a temporary or imperfect state of coma, its subsequent effect may be a quickly succeeding disorganization of the brain; and this may be either partial or general. (See case of Medley, p. 488.)

e. Concussion in other cases seems to cause death by rendering the brain unfit for its functions, without any obvious alteration of structure. (See case of King, p. 489.)

This effect, the most extraordinary of the whole list, perhaps, is curiously and beautifully exemplified by the occasional effects of concussion on the eye. I have, for instance, observed in that organ the following as distinct consequences of a shock:—

1. Disorganization of the whole of the contents of the sclerotic. (See case of Baker, p. 489.)

2. Partial alteration of structure.

3. Total destruction of sight; entire loss of visual function, without any trace of disease or perceptible alteration of structure. (Cases of McNaughton, p. 490, of a gentleman, and of Clewes, p. 493.)

4. Partial destruction, amounting only to impaired vision. (See case of Sullivan, p. 490.)

Mark how perfectly they correspond with the effects observed in the brain; and the confirmation thus furnished by analogy of the accuracy of my views on this subject is the more gratifying to me, that the facts came under my observation second in order, not originating, but explaining, that which carefully recorded symptoms and appearances had previously suggested to me as taking place in the brain.

f. Concussion sometimes gives rise, in addition to the diseased action in the head, to others which I shall term "*Dispersed*"

effects," or disease in distant parts. Under this head I place, for instance, abscesses of sudden formation, in the lungs, liver, joints, &c. Several strongly marked cases I related. (See M'Lellan, *Meat.* p. 449, 450.)

g. Under violent concussion neither pupil nor pulse in some cases will give any indication of irritation or inflammatory action, however violently and fatally developed in the brain or its membranes. The pupil will continue fixed and widely dilated, the pulse slow, laboured, and even feeble. (See case, Wm. Knight, p. 452.)

8. Compression rarely manifests the same controlling power over the pupils as that which I have attributed to concussion. Lesion occasionally does produce the same effect. (Case of Jennings, p. 522.)

Compression does not, even when great and extensive, invariably produce dilated pupil. (Case of Watson, p. 523.) Neither does it necessarily induce stertor. (See case of Frederick, p. 491.)

Compression may even produce coma of the most complete kind, and yet the pupil remain unaffected and perfectly natural. (See case, Watson, p. 523.) This I have never seen in violent concussion.

9. The continued labouring character and slowness of the pulse is one of the best signs of compression—pressure not necessarily from effused or extravasated fluid—it may be from pressure within the vessels; and this is easily determined by depletion, which in extravasation, &c. affords no decided relief; while in the latter form of compression its good effect is prompt and indisputable.

10. Lesion, unless very extensive, produces less impression on the different nervous centres, and in general fewer symptoms and effects than any of the elementary forms of injury enumerated. It assumes more the form and character of a local disease. The severity and variety of effects seem rather to depend on the degree of attending concussion or compression than on lesion.

11. Ramollissement will give all the symptoms both of concussion and compression. (Page 488, case of a gentleman.)

12. An intermittent pulse seems to depend not on any degree of injury to the head, but on some peculiar irritation. It is not a common symptom either

of concussion, lesion, or compression, and but rarely exists in concussion alone. I have occasionally observed it in complicated cases. (See Wm. Knight, page 521.)

Having now defined and described, as far as limited time will permit, the elementary forms of injuries of the head, and classified the numerous and complicated effects to which they give rise, I proceed to the treatment, which is comparatively simple; the difficulty lies in distinguishing the true character of the case. Unless the coma be of such death-like influence that it seems likely to extinguish life, in which case I would administer diffusible stimuli, I have invariably seen the best effects, and not seldom immediate relief from free depletion. And if the pulse present some volume with its sluggish character, this is the treatment I have successfully adopted in a very large number of cases; nor have I ever seen any injury result from the practice thus guarded.

Next to depletion I consider the free action of the bowels important; and for this purpose, if there be a state of coma, a purgative enema should be thrown up. If deglutition be possible, the patient should swallow a full dose of jalap and calomel, or calomel and colocynth, followed by a solution of the sulphate of magnesia, and small doses of tartarized antimony.

Next in importance, I place cold applications, and a shaven head. There was but one order in the military hospitals under my direction—viz. to shave the whole head within an hour of admission in all cases of head injuries, as the surgeon then both sees what he is about, and is enabled to make all applications to the head efficient.

The skin and the kidneys assist much in the antiphlogistic measures, and their action should be promoted; diaphoretics and diuretics combined at intervals with the purgatives. By these derivative or subdepletory measures, the surgeon will much diminish the necessity for large and frequent bleeding; but this must be resorted to without hesitation whenever the inflammatory action is manifested in the brain, or its membrane; and in many cases when stupor comes on after a partial recovery— xxii. , xxviii. , or 24 ozs., at a time, and repeated the same day if the symptoms do not indicate subdued

action. When the pulse changes its character from slow and languid beats, 40 to 60 per minutes, to a sharp, thrilly, and more rapid character, generally the dilated or natural pupil will become strongly contracted; these are your chief signs for free depletion; the same actions may exist without being manifest by these or any other symptoms. But when these are present, bleed, and bleed freely; purge and sweat the patient, or death is certain.

There is, however, an exception to this otherwise very general rule of practice, viz., when the subject of injury has been of a drunken and debauched character; when, in fact, the wound is followed by an attack of what may be termed, traumatic delirium tremens. And these cases require much discrimination to be distinguished, since complicated by a severe injury they do not offer the same broad and legible indications of the true nature of the constitutional disturbance. It behoves you to watch carefully and avoid an error which would in all probability be fatal. Notwithstanding the two contrary indications afforded by severe injury to the head on the one hand, and the delirium tremens on the other, you must not think of bleeding. On the contrary, stimuli, and even brandy, combined with opium and doses of calomel, will offer the best chances of safety, perilous as the treatment may seem.

With respect to depletion generally in head injuries, I must also beg you to bear in mind that large and repeated abstractions of blood have a direct tendency to induce irritability of fibre, which is a very general and unfortunate result of concussion, independent of any treatment which may be adopted. Never bleed, therefore, without a definite object and distinct indication, and bleed neither more largely nor more frequently than seems absolutely required. Stimulating the secreting organs, so as to produce increased discharge, will often answer all the purpose of repeated bleedings, and without their disastrous effects.

If any puffiness of scalp or burrowing of matter take place, one, two, or three free incisions to the bone generally stop the mischief, and they should be made without any unnecessary delay or hesitation.

In the long-continued irritability of cerebral fibre, bringing on pain of head,

giddiness, &c., on exposure to the sun, or the application of any other stimulus, I have in some cases found a mild mercurial course perceptibly diminish it.

Of the local treatment of all wounds or contusions of the head I have already spoken in a previous lecture.

With these simple but comprehensive directions for the general treatment, I must conclude my observations on injuries of the head. Although the subject is very far from being exhausted, the limit I had originally fixed has been exceeded. I trust, however, gentlemen, you will find that the time has not been ill bestowed. It was necessary, indeed, to consider these injuries and their effects, both comprehensively and in detail. Some of the principles I have endeavoured to establish are new; many of the opinions stated are at variance with those hitherto most in vogue with the profession. To have confined myself to a meagre statement of conclusions, without the facts and circumstances on which they were founded, would neither have been fair to you nor myself. I have preferred, therefore, giving them in a state so far complete as to admit of being maturely weighed, tested at the bed-side, and judged by results.

A CLINICAL REPORT

OF

TWENTY-THREE CASES OF UTERINE HÆMORRHAGE,

FROM ATTACHMENT OF THE PLACENTA TO THE NECK OF THE UTERUS.

By ROBERT LEE, M.D. F.R.S.

Physician to the British Lying-in Hospital, and
Lecturer on Midwifery at St. George's Hospital.

[For the Medical Gazette.]

Guillemeau was the first who stated that the placenta may present, or come before the child, that a dangerous flooding then takes place, and that the most safe and expedient means of arresting it is to deliver immediately, by passing up the hand into the uterus and turning the child.

Mauriceau likewise knew that the placenta sometimes presented, or came before the child; and in all cases of hæmorrhage from this cause he recommended immediate delivery, as Guille-

meau had done. Mauriceau has related seventeen cases of uterine hæmorrhage in the latter months of pregnancy, from presentation of the placenta; and in sixteen of these delivery was accomplished artificially, by passing the hand through the opening formed by the separation of the placenta from the uterus, rupturing the membranes, and turning the child. Two women died after this operation, and one, who would not consent to artificial delivery, died undelivered.

Paul Portal's treatise contains the histories of several cases of uterine hæmorrhage, depending upon attachment of the placenta to the inferior portion of the uterus; and he was fully aware, as early as 1671, that the placenta had not sunk down to the lower part of the uterus, but had been adherent to the internal orifice from the commencement of pregnancy. He employed the same treatment in all these cases that had previously been recommended by Guillemeau and Mauriceau.

Petit, Giffard, Røderer, Levret, Smellie, Douglas, and William Hunter, related many cases of flooding, in the latter months of pregnancy, from this cause, and recommended the operation of turning as soon as the orifice of the uterus was sufficiently dilated to allow the hand to be introduced without the employment of much force. All the best writers on midwifery during the last hundred years have recommended artificial delivery where the placenta presents, and hæmorrhage takes place in the latter months of pregnancy. Every practitioner knows that the operation of turning should be performed in such cases, when the flooding becomes profuse, and the orifice of the uterus is dilatable. But in some cases the orifice remains so rigid, as to render the introduction of the hand into the uterus impracticable, while a discharge of blood is taking place sufficiently great to endanger or destroy life. There are no cases more embarrassing to the accoucheur than these, and none in the practice of midwifery attended with greater hazard. That they are not uncommon, and that we possess no means of effectually controlling the hæmorrhage till the operation of turning can be safely performed, the following histories sufficiently prove* :—

CASE I.—Anne Cromer, æt. 42, St. James's Parochial Infirmary, 22d July, 1828. I was requested by the late Mr. Baker to see this patient, who was far advanced in pregnancy, and had been attacked with profuse uterine hæmorrhage a week or ten days before. The placenta was adherent to the neck of the uterus; but the orifice being rigid, the plug was employed for several days to check the hæmorrhage, till the operation of turning could be performed. A large quantity of blood was lost notwithstanding, both before and after delivery, and the exhaustion was so alarming, that it appeared very probable she would not recover from the immediate effects of the loss of blood. She, however, survived for eighteen days, and death then took place from inflammation of the left spermatic vein, and gangrene of the lungs on the left side.

CASE II.—(1828.) A patient of the British Lying-in Hospital, near the full period of pregnancy, was suddenly attacked with a profuse discharge of blood from the uterus. She had been exposed to no accident, and had not experienced any uneasy sensation about the uterus before the blood began to flow. She was conveyed from her residence to the hospital immediately after the occurrence, but she was dead before any of the medical officers of the institution could see her. I examined the body, and found the centre of the placenta over the centre of the internal orifice of the neck of the uterus. On the left side the connection between the placenta and uterus was broken to a considerable extent.

CASE III.—24th October, 1829. A woman in the seventh-and-half month of pregnancy, residing at 2, Parker Street, had a great discharge of blood from the uterus for thirty-six hours before I saw her. A large portion of the placenta was hanging through the os uteri into the upper part of the vagina. I proposed immediately to deliver, by turning the child; but she obstinately refused to submit to the operation, and I was apprehensive that she would die undelivered. The hæmorrhage continued with great violence for several hours, when the placenta and a dead

lated by Dr. Ramsbotham; one out of four, by Dr. Joseph Clark; and two out of eleven recorded by Dr. Collins.

* Eight cases proved fatal out of nineteen re-

fœtus were expelled without assistance. She remained long in a state of great exhaustion, but ultimately recovered.

CASE IV.—On the 8th February, 1830, I was called to a woman residing in Falconberg Court, who had been attacked with profuse uterine hæmorrhage at the end of the seventh month of pregnancy. The placenta was protruding through the orifice of the vagina. I immediately extracted it, and a dead child followed. A great hæmorrhage succeeded, and she remained for a considerable time insensible, without any pulse to be felt at the wrists. She, however, gradually recovered.

CASE V.—On the 24th of March, 1835, I was requested by Mr. French, surgeon to the St. James's Parochial Infirmary, to deliver a patient of the institution, who had uterine hæmorrhage, with presentation of the placenta. A great quantity of blood had escaped, and she was much exhausted. The os uteri being soft and largely dilated, I immediately proceeded to deliver, by passing the right hand into the uterus, through the opening made by the detachment of the placenta from its cervix, and by rupturing the membranes and turning the child. No difficulty was experienced in extracting the trunk, the head, and superior extremities of the child, and the placenta soon followed. The hæmorrhage immediately ceased, and the recovery was rapid. The child was dead.

Nothing could be more easy than the operation of artificial delivery in this case, and its performance required only a few minutes.

CASE VI.—A few days after the preceding case I was consulted by the late Mr. Gosia, about a patient in the eighth month of pregnancy, who had flooding from attachment of the placenta to the lower part of the uterus. A large quantity of blood had been lost, and it was evident from the effect produced by this upon the system, that she would speedily sink if artificial delivery were not at once performed. The orifice of the uterus was widely dilated, and a large mass of the placenta, detached, was distinctly felt through it. The operation of turning was immediately performed, as in the last case, the hand being passed up into the cavity of the uterus, at the part where the separation

of the placenta from the cervix had taken place. The placenta was soon after removed, and the hæmorrhage did not return. The child was still-born. The mother recovered rapidly.

CASE VII.—On the 26th April, 1835, I was called to a patient of the St. Marylebone Infirmary, who was more than seven months pregnant, and had been attacked fourteen days before with alarming uterine hæmorrhage. The first discharge of blood took place during the night, when she was at rest; it was not preceded by a sense of uneasiness about the uterus, and could be referred to no accident or injury of any kind.

A considerable oozing of blood still continued when I first saw her. The placenta presented. The orifice of the uterus was opened to the size of a crown-piece, but its margin was so hard and undilatable, that I found it impossible, without employing too great force, to pass the hand into the uterus. After a cautious trial for about half an hour to get the hand insinuated through the orifice, I was compelled to withdraw it altogether, as there was no hope of overcoming the resistance.

On the 27th the flow of blood continued. The strength remaining unimpaired, and the os uteri being not less unyielding, I resolved to wait till relaxation should take place, and moderate the discharge by the recumbent position, and the application of cold externally and internally.

28th.—A large quantity of blood suddenly escaped, which produced syncope. The countenance was afterwards pale, the extremities cold, and the pulse rapid and feeble. The os uteri being soft and dilatable, I immediately passed up the hand, and delivered by turning. The child was born alive. The placenta was removed soon after; but though no further loss of blood was experienced, she continued gradually to sink, and died in a few days.

CASE VIII.—On the 7th October, 1835, I was requested by Mr. Gairdner, of Foley Place, to see a patient residing in Frith Street, who had completed the seventh month of pregnancy, and had been attacked with uterine hæmorrhage three weeks before. A slight discharge of blood had continued during the whole of this period, but it had produced little

effect upon the system until a few hours before I saw her, when several pints of blood were suddenly discharged, and her whole strength seemed at once extinguished. The pulse was not perceptible. The extremities were cold, and the respiration feeble. The blood still continued to flow in great quantities, and it was evident death would soon take place if the uterus were not speedily emptied of its contents.

The os uteri was not dilated to the size of a crown, and it was so rigid that I found it absolutely impossible, though I employed a degree of force scarcely justifiable, to pass more than three fingers within it. The whole hand could not be made to pass, though it appeared certain that death would soon take place if delivery was not immediately accomplished. On the fingers being withdrawn for a short time, the flooding continued. I made another effort to turn the child, but the resistance could not be overcome. I then pressed forward the fore and middle fingers of the right hand between the placenta and uterus, so as to reach the membranes, which I succeeded in tearing open. Pressing the fingers still forward, they came in contact with one of the feet, which they grasped and brought down into the vagina. This was pulled lower and lower, till the whole extremity and nates were drawn into the os uteri; but so rigid did it continue to be, that although I exerted all the force I dared employ in dragging it down, half an hour elapsed before the pelvis of the child could be made to clear the orifice of the uterus. At last it was extracted, with the placenta, and the hæmorrhage ceased.

A violent rigor followed, which threatened for a time to destroy the patient. Bottles of hot water were applied to the feet and pit of the stomach, the whole body was covered with hot blankets, and brandy was liberally administered.

She slowly recovered from the effects of the immense loss of blood.

CASE IX.—On the 18th October, 1835, Mrs. Ryan, whose pelvis is greatly distorted by rickets, was attacked suddenly with profuse uterine hæmorrhage, in the eighth month of pregnancy. I had delivered her once by craniotomy, and induced premature labour six times. She refused to submit to the operation

on this occasion. On examination, at 4 o'clock the following morning, a large portion of the placenta was felt detached and protruding through the os uteri. The orifice, though little dilated, was in a state to admit of artificial delivery, but so great was the distortion of the pelvis that I found it impossible to introduce the hand within the pelvis to turn the child. The flooding still continued. There were no labour pains. I could feel the head above the brim of the pelvis, and I determined to endeavour to open and extract it with the crotchet. Mr. Brookes, surgeon to the British Lying-in Hospital, pressed hard over the fundus uteri, while I carried forward the fore and middle fingers of my left hand to the head, which I could scarcely touch. In the groove formed between these fingers, the point of the perforator was conducted to the head, and pressed steadily through the integuments and bone, and then the blades were opened. The undilated state of the orifice rendered this difficult, but it was accomplished without inflicting any injury on the orifice.

The crotchet was then introduced into the opening in the skull, and the head was dragged down, between the placenta and uterus, into the brim of the pelvis, where it stuck fast for a long time. The orifice of the uterus was still imperfectly dilated. After four hours very hard work, we succeeded in getting the base of the skull through the brim into the cavity of the pelvis, and delivered.

The placenta was removed soon after the child, and no hæmorrhage followed. This woman recovered in the most favourable manner, and she has since had premature labour induced twice, at the end of the seventh month of gestation.

CASE X.—At 6½ A.M., 28th October, 1835, I was called, by Mr. Cathrow, of Weymouth Street, to a patient seven months pregnant, who had been attacked with uterine hæmorrhage fourteen days before. It had occurred spontaneously. It returned slightly a week ago, and again went off. This morning it was renewed with increased violence, and was accompanied with labour pains. Mr. Cathrow examined, and found the placenta protruding through the os uteri. He drew it forward gently, and the whole ovum escaped without rupture of the membranes. The flooding ceased on the application of cold vinegar and

water to the external parts, and she was soon quite well.

A similar accident had occurred to her in a former pregnancy.

CASE XI.—At 11 A.M., on the 30th October, 1835, I was requested, by Mr. Crellin, Wellington Road, to see Mrs. S—, æt. 40, who was in the ninth month of pregnancy, and for fourteen days had suffered from slight uterine hæmorrhage. On the 29th, and morning of the 30th, it greatly increased, and was accompanied with alarming fits of faintness, succeeding each other rapidly. I found the os uteri dilated to about the size of a crown-piece, and rigid. The placenta, partially detached, was felt at the posterior part of the neck of the uterus. The membranes were distinctly felt at the anterior part, and the head of the fœtus presenting above them. The pulse was neither rapid nor feeble, and the strength did not seem much impaired. I endeavoured, with the nail of the fore-finger, to tear the membranes, and believed I had done so, but was mistaken. The hæmorrhage soon returned, when three doses of the ergot of rye were administered by Mr. Crellin; but, though pains were produced, the hæmorrhage continued, and at 4 P.M. I discovered that the membranes were entire, and that no liquor amnii had escaped. I drew the nail, like a saw, for some time over a portion of them, and at last the liquor amnii began to escape in large quantity, and strong uterine contractions followed. The head of the child was soon pressed down between the anterior portion of the neck of the uterus and the placenta, where the separation had taken place, and the labour was safely completed in an hour. There was no hæmorrhage after the membranes had been perforated. The child was dead.

This patient had not recovered from the effects of the loss of blood for several weeks, and for several months a constant sanguineous discharge from the uterus remained.

In several other cases, similar to the preceding, of partial placental presentation, the membranes were ruptured, and the delivery safely completed without the operation of turning.

CASE XII.—On the 10th of November, 1835, I was requested, by Dr. N. Grant, to see a woman, residing in Lower James Street, who had been sud-

denly attacked with profuse uterine hæmorrhage in the eighth month of pregnancy. Six days before, without any accident, when she had gone out to market, a great gush of blood took place from the uterus, which produced faintness. No fresh discharge occurred till this afternoon, when another immense flow of blood took place, and complete prostration of strength followed. When Dr. Grant was called to her, at 3½ P.M. the hæmorrhage continued, and she was almost completely insensible, with cold extremities and a rapid feeble pulse. He found the placenta presenting. At 4 P.M. the flooding continued. The vagina was partially filled with clotted blood. On passing up the hand, I found the placenta adhering all round to the neck of the uterus. There was no point where the organs were completely separated from one another, where the hand could be readily introduced into the cavity of the uterus. The os uteri was considerably dilated. I found, on attempting to pass the hand, that it offered great resistance. This was, however, gradually overcome, and the fingers were slowly insinuated behind, between the uterus and placenta, into the cavity, and the membranes were ruptured, and the child speedily delivered by turning. The placenta came away soon after, and an immense flow of blood immediately followed. This was soon checked by the external application of cold and the introduction of the plug; but the pulse became imperceptible; the face covered with a clammy perspiration; the lips and hands livid; the breathing hurried, with great restlessness, and she died two hours after. Stimulants were wholly ineffectual in this case.

CASE XIII.—St. Marylebone Infirmary, 17th November, 1835. A young married woman, the eighth month of her second pregnancy, was brought last night into the lying-in ward, in consequence of an attack of uterine hæmorrhage. She reported it to have been produced by great bodily exertion the preceding day. The hæmorrhage had almost entirely ceased on the 16th.

2 P.M. on the 17th, I examined, and found a portion of the placenta detached within the orifice of the uterus. The os uteri was slightly open, and rigid. Pulse not feeble; faintness entirely

gone. As she was not in a condition to admit of artificial delivery, rest in the recumbent position, cool air, &c. were recommended, until the circumstances should justify interference.

18th. — The hæmorrhage returned, and the edge of the placenta being distinctly felt passing into the membranes, they were ruptured, and the liquor amnii discharged. Labour pains soon came on, and a dead child was pressed down between the uterus and placenta, where they had been separated. The placenta was extracted soon after, and the hæmorrhage did not return.

This woman died afterwards in the wards of the Infirmary, from deep-seated inflammation of the uterus.

CASE XIV.—I was requested by Dr. Boyd, assistant surgeon to the St. Marylebone Infirmary, to see a patient belonging to the institution, who had been attacked on Christmas-day with uterine hæmorrhage, during a severe fit of coughing. It disappeared without producing faintness, but returned thrice, to a much greater extent, and produced a marked effect upon the constitution. The countenance, when I first saw her, was pale, the hands cold, the pulse rapid and feeble, and a considerable hæmorrhage still continued. There were no labour-pains. The movements of the child had been recently felt. The os uteri was so much dilated that the points of four fingers and the thumb could be readily passed into it. The circumference was not thin, but it was soft and dilatable, and I experienced no difficulty in introducing the hand between the anterior part of the orifice and the detached placenta, a portion of which was banging into the vagina behind. Before the whole hand entered the cavity of the uterus, or the membranes were ruptured, I had grasped one of the feet. The operation of turning was easily completed, and the child was born alive. The binder had been applied around the abdomen before the operation was begun, and it was tightened several times during the progress of it. I left the placenta for some time in its situation after the extraction of the child, to produce the effect of a plug: it was afterwards removed without difficulty, after the uterus had contracted, and the patient recovered in the most favourable manner.

CASE XV. — March 24, 1836, I was requested, by Mr. Saunier, to see a patient, seven months pregnant, who, after suffering for several days from slight uterine hæmorrhage, was suddenly reduced to a state of the most alarming weakness, from a great gush of blood taking place. When I saw her, the blood was flowing copiously. The placenta could be felt adherent at the back part to the cervix uteri; at the fore part I felt the membranes. The orifice was so rigid, that it was impossible to pass the hand into the cavity of the uterus, to turn. I ruptured the membranes, and a great quantity of liquor amnii escaped, after which the flooding entirely ceased.

The ergot of rye was given, but labour-pains did not come on till the afternoon of the 26th, the second day after the membranes had been ruptured, when the child and placenta were expelled without a renewal of the hæmorrhage.

On the 28th she had violent rigors, with headache, delirium, and a rapid feeble pulse. Symptoms of uterine phlebitis manifested themselves in a few days, and she died on the 11th of April, from inflammation of the lungs. For a week before death, she suffered excruciating pains in the right shoulder-joint and arm.

CASE XVI.—May 12, 1836, I was requested, by Mr. Kennedy, to see a patient who had awoke in the morning greatly alarmed by a discharge of blood from the uterus. The quantity lost had not been great, and the strength of the constitution was unimpaired. The orifice of the uterus was high up, and slightly open. I felt the placenta at the cervix. There were no labour-pains. Delivery was considered unadvisable at the time.

15th.—Hæmorrhage has continued, but not profusely, until this morning, when a great quantity of blood suddenly escaped, and she became extremely faint. There were no pains. The os uteri was largely dilated. I introduced the fingers of the left hand through the os uteri, and before the whole hand had passed into the cavity, I was able to lay hold of one of the feet and turn the child. The child was dead. The placenta was extracted soon after, and the flooding ceased. She recovered favourably.

CASE XVII. — On the 3d December, 1836, I was called, by a medical practitioner, to a patient seven months pregnant, who had been attacked, on the morning of the previous day, with uterine hæmorrhage. It returned twice in the course of the day, and again ceased, without producing any great effect upon the constitution. The ergot of rye was repeatedly given, without any attempt being made to ascertain whether or not the placenta presented.

At 1 A.M., when I first saw the patient, the extremities were cold, and pulse scarcely to be felt. She was extremely faint. The os uteri was widely dilated, and a large portion of the placenta felt at the posterior part of the cervix. The operation of turning was easily performed, and did not last five minutes. The child was dead. The uterus having contracted, the placenta was removed in half an hour after the child. No hæmorrhage followed.

For three days she appeared to be recovering. Rigors, urgent thirst, pyrexia, pain in the loins and right side of the abdomen took place, and she died about ten days after, with the usual symptoms of inflammation of the veins of the uterus.

CASE XVIII. — On the 20th December, 1836, Mr. Gaskell, of King's Road, Chelsea, requested me to see a patient residing in Lower Eaton Street, who had been attacked with repeated discharges of blood from the uterus, in the eighth month of pregnancy. The placenta was felt through the orifice of the uterus. The flooding had produced great exhaustion, yet the orifice of the uterus was not in a condition to admit of artificial delivery. For some days the hæmorrhage was controlled, but it returned with great violence, and Mr. Gaskell passed up the hand into the uterus, and delivered the child alive. The placenta soon came away, and Mrs. O. appeared for two hours to recover, and then suddenly expired without any further loss of blood.

CASE XIX. — On the 10th March, 1837, I was called, by a surgeon residing near Holborn, to see a patient who had been attacked with profuse uterine hæmorrhage four weeks before, when at the end of the sixth month of pregnancy. It had returned at intervals, but in a slight degree. During the pre-

ceding night a large quantity of blood had escaped. Twenty grains of the ergot of rye had been administered about half an hour before I saw the patient, although no examination had been made to ascertain the actual state of the case. Pain followed the ergot, and a great increase of the discharge. I found the orifice of the uterus soft and widely dilated, and a large portion of the placenta hanging through it, detached from the cervix. I passed up the hand readily into the uterus, and laid hold of one of the feet of the child before the membranes were ruptured. The child was extracted alive without difficulty. The placenta was left as a plug till the uterus had contracted. The patient speedily recovered.

CASE XX. — On the 19th July, 1837, Mr. Tucker, of Berners Street, requested me to see a patient in St. Martin's Lane, who had presentation of the placenta, and was reduced to a state of extreme exhaustion by the loss of blood. She was near the full period of pregnancy, and during the preceding seven days had, at short intervals, lost a large quantity of blood. I passed the hand readily through the orifice of the uterus, though it was not dilated more than an inch and a half in diameter, and after rupturing the membranes, grasped the feet of the child, and delivered without difficulty. The placenta was not removed for a considerable period. No hæmorrhage occurred, and the patient recovered after a severe attack of uterine phlebitis.

CASE XXI. — On the 11th June, 1838, Dr. Boyd sent to request me to attend an out-patient of the St. Marylebone Infirmary, who had been attacked, five days before, while in the seventh month of pregnancy, with uterine hæmorrhage. A great quantity of blood had been lost, and the discharge going on rapidly, with frequent fits of syncope, Dr. Boyd proceeded to deliver by turning. I saw her soon after, when the placenta had been removed, and the hæmorrhage had ceased. There was still great faintness, the extremities were cold, and the pulse scarcely perceptible. She recovered from the immediate consequences of the hæmorrhage, but afterwards died with all the symptoms of suppuration of the uterine veins.

CASE XXII. — On the 12th January, 1839, Mr. Jones, of Carlisle Street, Soho Square, called me to see a lady in the eighth-and-half month of pregnancy, who had been attacked with uterine hæmorrhage a month before. It first took place without any accident or pain, and the quantity lost was about half a pint, and it produced little effect upon the constitution. She remained quiet for several days, and then got up, and only felt a little weak. For ten days she went about, but the hæmorrhage returned on the fifteenth day after the first attack, but not to a great extent. Seven days after this a third and more profuse hæmorrhage took place; it gradually went off, but not so quickly as the other attacks.

At one o'clock, 12th January, it was renewed to an alarming extent, without any pain. About a quart of blood was suddenly lost, and she became extremely faint. At 4 A.M. the discharge still continued. When I first saw her, at 7 o'clock, she felt faint; the pulse was rapid and feeble; the upper part of the vagina was filled with a large clot of blood, which adhered to the os uteri. By displacing this at the back part, I could distinctly feel the placenta adhering all round to the neck of the uterus, which was thick and rigid, and very little dilated. The effect produced by the hæmorrhage was so great, that it was evident death would soon take place if the delivery were not speedily completed; and the state of the orifice was such, that it was certain the hand could not be passed but with the greatest difficulty. At 8 o'clock Dr. Merriman saw her with us, and agreed that immediate delivery was necessary. I passed the right hand into the vagina, and insinuated my fingers between the uterus and placenta at the back part, and reached the membranes; but the rigidity of the orifice was such, that though I employed great force for a considerable time, I could not succeed in getting the whole hand into the uterus. Dr. Merriman recommended rupturing the membranes; and I was proceeding to do this with the fingers, when I felt one of the feet of the child, which I grasped and brought down into the vagina enveloped in the membranes, which then gave way. Nearly half an hour elapsed before the version could be completed; and when it was effected, the neck of the uterus grasped

the neck of the child so firmly, that I experienced the greatest difficulty in extracting the head, and not till I had made pressure for some time with the fingers, and dilated the orifice of the uterus. A great discharge of blood instantly followed; the placenta was removed, and every means employed to stop the hæmorrhage; but the breathing became hurried, the extremities cold, and she died in less than an hour after delivery.

Dr. Merriman informed me that a patient of his had actually died under similar circumstances, before the head could be extracted.

The last case of hæmorrhage from placental presentation which I shall relate, occurred to Dr. H. Davies and myself, still more recently; and the circumstances were, if possible, still more distressing and unfortunate.

CASE XXIII. — Mrs. H. was attacked with uterine hæmorrhage at the beginning of February 1839, when seven and a half months pregnant. About twelve days after it returned a second time, and yesterday morning a third time. About half-past 12, on the night of the 5th March, 1839, Dr. Davies requested me to see her with him, as the hæmorrhage had returned in a dangerous form, and the orifice of the uterus was not in a condition to admit of delivery. We found the placenta adhering all round to the neck of the uterus, the orifice rigid and undilatable, and open to the extent of a crown; the head of the child presenting. By cold applied externally and internally the hæmorrhage was restrained till six o'clock in the morning, when it was renewed with violence; the orifice in the same state. Dr. Davies then pressed his fingers through the placenta, tore it in two parts, and perforated the membranes.

8½ A.M. — No hæmorrhage; slight pains.

11 A.M. — No flooding; head pressing into the orifice of the uterus. We were prevented at this time from perforating and extracting the head by the rigid state of the os uteri. She seemed to regain strength during the day, but at 10 in the evening, without any further loss of blood, she began to breathe with great difficulty; the lips were livid, the hands and feet cold, and it was evident she would soon die undelivered if we did not interfere.

I opened the head, and extracted it with the greatest difficulty, in consequence of the firm and rigid state of the os uteri. The operation was scarcely completed before she was dead.

ON THE
BLOOD-VESSELS OF TENDINOUS
TISSUES.

By JAMES PAGET,

Demonstrator of Pathological Anatomy, and
Curator of the Museum, at St. Bartholomew's
Hospital.

THE vessels of the long and rounded tendons, in which the structure peculiar to this class of tissues is found in the greatest purity, have not yet (so far as I know) been accurately described*. By some their existence has been denied; and by others it has rather been assumed from the powers of growth and repair which these tissues possess, than proved by actual demonstration. The subject which would at any time have been of some interest has of late become important, by the frequent performance of operations on the tendon of the gastrocnemius and other muscles.

The vessels connected with the tendons are of two kinds; one set being distributed in the loose filmy cellular tissue, or synovial sheath surrounding the tendon; and the other in its very substance. The vessels of the sheath are easily injected, and are those which are generally preserved in museums, and figured as the vessels of tendon. Their chief trunks are of considerable size, and pass to the sheath near the middle of the length of the tendon; their

branches are given off with great irregularity, and after traversing the tissue in a vaguely arborescent form, and frequently anastomizing, terminate in a moderately dense net-work. Each artery has two associated veins.

The vessels of the substance of the tendon are quite distinct from these. They run in straight and parallel lines, from one end of the tendon to the other, between the fasciuli, rarely giving off branches and rarely anastomizing. Of the few branches which are given off, the greater number separate gradually and at a very acute angle from the trunk, and then pursue their course parallel to it; but occasionally a branch passes transversely across the intermediate tendinous fibres, from one vessel to another adjacent to it. The vessels of the substance communicate but rarely with those of the sheath of the tendon, and are derived from the vessels of the muscle or of the part in which the tendon expands to be inserted; so that I have sometimes succeeded in completely injecting both ends of a tendon, while the vessels of the middle portion remained empty. Each artery is accompanied by a single vein.

According to the measurement of my friend, Dr. Baly, the diameter of the straight vessels is about 1-1650th of an inch; and they retain the same size through their whole length. The spaces intervening between the adjacent and parallel vessels are much wider than the vessels themselves; yet, in a well-injected and dried tendon, they are sufficiently close to give the whole mass a brilliant red colour when it is viewed from a short distance against a dark ground. In their degree of vascularity, I should place tendons between muscles and the compact structure of bones; the place which would also be suggested by a comparison of the respective activity and completeness of the powers of repair of each of those tissues.

The same general plan of vascular arrangement is found in all the tendinous tissues. In the aponeuroses and in the fasciæ which contain tendinous fibres, the arrangement is somewhat complicated; the cellular interspaces between the glistening tendinous fasciuli are larger than in the tendon, and numerous minute vessels pass irregularly through them, from one surface of the membrane to the other. A linear and parallel arrangement of the proper

* Among many works to which I have referred, I may mention, Ruysch, *Opera Omnia*. In *Thes. Anat.* Asser. 1, No. 6, and in *Thes. Max.* No. 203, *Injections of the sheaths of the tendons of the gastrocnemius and flexors of the toes.*

Albinus, *Historia Musculorum*, p. 11. He speaks of vessels both within and without the tendons, but does not particularly describe either.

vessels is, however, easily discerned, and where the membrane is composed of two series of tendinous fibres interwoven at right angles with each other (as in the palmar fascia, where it separates into slips near the articulations of the metacarpal bones with the phalanges,) there are also two sets of straight and parallel vessels crossing each other in different planes.

In the cord-like ligaments, the same arrangement of vessels is found as in the round tendons; and in the expanded ligaments the same as in the aponeuroses. In both, the vessels of the tendinous tissue are distinct from those of the cellular tissue enveloping or incorporated with it, and the general vascularity of the whole is in direct proportion to the quantity of cellular tissue. In the fibro-cartilages, also (as far as I have been able to inject them), the same plan exists. In the semilunar cartilages of the knee-joint, for example, vessels run in the substance of their thick margins, in arcs of concentric circles, following the course of the tendinous fibres.

It is not easy to imagine why it should have appeared so difficult to inject the vessels of the more perfect tendinous tissues. The material which I have employed is the common mixture of size and vermilion, which I have impelled with some force into one of the main arteries of the limb. The cellular sheath should be dissected off, and the tissue slowly dried, with care that it is not too much stretched. The first and best injection I have made is of one of the flexor tendons of the foot of a calf about a week old; and I imagine that young subjects are the best; but I have succeeded in effectually injecting all the tendinous tissues of the leg and arm in persons of between 30 and 40 years of age.

3, Serle Street, Lincoln's Inn.

CASE OF SCROFULOUS ABSCESS OF BOTH KIDNEYS,

IN A BOY, AGED TWELVE YEARS.

To the Editor of the Medical Gazette.

SIR,

I SEND the enclosed case for insertion in your valuable periodical, should you

consider it worthy of being recorded in your pages.—I am, sir,

Your obedient servant,

S. G. LAWRENCE.

Royal Military Asylum, Chelsea,
July 6, 1839.

Joseph Grant, aged 12 years, born at Gibraltar, was admitted into this institution in July 1836. A boy of scrofulous constitution, having a dry furfuraceous state of the skin, with occasional enlargement of the submaxillary lymphatic glands; rarely, however, in the hospital, except for trifling complaints of a few days' duration, until February 5, 1839, when he was admitted for severe ulcerated chilblains.

In the beginning of March he was attacked with fever, but did not complain of much local pain; nor was attention drawn to the state of his urinary organs until the 28th of March, when he complained of pain and smarting in making water, with very frequent desire to make it. On examination, there was œdematous swelling of the prepuce, with slight enlargement of the body of the penis; and a small circumscribed swelling, of the size of a small hazelnut, in the course of the urethra, just in front of the scrotum, very hard, and painful under pressure. Two or three of the inguinal glands in each groin were also enlarged, apparently from sympathetic irritation. He could assign no cause for this swelling, and said he had only perceived it a day or two. Pulse 120; dry, unperspirable skin; thirst; frequent micturition; and the general symptoms of fever. His urine was observed to be turbid and milky, soon forming a deposit, and, on being tested, had little or no effect on either litmus or turmeric paper. On the 30th March, the swelling had increased to the size of a small walnut, and fluctuation being perceptible, it was punctured, and about a tea-spoonful of pus evacuated. Mr. Stanley, surgeon of St. Bartholomew's Hospital, saw the boy with me at this time; and we sounded the bladder, suspecting calculus, but nothing could be perceived, excepting that it was in a very irritable state, and the operation appeared to give the boy much pain. In a few days the febrile symptoms were mitigated, but his pulse continued very quick, varying from 100 to 120; and the irritable state of the bladder remained the same, as also the

state of the urine. He was frequently asked if he had any pain in his back or loins: he always said he had not. The region of the kidneys was often examined, and pressure used, but he only complained of the continual desire to make water, with pain in voiding it—passing only from half an ounce to an ounce at a time.

April 6th.—The urine now passes both through the fistulous opening in front of the scrotum and orifice of the urethra; the meatus is also slightly ulcerated. The urine continues turbid and milky, and deposits a copious sediment very soon after it is voided. I took some of the urine to Dr. Prout, who was so kind as to analyse it. He stated that it was serous and purulent, and that it was strumous pus, and thought it most probably proceeded from the kidney; for, in his experience, he had never found such matter in calculous cases. He also prognosticated a fatal termination.

From this time the boy continued nearly the same, with very little variation in the symptoms, except that he gradually emaciated; and the character and appearance of the urine remained unchanged, but the purulent deposit varied as to quantity.

May 6th.—The urine now begins to dribble from him when in the erect posture, and an accumulation of it appeared to take place in the perineum behind the scrotum, forming a small pouch in the membranous part of the urethra; so that by pressing that part, it oozed out both from the fistulous opening and orifice of the urethra.

16th.—He now began to have evening febrile exacerbations, and regular hectic fever commenced. He still says he has no pain any where, except in the urethra and perineum; and is chiefly inconvenienced, and his rest disturbed at night, by the irritable state of the bladder requiring him to make water almost every hour. There is also more ulceration of the meatus urinarius, and excoriation of the scrotum is threatened by the constant dribbling of the urine.

27th.—The urine this morning contained an increased quantity of purulent deposit, with some ropy mucus; and emaciation more sensibly and rapidly increases. Hectic fever continues, and his appetite, which has been always very capricious, begins to fail. The pouch or deposit of urine in the peri-

neum does not enlarge, but, on pressure, is always found to contain a small quantity of urine.

June 4th.—To-day, for the first time, he complained of pain on the left side of his chest, and over the region of the kidneys, increased by pressure. He has also had, the last few days, a short dry cough; his countenance, at all times expressive of pain and anxiety, has now become more so, and he is evidently sinking; his pulse is very quick, and like a thread; and his appetite has entirely failed him.

10th.—He now speaks with difficulty, but is quite sensible. The stomach has become irritable, and rejects both food and medicine. The irritability of the bladder is extreme, but the turbid and purulent character of the urine has all along continued the same, and did not undergo decomposition or change on being kept for several days. The scrotum having been protected, has not excoriated; but there is deep ulceration round the meatus urinarius. He appears to suffer much, and is evidently dying.

11th.—He died at five o'clock this afternoon, being perfectly sensible to the last, and was apparently suffering less this morning.

Regarding the treatment it is not necessary to say much, as it could be only palliative. In the first instance it was antiphlogistic, with tepid baths, anodynes, &c.: afterwards tonics were employed, such as decoct. uræ ursi, quinine, light preparations of steel, &c., with good, nourishing diet; in short, the scrofulous diathesis was kept in view, and the medicines employed adapted to it. The peculiar, dry, furfuraceous state of the skin was remarkable, and a perspirable state of it could not be produced by any of the remedies.

Examination of the body: Thorax.—The lungs on both sides adhered to the parietes of the chest, but the adhesions were evidently of long standing. At the posterior part of both the right and left lung, a vomica of the size of a small hazel-nut was found, containing purulent matter; a few tubercles were also found dispersed throughout their substance, the greater part of which, however, was crepitating and healthy. The heart and pericardium were natural.

Abdomen.—On opening this cavity, the omentum, which was entirely desti-

tute of fat, and the whole of the peritoneal surface of the intestines and viscera, were studded with small yellowish tubercles; also between the folds of the mesentery; but the mesenteric glands were of normal size and appearance. The right kidney was next examined: on pressing it gently, previous to cutting into it, pus flowed freely out through the ureter to the amount of two or three drachms. On laying it open, several abscesses were seen; and the pelvis was ulcerated, abraded, and entirely denuded of its mucous surface. On slitting up the canal of the ureter, the mucous lining was only partially removed, there being several spots of ulceration on various parts of its internal surface. The left kidney also contained several abscesses, and, together with the ureter, presented the same appearance of disease as the right.

The bladder, which was much contracted, was then removed, together with the penis and urethra. On slitting up the latter, its mucous surface was found ulcerated and abraded, with two ulcerated holes in it, from which the urine and pus had evidently escaped, forming the small fistulous abscess which appeared in the urethra, in front of the scrotum, during life. There was also deep ulceration of the meatus urinaris. The incision was then continued to the fundus of the bladder, which was quite empty, its external muscular coat thickened, and the internal completely denuded of its mucous surface, contracted, and rugous.

The liver and other viscera exhibited nothing worthy of notice.

REMARKS.—It is rather curious to observe how the ulcerative process was continued throughout the whole of the urinary organs, from the kidneys even to the orifice of the urethra. I may here also mention, that this boy's brother, aged eight years, who was born in Scotland, and admitted into this institution, from Gibraltar, in July 1837, died, on the 28th April last, of marasmus and general tubercular disease. On the post-mortem examination, the lungs were found hepatized and tuberculated, some of the tubercles in the first stage of softening or suppuration.

The peritoneum, covering the abdominal viscera, was studded with numerous grey-coloured tubercles, of the size of small peas. The mesenteric glands

were much enlarged, and several of them converted into the peculiar, scrofulous, cheesy substance. The liver adhered firmly to the ribs and diaphragm, and contained several tubercles in its substance. The kidneys and urinary organs were in a perfectly healthy state.

The hereditary nature of tubercular disease was, I think, very strongly marked in the above instances. I am also sure, from the records which I have kept of post-mortem examinations for the last twenty years, that I may confidently assert that more than two-thirds of the deaths occurring among the children in this institution, are from scrofulous and tubercular disease.

I may add, that out of the great number of such examinations which I have made, this is the first instance in which I have met with any disease in the kidneys in children, and am therefore led to conclude that it is rare.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

The Discovery of the Vital Principle, or Physiology of Man. London, 1838. 8vo. pp. 566.

WE recollect that many, many years ago, when we were schoolboys, a valuable publication appeared on the 1st of April for several times running. It was called the *Quizzical Gazette*, and its contents corresponded to its title. If you wanted a receipt for preserving pigeon's milk, or an exact transcript, in obsolete short-hand, of the statutes on lunacy passed in the Madeiras (mad eras), this was the journal to consult. Who was the editor of the pleasant periodical was as great a mystery as the authorship of Icon Basilike, or Junius's Letters. We cannot help suspecting, however, that the editor of the *Quizzical Gazette* and the discoverer of the vital principle must be one and the same person. If so, it is to be feared that, in growing old and rich, his mind has become obtuse, while his body has been growing obese; for, to speak candidly, his jokes do not tell. They may have been well conceived, but they are not well brought forth; or, as the Irish-

man said, they have been changed at nurse; and in our humble yet infallible opinion, a sixpenny number of the *Quizzical* was worth the lusty twelve shilling volume before us twenty times over.

That the author labours under a superfluity of money is clear from the bigness of his book. An octavo of five hundred and sixty odd pages, nicely done up in fancy cloth, is not brought out for a song. No starveling scribbler, accustomed to write at so much a sheet, would ever think of giving away 500 copies of so corpulent a treatise. We say "giving away," for the thing is unquestionably as unsaleable as last year's Almanack, or Curtis on the Ear. Nay, "if this be appreciated, another volume is in contemplation, in which it is proposed to give a more enlarged and comprehensive view of the primary and henceforward all-important subject—the Disease of Man."—(Preface, p. x.)

Our prophetic imagination already sees "the Disease of Man" disposed of at four-pence a pound.

"Deferar in vicum vendentem thus et odores,
Et piper, et quicquid chartis amicitur ineptis."

"Our liberal author never stops,
But scribbles for the chandlers' shops;
What though no subject well he handles,
He's excellent on tallow candles."—*Anon.*

Just to shew you, gentle reader, that our author (or quondam editor) has become fatwitted by lapse of time, we will quote from the Preface the three propositions which he intends to demonstrate in his book:—

"1st. That an ovum was originally formed, containing within its circumference or boundary, all known matter in a solid, latent, and inactive condition. From this ovum has arisen,

"2dly, The fœtal or fluid state of matter, which has been endowed with active life for the purposes of organization; the heart being our sun, the other heavenly bodies—the several organs belonging to the fœtus: the whole (our earth included) progressing at the present period towards the structure of one complete human frame, analogous to that of *man*.

3dly. The future, or perfected existence of the present fœtus as a locomotive being of celestial substance and imperishable nature: this last period answering to the life of man subsequent to birth, which is the aeriform stage."

A capital programme, no doubt; but,

alas! the author makes nothing of it. The bill of fare is not the same thing with the dinner—as every one knows who has been at a bad, showy inn. The experienced diner asks, "What dishes are well dressed here?" Better to have good mutton, than fowls with every joint anchylosed.

If the Eccentric Society were to propose for their next prize dissertation the question,—Whether the present unsettled state of Europe does not arise from the decay of six-bottle men? it would be a sad balk if the candidates were to send in nothing but accounts of riots, and tables of the duty on wine. Now this is much the case with our author. Had he a scintilla of his former waggishness, such a programme would have afforded a mine of quips and cranks; he might have brought out a *Quizzical* daily, instead of yearly. Instead of this he gives us the contents of his common-place book touching carbon, iron, diamonds, and the like; and only relaxes now and then, as when he explains the "original formation of the moon or brain;" not neglecting to inform us that "the moon bears the same analogy to the earth as the head to the human fœtus."—(P. 265.)

But enough of this: those who want to learn more of our author's fancies must try to rescue a copy of this book from the dealers in such kind of paper.

—
An Inquiry into the Morbid Effects of Deficiency of Food, chiefly with reference to their occurrence amongst the destitute Poor: also, Practical Observations on the Treatment of such Cases. By RICHARD BARON HOWARD, M.D. &c. London, 1839. 8vo. pp. 77.

THE essay before us is the result of observations made by Dr. Howard, during a residence of more than eight years in the Royal Infirmary and Poor House, in Manchester. Exclusively of an introduction, there are seven chapters in the essay on the following subjects:—the nutrition and waste of the body; the symptoms of deficiency of food; general remarks on the morbid effects of deficiency of food; the pathology of inanition; the morbid appearances after death from inanition; diagnostic marks of the morbid states produced by starvation; the treatment of the morbid effects of the deficiency of food.

The following passage is instructive ; it is from the chapter on diagnosis :—

“Coma arising from exhaustion generally comes on gradually, though sometimes the attack of insensibility is sudden. It is not uncommon, for instance, for an individual exhausted with abstinence, to become giddy, stagger, and fall down senseless in the street. As soon as he is discovered, he is perhaps conveyed to an hospital, stupified and cold, with almost suspended action of the heart and respiration, and unable to answer questions. Now let us suppose that the miserable condition of the sufferer had attracted the pity of some passer-by, and that he had expended the pittance, bestowed upon him, at a dram shop, with the hope of reviving his prostrated strength ; the alcoholic draught would, very probably, by its powerful effect on so exhausted a frame, hasten that insensibility it was taken to avert. When in this state, his breath would be perceived to be tainted with the smell of spirits, and he would probably be considered by those who saw him to be in a state of disgusting intoxication, and left neglected to perish from cold and exhaustion. Such is by no means a rare case, and one which all who have been long attached to a public medical charity must have witnessed. The stupor, staggering, occasional wandering of the mind, and insensibility, consequent on exhaustion from starvation, are constantly mistaken by the public for intoxication ; and though, in the state of the pulse and pale collapsed appearance of the countenance, the medical man has symptoms to guide him in forming a diagnosis, yet, if an individual in the insensibility of intoxication has been long exposed to cold, the pulse becomes so much reduced, and the countenance so much altered, as to afford no certain criterion. Now, although it must be admitted that it is scarcely possible any error could be made in the treatment of such cases by any well-informed medical man who examined the patient, yet they do not the less shew, that the *cause* of the symptoms may often admit of doubt.”

On the whole, this is a plain, sensible essay, though not very striking. If Dr. Howard should re-write it, we would recommend him to deal less in generalization, or, at any rate, to give more of those minute and characteristic touches which shew that the painter is not

drawing from recollection, but with his subject before him.

It is a strange thing, by the way, that in a work on starvation, there should be no mention of the new Poor Law. Is this not like acting the tragedy of Hamlet with the part of Hamlet omitted—*by particular desire*?

MEDICAL GAZETTE.

Saturday, July 13, 1839.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”

CICERO.

SUCCESSFUL PHYSICIANS.

THERE are two perfectly opposite theories afloat concerning success in physic : the one has been forcibly expressed by Johnson, who says (in his *Life of Aken-side*), that “a physician in a great city seems to be the mere plaything of fortune ; his degree of reputation is, for the most part, totally casual ; they that employ him, know not his excellence ; they that reject him, know not his deficiency.” The contrary hypothesis is maintained by the authors of the *Lives of British Physicians* ; they assert that the gloomy observation of the great moralist points not to the rule, but to the exceptions ; and that study, diligence of observation, “and conscientious assiduity in practice, are crowned with all the distinctions which generous ambition aspires to reach.”

It is quite clear that Johnson’s apophthegm is a gross exaggeration ; for those who employ a physician commonly do so either on the supposition that the good sense which he shows in other things will not desert him in physic ; or by the recommendation of those who have had the opportunity of benefiting by his abilities. Dr. Johnson’s error seems to have arisen, in part, from taking too limited a view of the qualifications requisite for success, and consi-

dering physic merely as a science, forgetting that it is also a practical art. Thus Dr. Akenside's ill success might be deserved, although he may have been far from deficient in mere medical knowledge. Let us take, by way of illustration, an imaginary example. A boy with abilities above the average, of reserved manners and studious habits, has a taste for natural history. Chemistry and botany are his favourite pursuits; and should medical books or cases fall into his hands, he reads them with even greater avidity. He attends a course of lectures on comparative anatomy, and is delighted. This removes all doubt, if any doubt remained; his friends agree that he is evidently cut out for the medical profession, and as they are in tolerable circumstances, they make him a physician. Years roll on; he gets his dispensary, and writes an essay on the circulation, but still no practice comes; and as the disappointed family will not say "Tom was wrong, and we were wrong," they call him "the plaything of fortune," and aver that "his degree of reputation is totally casual."

They forget, or, as fondness is not critical, they have never seen, that his person is unprepossessing, his manner cold and dry; that he has an alarming talent for setting every one right, from my Lord Duke down to Sally the housemaid; and that the women cannot bear him, but universally say, that "he is very clever, only rather too serious for his age." Moreover—and perhaps this is the worst defect of all—he has no real taste for the practical drudgery of the profession. For, as many a man reads Horace with delight, who would shrink from bearing the fiftieth school-boy drawl through "*Donce gratus cram tibi;*" so many a physiologist will make able experiments on digestion, but fail in saying to his dyspeptic patients, "Chew your food; avoid cu-

cumber; pastry is an abomination." Yet without the constant repetition of the plainest facts, without the most sublime patience—nay, more, without the power of persuasion, physic, as a practical art, falls to the ground. The man who has not these qualities may teach physic to others, in as far as it is a science, but will not, and ought not to be sought after as a practitioner. To use the well-known illustration of the satirist, he will perform the part of a hone, which makes steel sharp, though itself unable to cut*.

Now we have not the smallest doubt that, in the majority of instances, those who have failed as physicians have been deficient in some of the qualities necessary to men whose success depends on diminishing the ills around them, morally as well as physically; for as the human body is often a more delicate test than the finest instrument, so public instinct will frequently point out defects which diplomas and medals, and papers in the *Philosophical Transactions*, might have hidden from our view.

On the other hand, it must be confessed that the authors of the '*Lives of British Physicians*' deal rather too summarily with the question, when they assert that the youthful reader will be satisfied from perusing their volume, that merit meets with its reward. For as they have professedly selected only the successful, how is the demerit of the unsuccessful to be learned from their book? No one will deny the talents of Huxham and Pringle; but how can we learn from their lives that the ill success of Akenside was merited?

It would be a difficult task, indeed; to weigh the merits of deceased practitioners in an accurate balance; to show how and why the impetuous Rad-

* ——— "Fungar vice cotis, acutum
Reddere que ferrum valet, exors ipsa secandam."

cliffe and the sober Fothergill equally attained an eminence which the poetical Akenside and the grave Aikin were unable to reach. But if this task would be difficult when its objects were the illustrious dead, how delicate would it become when performed upon the living? Who could venture, unswayed by preference or dislike, to analyse the compound, success, and show how much of it was made up of genius, industry, birth, fortune, and manner? Yet the author of a book which has just made its appearance* solves the difficulty by the simple expedient of one continued puff; he describes more than thirty London physicians of immense merit; and we are threatened with the portraiture of several more on some future occasion, who are now happily excluded for want of room. His praises are dealt out with such undistinguishing liberality, that they pall upon the palate, and become no more complimentary than the "pretty creature" of a parrot. Indeed, to praise with art is not quite so easy as might be imagined. Goldsmith says, "Though no people in the world flatter each other more than the English, I know none who understand the art less, and flatter with such little refinement. Their panegyric, like a Tartar feast, is, indeed, served up with profusion, but their cookery is insupportable. A client here shall dress up a fricassee for his patron, that shall offend an ordinary nose before it enters the room. A town shall send up their address to a great minister, which shall prove at once a satire on the minister and themselves†."

In order to improve this branch of science he proposes that we should copy some Eastern nations, and maintain professed flatterers. At certain Indian courts, he says, there is a *Karamatman*, whose business it is to

cry, *Karamat!* "A miracle!" whenever the king, from his smile and manner, is supposed to have said a good thing. It is clear, that this officer requires tact and discretion, as it is not every smile of the sovereign that demands the official exclamation. Now the author of "*Physic and Physicians*" is a very bad *Karamatman*, and continually calls out miracle! in the wrong place. In talking of Sir Henry Hallford, for instance, he says, "To be made a baronet—to have been for many years the chief court physician—to be for life, president of the first medical corporation in the United Kingdom—are, indeed, honours rarely, in this country, conferred on any one single individual." The plain fact is, that the President of the College is almost, as a matter of course, a Court physician, and is as sure of being made a baronet as a judge is of being knighted. Neither is he President for life, being subjected to an annual election. And when he sets about belabouring Sir Henry's Essays with his praises, he certainly exemplifies Goldsmith's censure, and flatters with very little refinement. Who but this mistaken person would speak of the "force and eloquence" in the President's paper "on the Education and Conduct of a Physician?" Elegant good sense is the characteristic of this and the other papers; great vigour there is not, and at eloquence there is no attempt.

Who but the compounder of "*Physic and Physicians*" would talk so boldly of Sir J. Clark's "unparalleled success in curing consumption;" who but he would say that before the publication of Sir James Clark's work on Consumption, "it was the generally received opinion in the profession, that *phthisical* disease was the common sequence of inflammation"? For ourselves we should be disposed to rest Sir James Clark's fame as a professional writer rather on his work upon Climate, than his treatise on

* *Physic and Physicians*: a medical sketch book, exhibiting the public and private life of the most celebrated medical men of former days; with Memoirs of eminent living London Physicians and Surgeons.

† Citizen of the World, letter 110.

Consumption. The author just quoted, indeed, dismisses the book on Climate in a line and a half; but he has such a wonderful knack at missing the best points, and expatiating on the wrong ones, that his brevity is a sort of confirmation of our opinion.

Again, in discussing the life and talents of Dr. Richard Bright, he tells us of his education, matriculation, and graduation; of his sketch of the zoology and botany of Iceland, and of his geological papers; nay, like an unfortunate player at blindman's-buff, he actually touches the desired object, though he cannot catch hold of it; for he mentions Dr. Bright's "admirable work on the Deranged Action of the Kidneys, as affecting the Cerebral Functions*," and his reports, which afford "practical information upon most diseases, but especially upon those of the kidney and the nervous system." But the great fact—the fact which has given Dr. Bright a European reputation—he misses. This fact (so well known that we are almost ashamed to mention it to our readers) is, his discovery of the connection between granulated disease of the kidney and dropsy with albuminous urine—a connection so frequent that the disease may be inferred from the secretion and the effusion. Dr. Bright has thus had his name conferred on a new disease, which is known on the continent as the *Maladie de Bright*, or *Morbus Brightianus*. Two lines stating this, or even alluding to it, would have been more to the purpose than the three pages dedicated to the biography of Dr. Richard Bright.

But what shall we say to the nonsense our Karamatman talks about Dr. Chambers? Of his "rising to the highest rank in his profession, although opposed by apparently insurmountable impediments;" of his coming to London "apparently friendless," and commencing his medical studies "under most

disadvantageous circumstances." If he knew how to praise—if he were acquainted with the best-known facts—he would have said of this distinguished physician, that though every thing has been in his favour—so that we have for many years heard him spoken of as one whose success was certain—yet has this been so great as to surpass the warmest hopes built on the most favourable auguries. Nor can we comprehend by what arithmetic the author makes out that the annual receipts of a physician whose "house is daily beset by patients," should only average "nearly 4000*l*." When detachments of the opulent sick besiege his doors, and his visits are limited only by his powers of physical endurance, we should conjecture that his fees must be considerably more numerous than ten and a fraction per day. Neither is it a whit more correct, notwithstanding what is said in "Physic and Physicians," that Dr. Chambers is either a lecturer on the practice of physic or examiner to the East-India Company, inasmuch as he relinquished both offices some years ago.

We shall probably return to this subject on an early occasion, and may also take some notice of what the author says concerning deceased practitioners. As he no longer thinks himself obliged to play Karamatman here, this part of his work is much superior to the sketches of living doctors, and will entertain the lovers of light reading. Yet how could he make so singular a mistake as the following one?—"Baillie (he tells us) was rejected at the College. He called the next day on Dr. Barrowby, who was one of the censors, and insisted upon his fighting him. Barrowby, who was a little puny man, declined it. 'I am only third censor,' said he, 'in point of age; you must first call out your own countryman, Sir Hans Sloane, our president; and when you have fought him and the two senior censors, then I shall be ready to meet

* There is no separate work on this subject by Dr. Bright.

you.”—(Vol. ii. p. 423.) We have heard of duellists whose pistols were loaded with currant-jelly; yet even such a combat would not be so safe as one between Baillie and the shade of Sir Hans Sloane—the latter having died nine years before Baillie was born. We need hardly add that Baillie was not plucked at the College, and that as he was a Scotsman, and Sir Hans Sloane an Irishman, they were not precisely countrymen. The compiler has evidently substituted Baillie for some other name; indeed we seem to have met with the story before, under better auspices. His *forte* is certainly rather in stringing anecdotes together, for the devotees of circulating libraries, than in the critical analysis of facts and characters.

ROYAL COLLEGE OF PHYSICIANS.

At the last *Comitia Majora*, Dr. Thos. Mayo, Dr. Richard Bright, Dr. George Burrows, and Dr. Robert Bentley Todd, were elected Censors for the ensuing year; and

Dr. George Gregory, Dr. Frederic Cobb, Dr. Henry Davies, and Dr. George Mann Burrows, were elected Fellows.

UNIVERSITY OF LONDON.

THE first examination for M.B. at the London University has just taken place. There were twenty-six candidates: of those, sixteen have passed, whose names we subjoin. We also give copies of the printed papers that our readers may be aware of the nature of the examination; and we may add, that, besides what appears in the printed papers, the candidates were subjected, during six hours on Thursday, and the like period on Friday, to *vivâ voce* examinations and demonstrations in anatomy, physiology, chemistry, materia medica, and pharmacy.

LIST OF GENTLEMEN WHO HAVE PASSED THEIR FIRST EXAMINATION FOR M.B.

First Division.

1. Ayres—University College.

2. Cooke—Webb-street School of Medicine.
3. Hindle—University of Edinburgh.
4. Lewis—University College.
5. Mackenzie—University College.
6. Mauger—Westminster Hospital School.
7. Quain—University College.
8. Smith—Birmingham School of Medicine.
9. Taylor—University College.

Second Division.

10. Girdlestone—University of Edinburgh.
11. Hobson—University College.
12. Lang—Sydenham College.
13. Nicholl—Aldersgate School of Medicine.
14. Purvis—St. Thomas's Hospital and Webb Street School of Medicine.
15. Storrar—University College.
16. Tones—King's College.

BACHELOR OF MEDICINE. 1839.

FIRST EXAMINATION.

Monday, July 1.—Morning, 10 to 1.

ANATOMY AND PHYSIOLOGY.

Candidates may illustrate their answers by sketching the parts they describe.

Examiners, MR. KIERNAN and DR. R. B. TODD.

1. Describe the clavicle and its relations to the surrounding parts, and in what respects the clavicle of the male differs from that of the female. What are the uses of the clavicle? in what manner are the motions of the shoulder impeded in fractures of this bone? in which fractures are they most, and in which least impeded, and which motions are principally impeded? On what anatomical arrangement does the difficulty of diagnosis, in certain fractures of this bone, depend?

2. Enumerate the different kinds of joints, and give examples of each kind. Describe the general mode of arrangement of the ligaments and muscles, and the motions which take place in each kind of moveable joint.

3. State the attachments of the diaphragm, the foramina by which it is perforated, the relations of those foramina to each other, and the parts which pass through them. Mention also the exact relative position of the convex surface of the diaphragm, on the right and left sides, to the parietes of the chest.

4. Enumerate the agents employed in effecting the act of expiration, distinguishing those which are employed in ordinary expiratory acts, and those which

are called into action in the more violent efforts of expiration.

5. Commencing the dissection at the integuments of the side of the face, how would you proceed to show the course and distribution of the internal maxillary artery and its branches, and the parts contained in the zygomatic fossa? Describe the steps of the dissection, mentioning the parts in the order in which they are met with, and describe the two pterygoid muscles, and their actions.

6. What changes does the air undergo in respiration, and how may those changes be accounted for?

7. Describe the position of the heart and its relations to the other contents, and to the parietes of the thorax.

Monday, July 1.—Afternoon, 3 to 6.

ANATOMY AND PHYSIOLOGY.

Candidates may illustrate their answers by sketching the parts they describe.

Examiners, Mr. KIERNAN and Dr. R. B. TODD.

1. Describe the crural canal. What are the varieties in the origin and course of the obturator artery, and what are the occasional relations of this vessel to the inner portion of the superior aperture of the canal?

2. State all the parts which are successively brought into view in dissecting an intercostal space from the skin to the pleura. Give their relative positions, and describe the intercostal muscles.

3. Describe the fundus of the bladder, and its relations to other parts, with reference to the operation of puncturing the bladder from the rectum.

4. What are the reasons for believing that the lymphatic vessels are absorbents?

5. Describe the origin and course of the first dorsal nerve as far as its junction with the brachial plexus. State the principal experiments which have been performed with the view of ascertaining the functions of the spinal nerves, and the conclusions derived from these experiments.

6. Enumerate the several parts of the organ of hearing in man, in the order of their relative importance. Describe the most important part, and state the reasons for considering it essential to the perfection of the sense.

7. Describe the origin, course, and distribution of the hypoglossal nerve, and the distribution and functions of the other nerves of the tongue.

Tuesday Morning, 10 to 1.

CHEMISTRY.

Examiner, Professor DANIELL.

1. What is meant by a degree of tem-

perature upon Fahrenheit's scale? and how does it differ from a degree upon the centigrade scale?

2. Define and illustrate the theory of latent heat with reference to ice, water, and steam; and state the manner of obtaining fixed points for the graduation of thermometers.

3. Explain the phenomena of "single elective affinity" and "double elective affinity," and illustrate them by examples.

4. Illustrate the meaning of the term "chemical equivalents" by example; and state the equivalents of the non-metallic elements upon the hydrogen scale.

5. Name the principal hydro-acids; state their equivalent numbers upon the hydrogen scale; and explain their action upon metallic oxides.

6. Explain the process for obtaining cyanogen; and describe its constitution and properties.

7. What is the constitution of carbonic acid? of carbonic oxide? of oxalic acid? Explain the action of concentrated sulphuric acid upon the latter.

8. Describe the general process for organic analysis, and explain the principles upon which it is founded.

Tuesday, July 2.—Afternoon, 3 to 6.

BOTANY, MATERIA MEDICA, AND PHARMACY.

STRUCTURAL AND PHYSIOLOGICAL BOTANY.

Examiner, Professor HENSLOW.

1. Explain the structure of Exogenous and Endogenous stems.

2. Describe fully the several parts of the stamen.

3. How do you distinguish between angulinnerved and curvinnerved leaves; and in which classes do they respectively predominate?

4. What are the normal characters of the fruit of Cruciferae and Umbelliferae?

5. Describe the stomata and their functions.

6. Explain the functions of respiration in plants.

7. What are the phenomena observed during the fertilization of the ovule?

8. Enumerate some of the chief means by which the dispersion of seeds is effected.

9. What are the stimulants necessary to secure the germination of seeds? and what the successive steps in this process?

Tuesday Afternoon, 3 to 6.

MATERIA MEDICA AND PHARMACY.

Examiner, Mr. PEREIRA.

1. Enumerate the officinal substances

ordinarily used as emetics. Specify the peculiarities attending the operation of each, and the maladies for which each is specially adapted.

2. To what part of the classification of Cuvier does *Cantharis vesicatoria* belong? What are the effects of this insect? In what maladies is it used? Enumerate its official preparations, with their doses.

3. State the chemical characteristics of good cinchona bark. With what substance is iodide of potassium frequently adulterated? How is the fraud recognised? With what substance is calomel liable to be contaminated, and how is the contaminating matter recognised and removed?

4. Briefly describe the botanical characters of *Momordica Elaterium*. Mention the Natural Order to which this plant belongs; also in what part of the Sexual System of Linnæus it is placed. Describe the method of preparing elaterium. What are the effects of this substance? In what maladies is it used? What is its medium dose?

5. What are the products of the reaction of sulphuric acid on ferrocyanide of potassium in the process for making *Acidum Hydrocyanicum Dilutum*, Ph. Lond.? How is the strength of diluted hydrocyanic acid determined? How would you treat a case of poisoning by this acid?

6. On what ingredient do the medicinal qualities of the mineral waters of Tunbridge Wells depend? In what classes of complaints do you consider these waters advantageous?

7. In what diseases is electricity employed? How would you apply it?

8. What are the primary effects of the cold bath? In what cases is its use admissible?

9. What are the effects of strychnia? In what diseases has it been used? What are the indications and contra-indications for its employment? What is the medium dose of it?

CASE OF POISONING WITH OPIUM.

By M. MOURE, Druggist.

ON the 4th of May last, Miss J—, aged 18, having been crossed in love, swallowed a liniment fasting, the prescription for which has been lost; but from the little I saw at the bottom of the phial, I presumed that it was composed of about a drachm of Rousseau's laudanum, and an ounce and a half or two ounces of oil of sweet almonds. I was called in two or three hours after it had been swallowed. I found the patient in a state of drowsi-

ness, which was interrupted only by the pain caused by the twitching of the tendons; her pulse was very full, and very irregular. When I attempted to put questions to her, she answered, that there could be no happiness for her on earth, and that she wished to die; so I assured her that she had not taken enough poison, that she would suffer horribly, and perhaps feel the effects all her life, but that she would not be able to die by it. "Well," said she, "give me any thing you like." Accordingly, I had a decoction made with two gall-nuts bruised; and, while it was making, I administered two drachms of sulphate of zinc, and then a cup of decoction of gall nuts, and several cups of tepid water, but without any result: the patient suffered much. A quarter of an hour afterwards, I made her take ten more drachms of sulphate of zinc, and immediately afterwards a second cup of luke-warm decoction of gall-nuts. In a few minutes vomiting came on, and I gave her five more drachms of the sulphate of zinc, and a third cup of decoction of gall nuts. I obtained on the whole four vomitings, and several cups of lukewarm water were given during the intervals, to encourage them.

I administered only three small cups of the decoction of gall-nuts, lest an excess should redissolve the precipitate formed at first. I employed the sulphate of zinc in preference to tartar emetic, because the latter would have been decomposed by the opiate. The patient being very thirsty, I gave her very strong coffee, without milk, to drink, and she took twelve or fifteen cups.

After the vomiting the patient was very tired, and complained of pain in the head, and lassitude all over the body. The pit of the stomach was painful even on slight pressure. I ordered a half enema, containing an ounce of sulphate of soda, which caused slight colic. Half an hour afterwards I administered another one, without sulphate of soda; and this produced the evacuation of the first, with but little fecal matter. The pulse continued irregular, and the patient experienced shiverings in every part of the body, alternating with insupportable heat. Towards the evening the pit of the stomach and the head became more and more painful. I saw that it was necessary to take blood; but I had done enough on my own authority. With some difficulty I persuaded the parents to send for a physician. M. Rogiet was called in, and recommended the application of twenty leeches to the epigastrium, and another half enema, containing an ounce of sulphate of soda, and advised the coffee to be continued, only less strong. The leeches were put on at

half-past ten in the evening; at eight the following morning the bites were still bleeding; a linseed poultice was put on, gum water, &c. given for drink, and other antiphlogistic remedies were ordered to relieve the irritation of the stomach. The patient continued to improve, and is now well.—*Gazette des Hôpitaux*, June 6th, 1839, from the *Hygie*.

According to the French Codex, twenty drops of Rousseau's laudanum weigh twenty-two grains; hence a drachm by weight (or seventy-two grains) will be equal to rather more than sixty-five drops. Now the Codex says, that twenty drops of this laudanum are about equal to two grains and a half of extract of opium; and therefore, if M. Moure is right in his conjecture, the patient took a dose equal to $8\frac{1}{4}$ grains of extract of opium.

The symptoms of irritation seem to have arisen from the treatment, which certainly erred on the side of vigour. Seventeen drachms of sulphate of zinc are no trifle; and a dozen or fifteen cups of French coffee will do any thing but quench thirst. Coffee, indeed, is recommended in cases of poisoning by opium, but not, we fancy, in such colossal doses. This was a case well suited for the stomach pump; but the instrument is little known in France.—*Translator*.

DISCOVERY

OF

MUSCLES WHICH ROTATE THE DORSAL VERTEBRÆ

(ROTATOIRES DORSI) IN MEN AND MAMMALIA.

By PROF. THEIL, of Bern.

THE *rotatores dorsi* are muscular fasciculi situated beneath the multifidus spinæ, and separated from its fasciculi by cellular tissue. They are found only in the dorsal portion of the spine, and are usually eleven in number on each side. They arise from the transverse processes of the dorsal vertebra, from the second to the eleventh, and each is attached by fibres running transversely inwards, to the arch of the vertebra next above that from which it arises. Each muscle, covered by the multifidus spinæ, is fixed by short tendinous fibres to the upper edge and posterior surface of the transverse process, and by fleshy fibres to the lower edge, and in part to the posterior surface of the arch, up to the base of the spinous process. The muscles have not all the same size; the lowest are largest, except the eleventh, which is small. The uppermost generally passes from the transverse process of the second

dorsal vertebra, over the first, to the arch of the seventh cervical.

Professor Theil has discovered perfectly analogous muscles in the dorsal portion of the spine in several species of *quadrumana*, *carnivora*, and *rodentia*.—*Müller's Archiv*, Heft ii. 1839.

FORMATION OF AN ARTIFICIAL ANUS,

BY OPENING THE DESCENDING COLON WITHOUT PENETRATING THE PERITONEAL CAVITY.

By M. AMUSSAT.

A LADY, in Paris, æt. 48, long subject to obstinate constipation, sometimes preceded by hæmorrhage from the rectum, had vague pains in the pelvis and the lumbar region. Nothing, however, could be discovered further than a slight affection of the uterus, polypous excrescences of the urethra, and an old crural hernia on the right side.

She enjoyed good health for some time in the country, but on the 13th of May last returned to Paris, having suffered for eight days from obstinate constipation. On the 29th M. Amussat was called in, the constipation still continuing. The rectum was found completely empty; but there was an obstacle above it, probably from a tumor in the pelvis, which no injections, nor any other mechanical means, could overcome. On the 2d of June, the constipation having existed twenty-four days, the tympanitis increasing, and the patient suffering intolerable pain, and earnestly requesting an operation, it was decided on and performed with the assistance of MM. Breschet, Recamier, &c.

The patient being laid on her face, a transverse incision was made over a prominence which was distinctly visible on the left flank, two fingers' breadth above the crest of the ilium, and extending from the outer edge of the sacro-lumbalis to the middle of the crest of the ilium. The several layers of muscle and fascia were divided till the adipose tissue immediately covering the intestine was exposed; this was then cut through, and two threads were passed through the walls of the intestine, at each end of the wound, to retain it and prevent it from collapsing. Having clearly exposed the colon, of which a large space was uncovered by peritoneum, a fine trocar was plunged into its most prominent and distended part, and gases and fluid fecal matter escaped through the canula. Immediate ease followed. A probe-pointed bistoury was passed in by the side of the canula; and when the aperture in the intestine was

increased in both directions, gas and fæces flowed out in abundance. The patient expressed the greatest relief, and her countenance lost all its anxious expression, and its livid hue. The intestine was washed out with injections, and the edges of the opening in it were attached to those of the wound in the abdominal walls by four sutures.

The consequences of the operation were in no respect unfavourable. Sixteen days after it the patient was perfectly well, and had returned to her usual habits, and every thing induced her attendants to hope that, as far as the tumor in the pelvis, from which the intestinal obstruction arose, would permit, her recovery would be permanent. — *Comptes-Rendus*, Juin 17, 1839.

VACCINE LYMPH.

To the Editor of the Medical Gazette.

SIR,

ABOUT the middle of last March I received a supply of vaccine lymph from the National Vaccine Establishment, and with it vaccinated six children. On the second day the arms shewed active inflammation where the matter was inserted, which ran on to the fourth day, the pock or pustule going on with great rapidity, so that on the fourth day it put on the semblance of a vaccine pustule of the tenth day. On the twelfth day a secondary eruption of small pustules broke out over the region of the shoulder, the children at the same time suffering from irritative fever. Not having experienced such results before, I became sceptical as to its protective power. Accordingly, three weeks after the eruption had subsided, I obtained some vaccine lymph from a pustule of the eighth day, that had undergone the usual phasis. The vaccine disease in the six children passed through the natural stages, precisely as if they had not been vaccinated. Probably it is not out of place to inquire whether Mr. Estlin, of Bristol, has proved by re-vaccination the power of the active lymph which he has recently used?

I remain, sir,

Yours most respectfully,

JOHN GRANTHAM.

Crayford, Kent,
July 8, 1839.

ERGOT OF RYE IN PROTRACTED LABOUR.

To the Editor of the Medical Gazette.

SIR,

IF we may judge from the numerous discussions which continue to appear, the

degree to which the ergot of rye is entitled to the confidence of the profession is any thing but settled.

Since I have commenced taking notes of my midwifery practice I have attended 420 cases, in 80 of which I have administered the ergot. Of these 80, the effect in 47 cases was very beneficial and very marked, while in 33 cases no appreciable effect whatever resulted.

As to the child, I find that in the 420 cases (producing 422 children) there have been delivered 26 still-born children, and five bearing marks of having died long prior to labour, making in the whole 31 dead children, of whom seven had only reached the seventh month. But in 80 of these cases the ergot was given; and among these there were 10 still born children, and one who had died prior to its employment; while in the 340 remaining births there were but 16 still-born, and four who had died prior to labour.

Although I do not presume to offer the above observations, so insignificant in point of numbers, as doing more than very slightly contributing to the division of the question; yet, as every man's practice is more or less guided by his own personal experience, I may observe, that in future I shall be more circumspect in the employment of this medicine; seeing that the cases in which I have employed it with undoubted advantage amount to little more than half the number in which it has been given, while the number of still-born children is so much increased.

Even such a trifling statement as the present, shews me the utility of every medical man keeping and occasionally consulting a record of his cases. For so striking are the benefits sometimes derived from the ergot, that they are apt to leave an undue impression upon the memory; and I could never have imagined, by trusting to my recollection alone, but that it had been successful in a much greater proportion.—I am, sir,

Your obedient servant,

JOHN CHATTO.

Leigh Street, July 7, 1839.

DEATH FROM PUMPING AIR INTO THE EUSTACHIAN TUBE.

To the Editor of the Medical Gazette.

SIR,

HAVING observed, in your remarks upon the case of Joseph Hall, in your last number, in which it is said, "Mr. Lyon not being, we suppose, a medical practitioner," p. 538, will you have the goodness to correct this in the forthcoming number. I have been a member of the Royal College

of Surgeons of London since the year 1823.—I have the honour to be, sir,

Your obedient servant,
T. LYON.

25, Montague Street,
Russell Square, June 9, 1839.

To the Editor of the Medical Gazette.

SIR,

Much misapprehension has arisen from a recent occurrence which I deeply regret should have happened under my roof. I allude to the death of Joseph Hall, on whom an operation was performed by Mr. Lyon, a surgeon, formerly, but no longer, residing with me; if (as I conceive it does) his being daily in my house from early morning until nine or ten at night constitutes a residence. With regard to that operation, I have only to repeat I had nothing to do with it. I did not authorize it—I was not cognizant of it—nor was I made acquainted with the result until three hours had elapsed. With regard to the case of Mr. Wm. Whitbread, which has been referred to in connection with the foregoing, I beg to say, that, to my knowledge, I never saw that individual, and certainly never performed on him any operation whatever; to which may be added, that a verdict of “Natural Death” was returned by the jury; thereby disconnecting the cause of his decease from the operation which Mr. Lyon had performed on him several days previously.

I am, sir,

Your obedient servant,
A. TURNBULL.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.
BY DR. VENABLES.

Cystic Oxide Diathesis—continued.

THE case which occurred to Dr. Prout was sent to him by Sir A. Cooper, to have the nature of a stone he had lately passed from the kidney ascertained. He was about 30 years of age, had been subject to urinary diseases since 1818, and, in consequence of severe cold, was seized with severe pain, accompanied by inflammation of the kidneys. Six months afterwards he first observed retention of urine, apparently from a calculus in the bladder. In 1820 a calculus was extracted, weighing upwards of two ounces, and was supposed to consist of oxalate of lime. The small calculus, which was the subject of investigation, was passed about a fortnight before, with considerable pain—passed down from the left kidney, and consisted of pure cystic oxide. Since that period he had been taking alkalines, and which appeared to ease the pain in the back more than any thing else. Dr. Prout states the properties of the urine as follows:—

“The urine voided in my presence about five P.M. was copious, of a yellowish green colour, and strong peculiar smell. Its specific gravity was 1.020; and almost immediately on being passed, a greasy-looking film was found on the surface, and at the same time rather a copious pale-coloured precipitate appeared, and the urine became alkaline. This film and sediment consisted chiefly of the triple phosphate of magnesia and ammonia,

mixed with a little of the cystic oxide. There was very little urea, and hardly a trace of lithic acid was perceptible on the addition of an acid.

“The urine passed the next morning early (all medicine having been in the meantime omitted) was more remarkable, and characteristic, I presume, of this affection. Its colour and appearance were much the same as the above, except that the former was a little deeper, and the peculiar smell stronger. It very faintly reddened litmus paper, and its specific gravity was 1.022. There was a slight deposition on standing for some time, consisting of a mixture of the cystic oxide with a little of the triple phosphate. A considerable proportion, however, of the cystic oxide was precipitated from the urine on the addition of acetic acid, which, of course, held at the same time the phosphates in solution.

“This gentleman seemed strong and robust, but was liable to affections of the stomach, which appeared to arise, in part at least, from sympathy with the derangement of the kidney. What is remarkable, he stated that he had a twin brother likewise subject to urinary affections, but of what kind has not been ascertained*.”

The case which occurred to myself is detailed at length in the Journal of the Royal Institution, and therefore I must refer you to that work for fuller particulars. The following, however, is a general outline of the circumstances of the case:—The patient, Mrs. Day, aged 47, a labourer's wife, stout, corpulent, and to all appearance in rude health, living at Mashbury, near Chelmsford, in Essex, was first seen by me on the 28th June, 1828, in consequence of my having discovered the nature of the calculus, the half of which I now present to you. It weighed when entire eighteen grains, is of a dull whitish appearance, and the external surface was studded with

* On Diabetes, pp. 166, 167.

a few white shining crystals of triple phosphate. Sawn through, it seemed of a waxy nature, but somewhat firmer in consistence; clogged the teeth of the saw as a waxy substance would do. You see that its internal structure is not laminated, but seems a confused homogeneous crystalline mass; its sp. gr. 1.714285. Before the blowpipe it gave out a peculiar foetid animal odour, but quite different and distinct from that of the lithic acid so treated, leaving an ashy, black, spongy residue. These properties were developed by heating a small portion on platina foil over the spirit-lamp, without the aid of the blowpipe; but urged by the blow-pipe, it ultimately left a white ash. The general chemical properties have been already enumerated. It was soluble in the sulphuric, nitric, and hydrochloric acids—in caustic potash, soda, and ammonia—and in the carbonates and bicarbonates of the former. In the caustic alkalies it dissolved with slight effervescence. From its solutions in the acids it was precipitable by alcohol and ether, but most abundantly by the neutral carbonate of ammonia. From its alkaline solutions it was precipitated by the acetic, citric, and tartaric acids. Therefore, in precipitating it from the urine, if alkaline, we should use the acetic acid, because this acid will hold the phosphates in solution; but if acid, then alcohol, or the neutral carbonate of ammonia, is the preferable precipitating reagent. It dissolved in nitric acid with very slight effervescence, and the solution, evaporated to dryness, left a whitish residue.

On the 30th June a specimen of this urine was brought to me. It was passed in rather large quantity. It was of a yellowish green colour, something like the rind of a melon when nearly ripe. The smell very peculiar, indeed something like that of the sweet-briar, tainted with a foetid, urinous, animal odour. Its taste was very slightly saline; its appearance was oily looking, somewhat resembling that of oil of vitriol, or perhaps more closely that of sherry wine. It was turbid, apparently from the suspension of an impalpable powder. On being left at rest for a considerable period, a pulverulent mass, enveloped in a kind of gelatinous-looking substance, formed; and separated by filtration, and examined, was found to contain a large proportion of the cystic oxide; specific gravity of the urine 1.022; it faintly reddened litmus paper. On being allowed to stand for several days, no further decomposition ensued, nor did the urine become alkaline. No precipitate was thrown down from the filtered portion on the addition of acetic acid or spirit of wine; but carbonate of ammonia threw down some cystic oxide. A film of the triple phosphate formed on the sur-

face, and the triple crystals attached themselves to the sides of the jar.

This urine was very deficient in urea; not a particle crystallized on the addition of nitric acid to the urine evaporated down to less than one-half, and even to the consistence of a syrup. Lithic acid was not precipitated on the addition of an acid even when the urine was concentrated by evaporation. This principle, however, was not wholly absent, as when evaporated to dryness, and acted on by nitric acid, and then dried, a carmine reddish stain was produced, which assumed a sort of purplish hue by the vapour of ammonia being admitted to it when slightly moistened. I had several opportunities of examining the urine in this case, and it exhibited the same general properties. Those who wish for a fuller explanation are referred to the case as originally published in the *Journal of the Royal Institution*.

From the examination of cystic oxide calculi, their great purity, and non-intermixture with the other principles of the urine, may be readily understood from the properties already detailed. Dr. Marcet remarks, that this diathesis exerts a more exclusive tendency than any other. Dr. Prout observes, "This observation seems to be confirmed by the examination of the urine above given, in which the absence of the lithic acid was remarkable. Like the other two species of urinary concretions, however, it may be evidently followed by the phosphates, as appears from one of the specimens of calculus above described, and also from the examination of the urine, in which the tendency to the deposition of the phosphates had been evidently produced by the use of alkaline remedies. This diathesis, like the mulberry, may also be followed by the lithic acid diathesis, as happened in one of the instances given by Dr. Wollaston, above quoted. Dr. Henry also mentions an instance of a lithic calculus having a nucleus of cystic oxide*."

When we consider all the circumstances—the general tendency to nephritic inflammation, the phlogistic diathesis, and the other phenomena, we cannot entertain any very favourable opinions respecting this disease. In most of the cases where the history could be traced, the disease seemed to be complicated with a diseased state of kidney, of which it was either the cause or the consequence; and in all, as remarked by Dr. Prout, an inveterate disposition to urinary disease, apparently inherited, was evident. In the case which I have just detailed, although the woman in appearance was lusty and in good health, yet she was very subject to

* On Diabetes, pp. 168, 169.

inflammatory affections, and sometimes would pass several small cystic oxide concretions united together by a sort of flat tape, as it were; but which, probably, was nothing more than flakes of fibrin thrown off by inflammation, and subsequently coagulated.

Treatment.—With respect to this part of the subject I can advance but little. However, evidently it must be regulated by circumstances. Great attention ought to be paid to the digestive functions, and the inflammatory tendency counteracted by regimen and mild means. The conditions of the urine, too, ought to be attended to; and if the urine be acid, we may prescribe the alkalies in moderate doses; if alkaline, the hydrochloric acid may begin with advantage. Dr. Prout, indeed, thinks, that if the irritation present would permit, the hydrochloric might in all cases be employed advantageously, not only with the view of holding the cystic oxide in solution, but of inducing the lithic acid diathesis.

In prescribing alkalies we should recollect how readily the urine may be rendered alkaline, which is not only very dangerous in diseased states of the urinary organs, but is also capable of inducing such. Upon occasions I found it necessary now and then to give some alkaline remedies to Day, but I generally then gave the citrate of magnesia*, mentioned in one of my former lectures.

Colchicum and the salts of morphia will be found useful in allaying the irritation of the urinary organs, and of the system in general; and perhaps the pills formerly mentioned would be found useful in this way.—Cupping the loins, or drawing blood by leeches, sinapisms to the lumbar spine, issues and setons, of course present themselves as remedies that would be likely to prove serviceable. Fortunately, however, this disease is so rare, that probably we shall not often be called upon to devise means for its relief or cure.

Phosphatic or earthy diathesis.—A deposition of the insoluble phosphates is very rarely indeed an original disease, but frequently succeeds to the deposition of lithic acid or oxalate of lime. Therefore it would appear to be, as it were, the ultimatum of all the other forms of urinary

gravel. The transition, however, from the original diseases is not sudden or abrupt, but a gradual process, during which the urine undergoes some very remarkable changes. From the observations already made, and from the dissection of calculi, we found that the urinary phosphates mostly had nuclei of some of the other forms of sediment—as the lithic acid, oxalate of lime, &c.; therefore it will probably be the better plan to consider the changes in the urine during the transition from the other diatheses to this.

Change from the lithic to the phosphatic diathesis.—We have already shewn that, in the lithic acid diathesis the urine is high coloured and remarkably transparent, free from cloud or sediment; but when this change is setting in, the urine becomes pale, and often its quantity is much increased, and its specific gravity reduced. At the same time, the lithic amorphous sediments are copiously deposited from the slightest causes. These sediments are for the most part of a pale colour, and, if examined, are found to be much more abundantly intermixed with the phosphates, and the quantity of the latter will often denote the progress which has been made towards the perfect completion of the phosphatic diathesis. The urine, too, generally abounds in urea; at all events, the proportion of this principle greatly exceeds that of health, inasmuch that if the quantity be not very inordinate, crystals soon shoot forth on the addition of nitric acid, but almost always on a moderate concentration of the urine. As this stage advances, it will be observed that the urine, on standing at rest for some hours, becomes covered on the surface with a thin iridescent film, which, if removed by a lamina of platinum, and examined, proves to be the ammonio magnesian phosphate. In this stage also, the urine, if allowed to remain, much more speedily undergoes decomposition, especially in warm weather, and becomes as it were putrid, assumes an opaque yellowish colour, and shining spicular crystals, of the triple phosphate, shoot out. Dr. Prout has seen them half an inch in length, in urine not remarkably unhealthy, which had been allowed to stand for a great length of time, and to grow putrid. At this period, too, a calculus may even exist in the bladder; an instance or two of which occurred to Dr. Prout, and their examination, when extracted, proved them to consist of pale-coloured lithate of ammonia, nearly pure.

Such a condition of the urine often occurs in sickly emaciated children, whose digestive organs are much out of order. At dispensaries and hospitals such instances are constantly occurring. Here is a specimen of urine from a case of this sort, from which you may readily obtain a

* Mr. Dinneford, of New Bond Street, has lately called my attention to a preparation of his own—namely, a solution of bicarbonate of magnesia. An ounce of a sample with which he favoured me a few days since yielded, on evaporation, about eighteen grains and a half of hydrated carbonate of magnesia. Three or four ounces of this solution, with a tea-spoonful or two of the acidulated syrup which accompanied the sample, formed an excellent and agreeable effervescent draught; and I think this preparation of magnesia might be both agreeably and advantageously used in some of the forms of urinary diseases, where a neutralization of the urine is desirable.

notion of its general characters and properties. It is apt to be induced in persons of an irritable constitution, and whose urine is apt to deposit lithic sediments, by the general causes formerly specified, or from the various derangements of the general health, or from local irritations of the urinary organs. In such, also, the individuals are mostly of an irritable habit of body, and are much subject to derangements of the digestive functions; and there is generally some uneasiness felt about the lumbar regions, more especially in adults. At this period it can, for the most part, be controlled or kept in check, provided care be taken to avoid all the exciting causes, and attending strictly to the means necessary for its relief; but if these be neglected, the phosphatic diathesis will be inevitably established, especially if there be already a calculus in the bladder.

After some time, the urine undergoes a still farther change, and assumes a pale wheyish colour. It is neutral when voided, speedily becoming alkaline, and not unfrequently is alkaline even when first voided. We now find that the quantity of the lithate of ammonia diminishes or perhaps disappears altogether, while the urea is more abundant. But the most remarkable change is, that the quantity of the phosphates, especially of the ammonio-magnesian, is greatly increased. In truth, this stage may be considered as but a minor degree of the more confirmed phosphatic diathesis, for it runs into this latter so gradually and imperceptibly that no real or distinguishing line of separation can be drawn.

Change from the oxalate of lime to the phosphatic diathesis.—We have seen that calculi, in some cases, consist of the phosphates deposited upon a nucleus of oxalate of lime. The first change is, that the urine, if examined, will be found to contain an unusual proportion of lime. As the quantity of lime increases, the quantity of phosphoric acid also increases, while that of the oxalic acid diminishes; and at last phosphate of lime, which, in fact, formed the external covering of a calculus of this sort. With respect to the state of the urine, it may be presumed that it will undergo somewhat similar changes, so far as compatible, to those attending the transition from the lithic acid to the phosphatic diathesis. In the oxalate of lime the urine is acid, but as it changes to the phosphates it gradually becomes neutral; becoming at last alkaline, and, in fact, presenting the usual characters of phosphatic urine.

Change from cystic oxide to the phosphates.—Little can be offered upon this subject, instances of which are so rare. In the example mentioned by Dr. Prout, the urine had a tendency to alkalescence, from the

internal use of alkaline remedies, and the ammonio-phosphate of magnesia was found intermixed with the cystic oxide. However, the above can only be regarded as an artificial condition; for in the case which I met with, the urine had an acidulous re-agency. But, from what we know, we may conclude that the urine, in such a change, assumes pretty nearly similar characters to what it assumes in the transition stages from the other diatheses to the phosphatic.

After the urine has continued in the condition we have noted for a period of time the length of which will depend upon various modifying causes, the phosphates begin to be deposited in a more decided and unequivocal manner. These, like the lithic deposits, may occur under two distinct forms—that is, it may appear either as crystallized gravel or as an amorphous sediment. In the case of the lithic diathesis, however, the amorphous sediments, compared with crystallized lithic gravel, is a mild affection, and of little consequence; but in the case of the phosphates, the amorphous is a much more formidable appearance, and the crystallized phosphates is comparatively a disease of a much milder character. As the analogies, therefore, between the lithic phosphatic diatheses seem in this respect to be completely subverted, we may commence, as in the lithic case, with the consideration of the milder form of disease—the crystallized phosphates.

1. *Of the crystallized phosphatic sediments.*—These always consist of the ammonio-phosphate of magnesia*, and have a white shining or glistening appearance. These frequently alternate with sediments consisting of pale-coloured lithate of ammonia, or even may be accompanied with the above or the amorphous fusible phosphates. The general symptoms consist of derangements of the primæ viæ, various forms of nervous irritation, a sense of lassitude or weariness, and indisposition to any exertion. There is also pain and uneasiness in the loins and back, more particularly in the region of the kidneys. The urine is, for the most part, pale-coloured, of a saline taste, nor is it of the usual aromatic odour of healthy urine. Its quantity is often abundant, and its colour then is paler; but if the quantity be less, its colour is deeper and the odour more sensible. The specific gravity varies with the quantity: if the urine be scanty, the spe-

* Dr. Prout states, that he has once or twice seen a crystallized compound, consisting of the mixed or fusible phosphates. "If I am not mistaken (he says), I have once or twice seen a crystallized compound of the triple phosphate of magnesia and ammonia, and the phosphate of lime. These crystals were much larger than those of the triple phosphate, and less distinctly formed."

cific gravity is high, from 1.026 to 1.030; but when passed in large quantity, the specific gravity will, perhaps, not exceed 1.010 or 1.015, and probably may be even less. Upon standing for some time, an iridescent film, such as you see here, forms upon the surface; and you will often find that persons will tell you, under these circumstances, that their urine has the colour of the rainbow; which appearance depends upon the refraction and decomposition of the light, and evolution of the prismatic colours, by the film of triple crystals of which this pellicle consists. After a time, also, small minute crystals attach themselves to the sides of the jar in which the urine has stood, and they form much sooner if the sides of the jar have been previously rubbed or scratched, and to which portion of the jar they attach themselves in preference, as you see in the instances before you.

Urine of this description also abounds in urea, which, as you see here, soon crystallizes on the addition of nitric acid. It is in such cases that the specific gravity is high, and the quantity of urine comparatively small; but even when the quantity voided is large, and the specific gravity low, yet the proportion of urea much exceeds the healthy standard, for if the urine be concentrated, a little nitric acid causes the crystallization to take place; or the urea collected will be found to greatly exceed the healthy proportion. If potass or any other neutralizing agent be added, the ammonio-magnesian phosphate precipitates abundantly.

When the triple salt exists in very large quantity in the urine, the crystals separate before the urine is voided, and are found already existing when it is first discharged from the bladder, and immediately sink to the bottom of the vessel. The urine in such instances, will, if examined, be found to have an alkaline reactivity, even when first voided; but in general, however, the crystals do not begin to form till the urine has become cold, or not even till it begins to putrefy. The length of time which elapses between the passing of the urine and its becoming cold, may be considered in some degree an index, as it were, of the degree of severity of this affection.

The causes which induce a superabundance of this salt in the urine, are the various causes which act upon the nervous system. Thus mental emotions of every description will often induce an excess of the above principle. The same may be said of many articles of food; various diuretic medicines; and especially those salines formerly mentioned as tending to produce an alkaline condition of the urine, together with diuresis. In irritable habits, mercury will often induce an excess of the triple salt, and even of the mixed phos-

phates, and will even lead to their deposition from the urine before it leaves the bladder. The slighter causes will produce little or no effect, except upon those who are greatly predisposed, or are subject either to this or some of the other diseases of the urinary organs. But in persons who have long suffered from a bad state of health, or in whom the health is much impaired, and the constitution, as it were, broken up, this salt will be found either actually existing in excess, or an excess of it may be easily superinduced.

It has been remarked, that children are much more subject to such a deposition than adults, which may probably be referred to the greater irritability of that age, and the more frequent derangements to which the digestive functions are exposed at that period of life. Children of a scrofulous diathesis, with tumid abdomens, frequently suffer from this, or more, perhaps, from the other variety, the deposition of amorphous sediments consisting of the mixed phosphates; or sediments consisting of an unnatural proportion of lime, combined with carbonic acid.

When these phenomena occur but seldom, and but occasionally from the causes above enumerated, their duration is generally but short, and the disorder soon goes off, and is of but little moment. But when occurring in more advanced life, and complicated with organic disease of the urinary organs, or that there is an habitual recurrence of the symptoms from very slight causes, the danger is proportionally greater, that the disease may become permanent, and perhaps not easily to be eradicated.

2. *Of the amorphous phosphatic sediments.*—These always consist of the mixed or fusible phosphates, that is, the ammoniophosphate of magnesia with the phosphate of lime. The proportions, however, of the two salines differ in different cases. In some instances the phosphate of lime predominates very much indeed over the other principle. When this is the case the disease is of a much more decided and severe character, and generally indicates organic disease of the mucous lining, and generally of all the coats of the bladder. Indeed, many believe that the phosphate of lime is principally, if not wholly, derived from the mucous coat of the bladder; but still a great proportion is often derived from the kidney itself. When, however, there is an unusually large proportion of phosphate of lime, we shall generally find the mucous coat more or less diseased, "the inner coat of the bladder apparently assuming, in such instances, the character of the inner surface of the abscess sometimes found in the prostate gland, which is known to secrete this earthy salt in great abundance. I am

doubtful, however, if any portion of the triple phosphate is ever derived from this source, but from the kidney only, from which same source, in various cases, a large proportion of the phosphate of lime is likewise undoubtedly derived*."

When a deposition of the mixed phosphates from the urine, as above noted, takes place, the general symptoms are of a very severe and harassing description. Thus there is very great irritability of system. At the same time there is a great tendency to flatulency, attended with nausea, or even vomiting. Sometimes constipation attends, or the patient is attacked with severe purging, on the cessation of which the bowels become obstinately costive, and so these two frequently alternate with each other. The evacuations, too, are black, or clayish, or otherwise very unnatural, and very often undergo active fermentation, as if mixed with yeast. The patient is at the same time harassed with severe griping pains of the stomach and bowels. Pain, and a sense of uneasiness and weakness, is felt all over the back, most severe in the loins, but extending downwards to the bottom of the sacrum, and upwards between the scapulæ to nearly the top of the back. The expression of the countenance also becomes peculiar, presenting a sallow, haggard-looking appearance. As the disease advances, great languor, with depression of spirits, habitual coldness of the extremities, anaphrodisia, and the other general symptoms of extreme debility, set in. The mind, too, in many instances, partakes of the general morbid condition of the body. Sometimes the patient is listless, indifferent, and almost insensible to every thing; in other instances there is a preternatural sensibility, and the patient is apprehensive, timid, and fearful, and, as they express themselves, extremely nervous, and in some even a degree of melancholy takes place.

The urine is always pale coloured, frequently opalescent, and for the most part voided in large quantity. When passed in large quantity it is generally transparent, and colourless like spring water, devoid of taste or smell immediately on being passed. It is then of very low sp. gr. about 1.001 to 1.002. It deposits no sediment, and is generally neutral; or, if any thing, has a slight alkaline reaction. When passed in smaller quantity it is generally opalescent; its sp. gr. much higher, from 1.020 to 1.025. Its reaction mostly neutral, but it soon becomes alkaline. It deposits, after standing for some time, a copious sediment, consisting of the mixed phosphates, in the form of an impalpable powder. This urine generally abounds

in urea, which soon crystallizes on the addition of nitric acid. In both cases the urine soon becomes alkaline, carbonate of ammonia is evolved, the pungent odour of which is readily recognized, and it emits a most intolerable smell or stench, such as any who has once experienced can never fail to recognize. Any of the neutralizing agents will at once throw down the mixed phosphates, if the urine be not voided in a condition favourable to their immediate subsidence. Dr. Prout states, that the diuresis is more profuse by day than at any other time; and as the diuresis is not constant, but occurs at certain times, either spontaneously or from the action of the slightest exciting causes, and as these are more likely to be applied in the course of the day more than at any other time, we can readily reconcile Dr. Prout's observation. The urine frequently contains diseased mucus or pus.

With respect to the causes, they appear to be of a mixed character, partly general and partly local. Injuries of the back, such as sprains, are very frequently the only assignable cause; such are falls, concussions, over-exertion, and the like. Mental emotions, fatigue, and all debilitating agents, may give rise to conditions of this sort of the urine. The causes of local operation are, for the most part, some source of irritation, especially about the bladder or urethra, more especially if continued for a considerable length of time. Thus, any foreign substance introduced into the bladder may become the immediate exciting cause of a deposition of this sort, and the nucleus of the concretion subsequently formed*. In this way a calculus of any sort retained in the bladder may be ultimately incrustated with the fusible or mixed phosphates, of which you here see examples. Strictures of the urethra, in particular constitutions, and the frequent or habitual introduction of catheters or bougies, from the irritation which they excite, may induce a condition of the urine such as that now described, and a proneness to deposit the mixed phosphates, and hence it is that foreign substances retained in the bladder almost

* Mr. Smith, of Bristol, has very lately favoured me with some lithographic delineations, of interesting forms of calculous concretions. In one, a pin was found in the bladder of a female, partially encrusted with the ammonio phosphate of magnesia. In another, a common cinder is coated with carbonate of lime; but Mr. Smith doubts its ever having been in the human bladder. In another case, a piece of stick, thrust down into the urethra, having entered the bladder, divided into four portions, and became the nucleus of a fusible calculus, which was afterwards extracted from the bladder by operation. In another instance a tooth was found to form the nucleus. There are many instances of foreign substances getting into the bladder, and subsequently forming the nuclei of fusible incrustations.

* Dr. Prout, p. 177, note.

always become incrustated with the phosphates, and not with the lithic acid. I myself have seen three instances in which the urine became of the general characters above described, and in one a quantity of carbonate of lime appeared in the urine. I need hardly observe, that repeated gonorrhœa, by the irritation it causes, and lues through medium the of mercury, may induce this condition of urine.

The event in such cases will depend much upon the particular circumstances of the case; such as the nature of the causes, the length of time they have continued to operate, and the degree of severity in the existing affection. When arising from severe injuries of the spine, the case may be looked upon as unfavourable; for though relief may be obtained by care, and due observance of the necessary regimen, yet it will be very apt to recur upon the least irregularity, or upon leaving off the means necessary to keep this diathesis in check.

When there is a stone in the bladder, or that any other of the enumerated causes of irritation are in operation, the event will depend much upon the time they have been in operation, and the degree of severity in the symptoms which they have superinduced. But there is one very favourable circumstance attending this form of deposition, that it very rarely gives origin to stone in the kidney.*

OBSERVATIONS

ON

COMPLICATED SURGICAL INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

[Continued from p. 554.]

VII.—INJURIES OF THE SPINE. — ON THE NATURE OF VARIOUS LESIONS—THE SYMPTOMS AND EFFECTS REFERABLE TO EACH.

Principle controverted that immediate death follows fracture above fourth cervical vertebra; case proving.—Occasional absence of all urgent symptoms in fracture of spine; case.—Fatal injury within spinal canal not occasioning paralysis; case.—Sir Astley Cooper's opinion on non dislocation of heads of ribs. Two cases of this injury.—Necessity of a careful and guarded diagnosis in spinal injuries.—Analysis of causes producing three degrees or kinds of paralysis in sphincters and bladder. 1. Loss of voluntary muscular power. 2. Loss of power in the in-

luntary muscular fibres. 3. Impaired elasticity of structure surrounding neck of bladder; cases and facts in illustration.—Importance of these views in diagnosis.—Principles of treatment.

In considering these injuries, we pass but nominally from one class to another. The spine is, in one sense at least, a continuation from the head; and violence to the one very frequently involves the other, as we have seen. But here the order is inverted: I have now to show you how the true spinal system implicates the cerebral, as I have already pointed out the reaction from the encephalon to the spine.

You will continually be struck by points of resemblance between these and the injuries last considered. The spinal column is another set of bones, in which the fracture is of importance in relation to the injury inflicted on the parts which they sheathe and inclose.

Their compact form, spongy structure, and cartilaginous attachments to each other, defend them so well, that no common degree of violence detaches or fractures them. The spinous processes projecting towards the surface of the back, composed of thin laminae, and less supported than any other part, are the most liable to fracture; and these may be broken without injury to the spinal canal or its important contents. To break the bodies of the vertebræ, the violence and shock must have been great enough to produce many worse and more fatal effects than those properly appertaining to the worst forms of fracture, such as concussion of the brain—the cord, and lesion of the spinal cord.

Paralysis more or less complete of all the parts below the fracture, except in the organs supplied by the great sympathetic—that is, in all muscles of voluntary motion—is the common consequence of these fractures.

There may be paralysis of all voluntary muscles, from the communication with the cerebrum—the source of all voluntary motion—being cut off by the lesion of spinal cord; but very generally the true spinal system is affected, whether that reside in the grey matter of the cord, as Mr. Grainger has endeavoured to demonstrate, or elsewhere, it matters little. Certain it is, that the centre of power for the excito-motory system is within the spinal column; destroy that, and the permanent functions of the system, and all reflex motions,

* Prout on Diabetes, &c. p. 182.

cease. Thus the usual result of severe injury to the spine is relaxation or paralysis of the sphincter muscles of the anus and bladder: the lower limbs may be pinched or cut, and yet there is no power to withdraw the limb from injury. Were it cerebral paralysis only, although the patient could not voluntarily move the limb, it would under such circumstances be involuntarily withdrawn by the reflex action through the spine. I need not dwell upon these distinctions, since you have seen all the facts demonstrated by experiments on living animals, by your distinguished Professor of Medicine, in this theatre. The bladder, I must remind you, becomes distended with urine, and yet no sensation is communicated; and I more particularly draw your attention to this fact, that you may always, as a first step in these injuries, examine the bladder, and relieve it of its contents.

These effects, however, do not always follow; and further, *considerable injury to the canal, and even partial displacement, is not necessarily or immediately marked by any urgent symptoms.* The two following cases will leave no doubt on this subject; they show, also, that the generally received axiom, that fractures above the third cervical vertebræ are fatal, should at least be understood to mean ultimately, and even remotely.

Case I., showing the occasional absence of all urgent symptoms in a Fracture of the body of the Second Cervical Vertebra.

William Barrowcliffe, on the 28th of May, 1836, was struck in the mouth by a musket-ball, which passed inwards, breaking the two upper incisor teeth, and was supposed by the patient to have been spit out.

The wound of the lip speedily healed, no symptoms presented indicative of any further injury, and on the fifteenth day after admission the patient was discharged to duty at his own request.

Admitted again in thirty-eight days with great difficulty in swallowing; pain and stiffness of the back of the neck; slight obstruction to respiration, and inability to protrude the tongue. Pain in the shoulder-blades, up the side of his head, and on the left side of his neck. A blister was applied to the back of the neck, which he said relieved the pain of head.

3d day of his second admission.—Slight enlargement, of a puffy soft feel,

Fracture into Spinal Canal, between Second and Third Cervical Vertebræ.

just over the parotid gland of the right side, but most pain is felt on the left side of the neck.

4th. — Complains much of pain in both shoulder-blades, and up the side of his head. On passing over the course of the carotid, at the lower portion of the cricoid cartilage, rather more than normal resistance is offered to the finger; and if the pressure be continued, he complains of instant dread of suffocation—increased difficulty of deglutition.

He died on the 25th day after his second admission, the case presenting no other features. His appetite had not failed, he was able to go about, and his general health, to within twenty-four hours of his death, was good. A sudden change took place; he rapidly sunk and died.

Post-mortem.—No appearance of diseased structure presented itself until the trachea and œsophagus were removed, when a discoloration of the surrounding parts was exhibited behind the pharynx, and superior to the epiglottis. A dark spot close to the second cervical vertebra directed attention to that part; and it was found that the ball had entered the body of the vertebra, leaving many fragments of broken bone in the cavity formed by it. The whole substance of the body of the vertebra had been penetrated, exposing the theca vertebralis, which was however uninjured, beyond what might have been expected from the subsequent inflammation. Caries of the second and third vertebræ had proceeded to some extent. The course of the ball had been in at the mouth, passing through the back of the pharynx, above the epiglottis, and into the body of the second cervical vertebra. (See fig. 1 and 2.)

Second Case, showing the absence of all urgent symptoms indicating injury to Spinal Column.

Captain C—, on the 6th of June, 1836, was wounded by a musket-ball,

which entered the left buttock, and from examination at the time was supposed to have lodged in the pelvis. I passed my finger into a portion of the ilium for some distance, in a bony canal rough with crumbled fragments. At the time of receiving the injury he experienced little or no inconvenience from it, and walked into town, a distance of some three miles.

On arriving at his billet, blood was abstracted from his arm to the extent of ʒxx., and a strict antiphlogistic treatment adopted.

During the first eight days there was no perceptible alteration in his health. After this period suppuration was established, and purulent matter discharged in considerable quantity, accompanied occasionally by very small spiculæ of bone; and from that time the powers of the constitution gradually gave way, occasional attacks of diarrhœa and hiccough supervening. He also complained latterly, at times, of a cold sensation in his feet, which was attributed to some lesion of the nerves distributed to these parts. He died August 2, nearly two months after the receipt of the injury.

Post-mortem. — Greatly emaciated. On opening the cavity of the abdomen, for the purpose of tracing the exact course of the ball, it was discovered that it had not entered the pelvic cavity, but had passed in a slightly oblique direction through the gluteal muscles, through a portion of the os innominatum, and had lodged in the upper portion of the os sacrum, superior to the spinal cord where it joins the vertebral column.

On passing a director in at the broken orifice of bone, it passed within an inch of its whole length along an irregular and comminuted bony channel, and presented, covered only by the muscles, over the sacrum, a little to the left of the centre, and as nearly as may be at the junction of the sacrum with the last lumbar vertebra. The ball was found lodged at this point, but apparently prevented from pressing upon the spinal cord by the broken fragments of bone, which, impacted, formed a kind of bridge and bed. The ball was a good deal grooved and scraped, but not at all flattened or jagged by its traverse of some three inches in bone, which it had comminuted and pulverized in its course.

For the first two or three weeks he

was in good spirits, free from pain, and seemed but little affected. The wearing away was very gradual subsequently, and he retained his freedom from pain, hope, and appetite, to the last. His most distressing symptom was *hicough*, which set in for the last two or three weeks with very little intermission. Diarrhœa came on at intervals, but was not obstinate, and rather seemed to depend upon some irregularity in his diet than the wound.

At other times, although more urgent symptoms attend these injuries, yet, with fracture of the canal and some degree of pressure, no paralysis follows, only a pricking sensation in the feet—even in cases where the mischief to the cord extends upward to the brain, and with extravasation sufficient to produce considerable pressure within the theca, of which the following is an example:—

Case shewing fatal consequences from Injury to Spinal Canal and Medulla Spinalis, without Paralysis; also, Dislocation of the Ribs at their articulations with the Spine.

George Cusack, wounded on the 1st of August, 1836. A musket-ball entered about three inches to the side of the spinous processes, entering the chest at the edge of the eleventh rib, fracturing it between its neck and angle, and lodged in the angle of the last dorsal vertebra, together with a piece of red coat and wadding. The head of the twelfth rib was dislocated on the body of the succeeding vertebra. Near the last dorsal vertebra the diaphragm was torn, and superficial ulceration appeared on the surface of the liver and kidney, in contact, probably caused by the grazing of the ball. *The theca and spinal cord ruptured, and portions of broken bone forced in upon it.* (See fig. 3.)

In detailing the symptoms of so complicated and extensive an injury, of course only a few of them can apply to spinal injury: to these I shall chiefly confine myself.

On the introduction of the finger the lung was felt acting against it; and at his admission he expressed great agony by his cries. His chief complaint was *severe pricking pain of the ankles and feet, with difficulty of breathing.*

V.S. ad 5xx. Antimonial mixture and opium administered in separate doses.

The next morning he was easier; had

FIG. 3.

Fracture into Spinal Canal; Ball lodged.

Description of the Bone after Maceration.

a, The inner surface of the body of the last dorsal vertebra, forming the base of the canal, for the spinal cord is in a state of partial caries.

b, The superior surface of the body, forming a small circular line near the ball, broken.

c, The ball, with a piece of red coat and white coarse lining, firmly impacted in the angle of the body, and presenting a smooth round surface.

d, Both the upper and under surface of the body considerably discoloured, in an irregular circle round the ball, which projects a little into the spinal canal.

not slept much, but was relieved by the bleeding; pulse 100, full; skin hot; tongue furred; two stools; breathing less difficult.

Delirium came on in the third night, which, with the pains in the feet, continued to the last, with occasional intermission. On the evening of the 4th day he laboured under retention of urine, which, on being relieved, did not return. Pulse accelerated throughout; air passed through the wound.

On the 10th day symptoms of trismus supervened, with some degree of opisthotonos.

Post-mortem.—Injury and course of the ball have been described.

Thorax.—Right lung adhering, except around the wound, where some yellow turbid serum was collected. The

lung being unattached here for an extent equal to the palm of the hand, a considerable quantity was found. The pleura itself was much thickened by the adhesion of a thick layer of tough yellowish white lymph, presenting externally a granulated corrugated appearance, of which a portion is here preserved. The left lung was perfectly healthy.

Head—On opening the cavity of the cranium, and reflecting back the dura mater, the pia mater was found somewhat injected; substance of brain not unnatural; ventricles normal. At the base of brain, however, there was a considerable quantity of serum. Integuments and muscles of neck and back infiltrated with serum.

Arterial coloured blood in considerable quantity was found extravasated in the internal surface of the whole of the cervical part of the theca vertebralis, and its remaining part was vascular.

When the spinal cord was removed from its canal, the inner plate of the body of last dorsal vertebra was found to have been irregularly forced inwards by the ball, which was firmly lodged, as described, in the cancellated structure. The portions of bone forced inwards projected a considerable distance within the spinal canal, and had lacerated the theca for about half an inch, while a small portion of spongy bone was found entangled within the medulla, without, however, any perceptible lesion.

None of the spinal nerves appeared to have suffered any laceration, but extending downwards over the cord æquina from the lacerated part of the theca, a fine coating of yellow lymph was observed, and the tortuous vessels of the remaining part of the cord were rather more than usually injected.

It is rare that an injury and its symptoms should, in their relation to each other, be so well and distinctly marked. Here is a severe injury of the lower portion of the spinal column, without paralysis; the cerebral system, in the first instance, as well as the sympathetic, but little affected. The true spinal system is the seat of injury; and what are the signs? First, there is impeded respiration, and the extravasation of blood in the theca of the cervical portion of the fluid in the base were alike found, as further evidence or cause. The

pricking and very distressing sensation in the feet may very naturally be referred to the spicula of bone pressing upon the medulla. Towards the fourth 24 hours there is further impaired power of the true spinal system, and the cerebral also becomes gravely implicated; in evidence of the first there is loss of sensation in the bladder, retention of urine; of the second, delirium.

The next day the impaired action of the whole excito-motory system ceased, gradually became excited, and finally ended in trismus and opisthotonos.

I laid some emphasis on the fact of the dislocated rib, because it is stated, on high authority, Sir Astley Cooper's, whose talents and experience necessarily give great weight to all his opinions, that he has never seen such a case, and thereby almost implying its impossibility. Nor is this injury confined to gun-shot wounds. Here is another case which sets that question at rest, a case of great interest in many points, and to which I would particularly call your attention, as I shall hereafter have to allude to some of its features.

Case of Injury to Spine, and Dislocation of the heads of the 6th, 7th, and 8th Ribs, from Contusions.

Richard Powell, Feb. 5th, 1837, received several severe injuries about the body and spine, from the falling in of part of the roof of an old house. The spinous processes of the 6th and 7th dorsal vertebrae were found to be broken; and from paralysis and other symptoms it was presumed serious injury had also been inflicted on the medulla spinalis. The notes of the first three days have been mislaid. On the fourth day of the accident he was found to have slept little, being affected with a very frequent and harassing cough. There was paralysis of the bladder, and the stools passed involuntarily, Pulse 90, weak and small; experiences little pain in the back, except when moved. The urine is drawn off by catheter to relieve retention.

R. Ext. Conii, gr. v.; Morphine Acet. gr. ss. ft. pil. st. s.

5th day.—Lower part of abdomen insensible; much pain complained of in the epigastric region, but no tenderness on pressure, evidently proceeding from irritation of sentient nerves, and not

inflammation. Enema, cum $\frac{3}{4}$ ss. Ol. Terebinth., no stool having passed for 24 hours.

6th.—Bowels continue constipated; evident impaired action in the abdominal muscles. Epigastric pain appears relieved by the application of a blister.

Ol. Tiglii, gtt. i. st. s. Rep. Enema.

7th.—Passed a tranquil night; bowels evacuated by enema, &c. Urine deposits a thick sediment; temperature not lowered in the paralyzed limbs. Since the application of blister, says he breathes more freely; cough less frequent and difficult.

8th.—A quantity of mucus passes when the catheter is used; little pain when undisturbed.

9th.—Flushed face, and increased strength and velocity of the pulse.

10th.—Involuntary discharge of fæces; urine more thickly surcharged with deposit.

11th.—*Involuntary discharge of urine.*

14th.—Little change in the intervening days; now considerably deteriorated; complains of renewed pain of abdomen; secretion of urine much diminished; pulse hardly perceptible; and on the 15th day from the receipt of the injury he died.

Post-mortem: external appearance.

—Abdomen tumid with gases, apparently generated during the rapid decomposition of the body. The scrotum was inflated to the size of a child's head, and puncture by the scalpel was followed by the escape of gas. An extensive slough had formed over the sacrum. On removing the coverings of the spinal column the following injuries were found:—

Fracture and depression of the spinous processes of the 6th and 7th dorsal vertebræ; complete fracture and separation of the body of the 6th dorsal vertebra, by the depression of one part of which the spinal canal was intersected by an angle of bony substance, and the spinal sheath and cord crushed and lacerated. On both sides of this part of the spine the 6th, 7th, and 8th ribs were fractured, and *two of them had their heads dislocated from the articulation with the transverse processes.*

Now here is a similar case without any gun-shot injury. Two cases in one

year sufficiently prove the possibility. There is attendant fracture in both, but this would rather tend to diminish than increase the liability to dislocation. There are instances of injuries in military hospitals which probably in a long life do not fall under the observation of surgeons in civil practice. Yet are such cases most valuable, filling up many blanks, and establishing numerous facts and principles, which, in the accidents and injuries of towns, would be little likely to be developed. And thus you will also perceive, that whoever has studied the more complicated forms, must come to the treatment of a more limited range with great advantages. In this conviction at least have I felt it a duty to devote a series of lectures to these grave complications in surgery, and to bring such cases as these before you in the hope and belief that their consideration would prove of essential service hereafter.

The first two cases described have been brought especially under your notice, to enforce the necessity of a guarded and careful diagnosis in all cases of injury in or about the spine. To impress upon you a fact which may be of no small importance to your credit hereafter in practice, that in fractures of the spine and pelvis the absence of severe symptoms is no sure proof of non-fracture, nor, indeed, of the absence of lesion into the spinal canal. That not only lesion of the bodies of vertebræ and infraction of the bony canal, do not necessarily occasion paralysis, but even extensive injury to the spinal cord itself, occasionally fails in producing it.

There is another point in reference to these injuries not so generally understood as its importance to our diagnosis requires, viz., the degree and mode in which the action of the bladder and rectum, as depository organs of the excretions, are affected by spine injuries.

Here both the cerebral and the true spinal system are generally combined to produce the effects observed. The muscles are of the mixed character, voluntary and involuntary; the former of these is more easily impaired than the latter. A loss of voluntary motion, therefore, is generally the first stage or degree of paralysis observable; and then, although the patient cannot at will evacuate either bladder or rectum, yet there is neither retention of urine

nor obstruction in the bowels. These acts, in truth, are chiefly under the control of the true spinal system, and therefore, when the contents in either cavity accumulate, the sentient nerves convey the impression to the spinal centre, and a reflex motor action is induced, causing the contractile action of the muscular fibres surrounding them, relaxation of the sphincter, and the expulsion of the contents.

In a second degree, however, or rather another kind forming only a second degree in effects, the true spinal system is the seat of injury, its power is impaired, the sentient and motor nerves of that system are alike more or less paralyzed, the contents of the two cavities accumulate, and no reflex action from sensation to motion through the spinal centre takes place; and if relief be not artificially afforded, distension may go on until it produces gangrene of the parietes by pressure.

But if this paralysis be more complete, the muscular fibres guarding the orifices of the rectum and bladder are both relaxed; the contents of the rectum are passed involuntarily, but probably not the urine. There is retention; and how is this? A much more complicated apparatus is formed by the bladder and urethra than by the rectum. The mere relaxation of the sphincter vesicæ, or muscular fibres around the urethra, is not enough to produce immediate discharge. If the bladder be not very full, so that the fluid is above the level of the bladder, even if the passage were open, no urine would flow, unless there was some muscular power to squeeze the bladder and project forward its contents. But this is not all; even when the urine, by a law of gravity being above the orifice of the urethra, would pass out, and when the sphincter muscular fibres are relaxed, the elastic tissue round the neck will still sufficiently close the opening to prevent the flow or passage of the water when there is no muscular force to propel it and overcome the resistance.

It was stated by Mr. Hunter, that the action of elasticity was continual; and his commentators, proceeding a step farther, assert that elasticity in animals does not, like muscular contraction, depend on life, an elastic body possessing that property as perfectly after death

as before. At a first glance this assertion seems very plausible and natural, yet I believe it is incorrect. Whatever physical properties any animal structure may be endowed with, there is reason to believe that such properties are all modified, increased, abated, &c. by vital influences, as those of the nervous system. And the fact in question, relating to the retention of urine, subsequently followed by incontinence, seems to me a proof in point.

It is only in the most complete degree of spinal paralysis, then, when not only all involuntary muscular fibres are entirely relaxed, but even the nervous power, upon which the elastic tissues must in some degree be dependent for their elastic or contractile power, is withdrawn, that you find incontinence of urine.

Thus we may distinguish three well-marked stages, the result of impaired power from injuries of the spinal column.

1. Loss of voluntary power to induce expulsion of fæces or urine.

2. Loss of power of involuntary muscles and relaxation of the sphincters, giving *involuntary discharge of the contents of the rectum and retention of urine*.

3. Total paralysis of all nervous power derived from true spinal system, on which the *tone* of all tissues depend, giving incontinence of urine.

It will be evident how concussion and other cerebral injuries may induce precisely the same degrees and effects, in proportion as the cerebral functions only, or the excito-motory system in addition, become complicated.

You will find in many works of authority in surgery, that, in reference to injuries of the spine, it is broadly stated, that "if any of the cervical vertebræ be broken above the fourth, death is immediately the result." The case of Cusack can leave no doubt in your minds that this must be taken *cum grano salis*; that it is, in truth, somewhat too sweepingly stated. I have no doubt all such injuries prove ultimately fatal, but certainly not immediately. The following is a very interesting case,—

Showing a very high Division of the Spinal Cord, not causing death until the third day.

Sergeant Moreland, on the 25th of July, 1833, in Oporto, was wounded by

a musket-ball, which passed directly through the back of the neck, evidently injuring the spine about the fourth cervical vertebra. A complete paralysis of all the body below the wound immediately followed.

2d day.—Little hæmorrhage; he is exceedingly low, breathing with difficulty. He conversed rationally until the 2d night. About three hours before death he became insensible. The next day, early in the morning, he died.

Post-mortem.—The arch of the spine, between the fourth and fifth cervical vertebra, was found comminuted, and the spinal cord entirely divided. I am not aware of any other instance on record of a complete division of the spinal cord so high, where life was preserved so long. The bowels were not acted upon until the morning of his death, when both fæces and urine passed involuntarily: a case proving beautifully, and far more indisputably than all the experiments devised for this purpose, that the true spinal system does exist, and may exist, independently of the cerebral. Paralysis of this, as shown by the continued action of the sphincters, only took place when all the powers of life failing, ushered in his death. Here, also, we see an instance of the mutual independence, to a certain extent, and for a time, of the cerebral and true spinal systems, both remaining unimpaired, though cut off from each other, until the approach of death.

There was a coagulum of blood above and below the wound, between the medulla and theca spinalis; and this membrane was red and injected for a considerable distance. Lungs natural; intestines, bladder, and kidneys, were covered with dark patches of an ecchymose character. Gall-bladder empty; liver pale and flaccid.

There was no one symptom indicating any inflammation in the abdomen, the severe cramps alone drawing attention to that part. How far pure nervous irritation may have induced the inflammatory action or lesion of organic nervous fibres, I will not now attempt to explain.

The state of the bladder confirms all that I have advanced on that head. As the true spinal system became more deeply involved, we see the superven-

tion of distressing spasms in the upper as well as lower limbs, and impeded respiration.

In some rare instances, inflammation in the coats of the abdominal viscera is an attendant on severe spinal injury. How far this may be considered as a direct consequence is difficult to determine; but that it is developed in some manner by the injury is less doubtful. I am inclined to regard this effect as analogous with the inflammation which supervenes in the conjunctiva of the eye, on division of the second cervical ganglion interfering with the nutrition of the organ. In such injuries as those now described, lesion of organic nervous fibres must be a frequent attendant. I will relate to you a case interesting in many other points, where this effect took place very extensively;—and here is the preparation showing the exact nature of the injury to the vertebæ.

Fracture into the Spinal Canal.

Case of Injury to Spine, showing as an occasional attendant or consequence extensive ecchymosed patches of the abdominal and pelvic viscera.

John Got was admitted October 1, 1836, having been wounded by a musket-ball, which entered over the angle of the eleventh rib, and was extracted on the right side, by incision over the curvature of the ninth rib.

I found the pulse slow and steady, not small; skin cold; face pallid; aspect weak and anxious. He was moaning constantly, with pain and cramp at the lower part of abdomen, and both thighs, legs, and feet. No pain on pressure of abdomen; extremities cold.

Cap. Tinct. Opii, ℥xx.; Sp. Ammon. Arom. 3ss.; Aquæ, ʒij. statim.

The draught was repeated thrice.

1 o'clock A.M.—Paralysis of lower extremities, with severe abdominal pains.

2d day.—Had slept a little during the night, and the pain was less in the back; pulse was very full and quick. On examining the hypogastric region, I found the bladder contained a considerable quantity of fluid, capable of being pressed by the hand mechanically from the urethra. Bowels have not acted since his admission.

On the 3d day he was easier. On the

4th the retention of urine was converted into incontinence. He was cupped near the site of injury to twenty ounces, and two drops of croton oil were administered. No constitutional irritation was manifest, and but little pain experienced.

On the 5th day the bowels, with the aid of a terebinthine injection, were relieved; the pain of spine and restlessness were considerable.

On the 6th, at 4 o'clock A.M., he was attacked by distressing spasms and pain of lower extremities; the arms were drawn up across the chest; respiration became more and more prolonged, and performed with an excessive effort of the respiratory muscles; and at 10 o'clock he died.

The jar or concussion attending many of the worst forms of injury to the spine, occasionally produces effects in the cord analogous to those I have described at some length as resulting in the brain—softening and disorganization; it also leads, as has been shown in one of the cases quoted, to effusion at the base of the brain, and consequent pressure; also, extensive effusion within the theca.

Whenever there is paralysis of the lower extremities, generally a similar effect, in one or other of the degrees described, exists in the bladder and rectum, unless that paralysis shall have arisen from lesion simply of the cerebral motor tract.

The treatment of these injuries offers little that is satisfactory to communicate. By no local apparatus can the surgeon attempt to restore the bones when displaced, even could he accurately discover when it existed, or in what form, which, of course, he cannot. Any operation for removing portions of bone which may be supposed to be pressing upon the spinal column, is inadmissible, I conceive, on two grounds:—

First, the indication of the depression cannot be sufficiently distinct.

Secondly, to cut through the deep layer of longitudinal muscles, beneath which the bodies of the vertebræ lie, and on which wound the patient will most likely be compelled to rest; and then to inflict the violence necessarily required, both on soft and bony structure, to conclude the operation, leaves no sufficient hope of a successful result when added to the original mischief. Two fatal cases of operation in this town are on record. Even had this pro-

ceeding the merit once ascribed to it, of "giving no pain," I must, with all due deference to high authority, declare I think it a bad operation. It may readily be conceived that I am tolerably familiar with the knife, and not likely to hesitate in its use whenever it may seem necessary. I would not, however, use it in such a case, from my conviction that no beneficial effect would be likely to result.

To such local and general means as are best adapted, to check inflammation, and diminish the general irritability of the system—to promote the ease and comfort of the patient as regards the position—with friction of the abdomen when distended—there is, I fear, little to be added.

It generally happens that injuries of the spinal cord give rise to an irritation of the nervous system of the most serious kind, often ending in inflammation and effusion in the brain. Care must be taken to draw off the urine at least twice in every twenty-four hours, if there be retention—to insure the greatest cleanliness when there is involuntary discharge of the fæces, &c., and carefully guard against the formation of bed-sores, which, if they do not hasten the dissolution of the patient, must at least have the effect of adding greatly to his sufferings and discomfort. There are a great many imaginary evils in the world; but in the treatment of your patients let me beg you ever to bear in mind, that pain is a real evil, and one of the greatest of this life. It might cost me little to forgive any man's shortening by a few weeks or months my life; but in my conscience I think no one deserves forgiveness who, either by carelessness or wilfulness, makes any portion of it miserable.

OBSERVATIONS
ON THE
OVA OF THE MAMMIFERA,
BEFORE AND AFTER IMPREGNATION.
IN REFERENCE TO
*Dr. Martin Barry's "Researches in
Embryology*."*
BY T. WHARTON JONES.
[For the London Medical Gazette.]

§ 1. AMONG the observations with which Dr. Barry enters upon the first series of

* 1. *Researches in Embryology: First Series.*

his "Researches," are the following words, at page 302:—

"It may not be improper, in the first place, to furnish an idea of what has been already published on some branches of the subject; for it is one to which the attention of physiologists in this country has scarcely begun to be directed."

If the reader will refer to the *Philosophical Transactions*, Part II. for 1837, page 339, he will, perhaps, see reason to demur at the accuracy of this assertion, when he reads there a paper entitled, "On the First Changes in the Ova of the Mammifera, in consequence of Impregnation; and on the Mode of Origin of the Chorion." He will perhaps demur still more at the accuracy of the assertion, when he finds, moreover, in the introduction of the paper here mentioned, reference to another, describing the structure of the ovum of mammiferous animals, as it exists in the ovary before impregnation*.

The latter paper, which is entitled, "On the Ova of Man and Mammiferous Animals, as they exist in the Ovaries before Impregnation; and on the Discovery in them of a Vesicle analogous to that described by Professor Purkinje in the Immature Egg of the Bird," was read before the Royal Society, June 18th, 1835. It was *not* published in the *Philosophical Transactions*, for the reason, I believe, that I was not in London at the time to demonstrate what I described; but the manuscript, with the drawing illustrating it, is in the Archives of the Royal Society, and it is printed in full in the first volume of the *MEDICAL GAZETTE*, for Session 1837-38, pp. 680-688; London, 1838.

§ 2. Having made this statement, which, in justice to myself, I feel called upon to do, I will now enter into an examination of the pretensions to novelty, originality, and correctness, which Dr. Barry has introduced into both series of his "Researches."

§ 3. At page 301, Dr. B. says in a note:—

"Professor Baer called the vesicle he

By Martin Barry, M.D. F.R.S.E. &c. in *Philosophical Transactions*, Part II. 1838.

2. *Researches in Embryology: Second Series.* By Martin Barry, M.D. F.R.S.E. &c. in "Proceedings of the Royal Society," No. 38, 1839.

* Had there been no other, the labours of Dr. Allen Thomson in this field ought to have been sufficient to have obviated the reproach so sweepingly implied, in Dr. Barry's allegation, against the physiologists of this country.

discovered in the ovary not the *ovum*, but the '*ovulum*.' If, however, it can be made to appear extremely probable that the chorion, or external membrane of the ovum of the uterus, is a primitive part of the ovarian vesicle of Baer, it is perhaps better to call the latter an *ovum*, as will be done in this memoir."

In reference to this point I will take the following extract from my first memoir, read before the Royal Society in 1835:—

"*Of the ovum.*—Baer calls this *ovulum*, not so much on account of its very small size, as from considerations which, in the course of this memoir, I shall attempt to show are unfounded. I apply to it the name *ovum*, in the same sense as I would apply the term to the egg in any other class of animals." And again I say, further on, "From what I have said, I think I am justified in concluding, that in the small body discovered by Baer in the Graafian vesicle, and which I have described in this memoir under the name of the *ovum of the mammifera*, we have the analogue of the egg of the bird and that of other ovipara."

The above quotations are sufficient to show that, in the presence of the Royal Society, in the year 1835, the body discovered by Baer in the ovary was designated by the name of *ovum*, and that for reasons which, I apprehend, no one gainsays. In his second memoir, Dr. B. acknowledges his having been in error regarding the mode of origin of the chorion: hence the particular reason he adduces for calling the ovulum *ovum*, goes for nought.

§ 4. At page 303, Dr. B. says, "It will presently be shown that a perfect analogy does not exist between these bodies," *i. e.* the bodies expelled respectively from the ovaries of mammalia and those of other vertebrated animals. I would remark, that the observations contained in my paper, in Part II. of the Philosophical Transactions for 1837, comprehend striking and beautiful illustrations of the closeness of the analogy on which Dr. B. attempts to throw a doubt; and I shall by and by show that the reasons against a perfect analogy, to which Dr. B. refers, are substantially confuted by his subsequent admission of error regarding the mode of origin of the chorion.

§ 5. At page 311 of Dr. B.'s paper, in the Philosophical Transactions, appears the following note:—

"T. W. Jones (London and Edinburgh Philosophical Magazine, No. 39, Sept. 1835, page 209) mentions the germinal vesicle as 'having on one side a small elevation, which, projecting among the grains composing the granular sac, fixes the vesicle in its place.' I have never observed this 'small elevation,'" continues Dr. B., "nor do I find any mention to have been made of it by either Coste or Valentin, who had previously described the germinal vesicle in mammalia, or by those who have since written on it."

If Dr. B. had, instead of quoting from the abstract, unauthenticated by my revisal, of my paper read to the Royal Society in June 1835, referred to the original manuscript and drawing in the archives of the Royal Society, or to the paper as it is printed in the first volume of the MEDICAL GAZETTE, for the session 1837-38, he would have learned what this "small elevation" is; it would have been seen by the figures that it is nothing more nor less than the so-called germinal spot of Rudolph Wagner; he would have seen fig. 7, representing, within a square area, the human germinal vesicle isolated, and on one side of it the "small elevation." In fig. 3 he would have seen the human ovum represented, as viewed under the microscope by transmitted light; and on one part of the surface of the yolk a "small spot," which is the "elevation" on the side of the germinal vesicle. Again, in fig. 6 is exhibited a "spot on the surface of the granular sac." This spot, it is remarked, "which may be considered as the cicatricula, is the elevation on the side of the germinal vesicle." Figs. 8, 9, 10, also represent the "small spot," or "small elevation."

If Dr. B. had referred to the memoir itself, he would have found, in addition to all this, the following remark, in a note, regarding the "small elevation," or "small spot":—"I shall not at present venture on any speculation regarding the nature of this part; but that it performs an important function there can be no doubt."

I believe we are as far from knowing the function of the spot now as when I wrote; the name *germinal spot*, therefore, given to it by Rudolph Wagner, can only be employed in a general sense, and by no means as expressive of its particular nature or function.

But Dr. B. objects to the expression

"small elevation." That the germinal spot of the germinal vesicle of the mammiferous ovum forms a "small elevation," as I say, is proved by the following circumstances, which I particularly noticed at the time I made the observations:—

1. In most ova the germinal vesicle itself is covered by the granules of the yolk, and not seen until the ovum is dissected, or compressed; but in many ova a small spot is seen (as in my figs. 3 and 6) peering from among the yolk grains. That this spot is the so-called *germinal spot*, is proved by the circumstance that, in other ova, it is distinctly seen at the same time with a part of the circumference of the vesicle. Now if the spot were not elevated, it could not be seen while the vesicle itself was covered by the yolk grains.

2. By varying the focus of the microscope, and observing the distinctness or indistinctness of the spot in relation to the other parts, the spot appeared to me elevated.

Here I may mention, that I used the simple microscope—an instrument much less likely to lead to error, under such circumstances, than the compound microscope.

Bernhardt's figure, copied by Dr. B. (plate viii. fig. 72), represents the spot, but the rest of the vesicle is concealed by the yolk grains.

§ 6. At page 312 of Dr. Barry's first paper we read the following:—

"*The ovisac of birds ('chorion' of authors) compared with the ovisac of mammals.*—The ovarian calyx of the bird, if deprived of its peritoneal investment, and what there is of the parenchyma of the ovary, would, I apprehend, present a structure analogous to the Graafian vesicle of mammals; that is, a structure consisting of an ovisac that has acquired a proper (and in the later stages, a highly vascular) covering. Yet the ovisac of birds has been mistaken for a vesicle corresponding to the chorion of mammals; and accordingly it has been called the 'chorion.'"

Again, at page 314, Dr. B. says:—"From the foregoing it appears that the Graafian vesicle is not, as it has been supposed to be, a structure peculiar to the mammalia. Nor is it correct to consider the Graafian vesicle of mammalia as analogous to the whole calyx of other animals. It corresponds to no more than the two internal membranes,

viz. the ovisac and its proper vascular covering, the remainder of the calyx being derived from the ovary, with—in birds, some amphibia, and some fishes—a peritoneal covering; and however inconsiderable this portion of the calyx may appear, yet, for the sake of analogy, the distinction is not unworthy of being made."

All this is true; but I dissent from the correctness of the allegation, that it was not clearly stated before. I can answer for myself, that I am not one of the authors who have mistaken the ovisac of birds for the analogue of the chorion of mammals. This, I think, the following extract from the first memoir I presented to the Royal Society will show:—

"In birds, the yolk and its membrane are the only parts of the egg which are formed in the ovary. The chalaziferous membrane, the chalazæ, the albumen, the membrane of the shell, and the shell, are added in the oviduct. The ovary of the bird may be described as a cluster of capsules, with their contained yolks, varying in magnitude from that of a millet-seed to the full-sized yolk. The stroma which surrounds these capsules is a laminar cellular tissue, delicate, and in small quantity. The indusium is derived from the peritoneum; it envelops almost entirely each capsule, and forms, along with the vessels of the latter, a pedicle, by which the capsule is attached to the body of the ovary. The very small capsules not being so completely enveloped by indusium, are not pedunculated, but sessile. The capsule in which the yolk and its membrane are found, is composed of two laminæ—an outer, cellulo-vascular; and an inner, soft and spongy, which receives small vessels from the larger branches ramified in the outer."

After this I consider the yolk and its membrane; and having described the vesicle of Purkinje, I gave the annexed diagram (No. 1) of the whole structure; a little further on the diagram (No. 2) of the Graafian vesicle and its contents; and then, still further on, say—"There can be no doubt that the capsule, which contains the yolk in the hen's ovary, is analogous to the capsule of the Graafian vesicle."

§ 7. I now come to p. 315 of Dr. B.'s first paper, where is found a section, entitled, "*The proper Membrane of the Yolk in Mammals.*"

THE OVA OF THE MAMMIFERA.

DIAGRAM, No. 1.

Fig. 1 is a diagram representing a section of the hen's egg within the capsule of the ovary, and the position of the vesicle of Purkinje. *a.* The granular membrane, forming the periphery of the yolk. *b.* The vesicle of Purkinje embedded in the cumulus. *c.* The vitellary membrane. *d.* The inner and outer layers of the capsule of the ovum. *e.* The indusium of the ovary. Betwixt the indusium and the capsule the stroma is seated. *f.* The pedicle by which the capsule is attached to the ovary.

DIAGRAM, No. 2.

Fig. 2 is a diagram of a section of the Graafian vesicle and its contents, shewing the situation of the ovum. *a.* The granular membrane. *b.* The proligerous disc. *c.* Ovum. *d.* The inner and outer layers of the wall of the Graafian vesicle. *e.* Indusium of the ovary derived from the peritoneum, the stroma immediately underneath which is condensed so as to form the *tunica albuginea*.

On the correct determination of what is the vitellary membrane, correct notions regarding the mammiferous ovum and its analogies both before and after impregnation, entirely depend. We must therefore be extremely cautious on this point, and not admit the existence of any structure on light or doubtful grounds.

Dr. B. commences the section thus:—"Several distinguished authors have not described this membrane;" and in a note says, "among these are Coste and T. W. Jones." This is quite true; neither Coste nor I have described such a membrane as that the existence of which Dr. B. here tries to establish. What Coste and others, as well as I, have described as the vitellary membrane, is the thick transparent coat of the ovarian ovum; the part described by Dr. B. at p. 316, under the title of "the true chorion, or structure superadded within the ovary in the class mammalia."

What Dr. B. calls the true chorion, then, and Coste, others, and myself, the vitellary membrane, is supposed by Coste (according to Dr. B. correctly*) to become the chorion in the uterus. When I wrote my first memoir, I also participated in this opinion; my subsequent researches, however, as detailed in my second memoir, proved the incorrectness of it†.

Baer considered the outer membrane of the body he discovered in the ovary analogous to the membrane of the shell in the bird's egg; and he entertained a peculiar notion regarding the vitellary membrane, both of birds and mammals. On this opinion I remark (in describing the ovum of birds), in my first memoir:—"The yolk consists, at first, of a granular membranous sac, within which is contained a fluid with granules suspended in it. The vitellary

* At the meeting of German naturalists, held at Prague, in 1837, M. Coste gave a short exposition of his views regarding the ova of the mammifera. Being present, I combated the opinion that the membrane in question forms the chorion, and described the origin of the chorion as I have laid it down in my paper in the *Philosophical Transactions* for 1837. Professor Purkinje, who was president of the section for the day, remarked, that my views were more consonant with analogy, but thought further observation desirable. In reference to Coste's opinion, that the chorion and vitellary membrane are the same, Dr. A. Thomson (*Contributions to the History of the Structure of the Human Ovum and Embryo before the third week after Conception*, with a description of some early Ova, Part I., in *Edinburgh Med. and Surg. Journal*, for July, 1839) remarks, after speaking of M. Coste's error regarding the formation of the amnion, "In subsequent parts of his work, the confusion introduced by M. Coste's considering the chorion and vitelline membrane as synonymous, is altogether surprising in one who has enjoyed such excellent opportunities of studying the subject of development, and who has given to the public several new and valuable observations regarding this branch of science."

† Having founded no argument on this view, the contradiction of it involves no other.

membrane is at this period extremely thin and transparent, and adheres very closely to the inner surface of the capsule. From these circumstances it is not readily seen, unless carefully looked for with the assistance of a magnifying glass. It is from not having noticed it at this early period, that Baer has mistaken the granular membranous sac of the yolk for it. Thus he says, '*vitelli membrana hoc tempore crassissima et granulosa est ita, ut optime mereatur nomen membranae granulosa, quam Purkinje quoque ita describit.*' This granular membrane, he supposes, divides afterwards into the proper vitellary membrane, and a granular layer forming the periphery of the yolk. His words are, '*Posthac membrana granulosa in stratum externum laeve, continuum—membrana vitelli puta—et stratum granulosum, vitelli peripherium efficiens, sejungi mihi visa est.*'" In regard to Baer's application of this opinion to the mammiferous ovum, I say—"He accounts for a vitellary membrane by conjecturing that there forms, on the outer surface of the granular membranous sac, which is the vitellus of the ovum, a thin pellicle, in the same manner that he erroneously supposes the vitellary membrane of the bird's egg is produced. There is no such pellicle as that spoken of by Baer, and all analogy leads us to suppose that the external envelope of the ovum of the mammifera does not correspond with the membrane of the shell of the bird's egg, but rather with the vitellary membrane."

A bias towards this opinion of Baer, and a desire to give congruity to the idea that the thick transparent coat of the ovum forms the chorion (a notion which Dr. B. relinquishes in his second paper, as I have already hinted), appears to have led Dr. B. to strain so hard, with such very slender evidence, to establish the existence of a membrane (which he might call vitellary) in addition to the thick transparent coat of the ovum. Dr. B. admits, that "it is not easy to demonstrate the separate existence of such a membrane in the class mammalia generally, at those periods in the formation of the ovum, when the latter is usually examined. . . . In later stages, *ante coitum*, I have sought this membrane in vain, as a distinct structure."—P. 315.

The figures which Dr. B. gives

of the pretended vitellary membrane shew nothing but the outline of the periphery of the yolk. In regard to Professor Krause's observations, which Dr. B. quotes, in proof of the existence of a vitellary membrane distinct from the thick transparent coat of the ovum, I believe they admit of a different explanation. In reference to the point I remarked in my second memoir, "In the ova of the rabbit, &c. before impregnation, the proligerous disc, in which the ovum is embedded, is observed to be composed of a gelatinous substance, interspersed with grains, but as yet there appears no distinctly circumscribed envelope." To this I add, in a foot-note, "Dr. Karl Krause, of Göttingen*, however, in a late number of Müller's Archiv, speaks as if the gelatinous substance really formed a well-defined envelope." In referring to Krause's observations since, he appears to represent this gelatinous substance as forming the zona pellucida; but he describes within it a vitellary membrane which latter I cannot, after examining his figure, admit to be any thing but the thick transparent coat of the ovum and the other substance, which he describes as an albuminous-looking fluid enclosed in a proper membranula, no thing more than, as I have above said the gelatinous-like substance in which the ovum is embedded. Dr. Barry certainly does not understand Professor Krause when he says, that having examined the ovum of the goat, he can attest to the accuracy of Krause in his representation of the *membrana vitelli* in this animal; adding, "I did not, however, in any instance find the *membrana vitelli* surrounded by a fluid, as described by Krause, but by the perfectly-formed and consistent chorion."

To continue the quotation from my second paper—"The gelatinous-looking envelope of the ovum I have just described, must not be confounded with the vitellary membrane of the ovum which was fully considered in my former paper. * * * That it, and not the vitellary membrane, as I formerly imagined, forms the chorion, will be made evident by the following observations," &c. &c. Dr. B. also quotes Rudolph Wagner, who, he says, pointed it (Dr. B.'s so-called vitellary mem-

* Incorrectly; Dr. Krause is professor in Hanover.

brane) out to him in the cat, but does not appear to have discerned it in any other instance. I have not seen the memoir of Wagner (Beiträge zur Geschichte der Zeugung. In Abhandlungen der mathematisch-physikalischen Klasse der k. Baierischen Academie der Wissenschaften, B. ii.), and the notice of it in Müller's "Jahresbericht" contains only the following:—"Rudolph Wagner describes the ovum of the rabbit, immediately after impregnation, as it was found in the uterus before adhesion. It consisted of two membranes; the outer quite transparent, without structure, and thinner than the chorion or zona pellucida of the ovum in the ovary. The inner membrane separated from the outer after the ovum had lain in water. It was beset on its inner surface with small globules. In regard to the outer membrane he inclines to the opinion of Baer, who thinks it forms the chorion. The second or inner is the vitellary membrane." This cannot be laid hold on as pertinent to the point under discussion.

I consider it entirely inconclusive to infer, as Dr. B. does, the existence of a proper membrane of the yolk, different from that thick transparent inner membrane of the ovarian ovum, which I have described as the vitellary membrane, from what is observed to be produced on ova by maceration, viz. "when the thick chorion, imbibing fluid into its interior, becomes distended beyond the size of the yolk-ball; but the latter retains its form, which certainly would not be the case were not the yolk circumscribed by a proper membrane." I have delineated (fig. 6.) the appearance here described by Dr B., which he himself illustrates by a figure borrowed from Bernhardt; and I have broken up and dissected the ovum in this condition, but never found any such membrane; on the contrary, I have always found the ovum as I have described it in my first memoir, viz.: "The ovum has a soft external envelope, which is transparent and very thick; hence is produced the appearance of a broad transparent ring, forming its circumference, when the ovum is viewed with the microscope by transmitted light. Within this transparent external envelop is seen a substance composed of grains adhering together

by the intervention of a delicate mucous tissue, so as to form a sac, which I have sometimes succeeded in withdrawing entire (see fig. 5.) Sometimes the grains do not hold together; hence, when the external envelope is torn, they escape, and diffuse themselves in the water surrounding the ovum. Baer appears to have misconceived the structure of the external envelope, for he describes it as a hollow sphere with thin walls, separated by a transparent interval from the central part of the ovum."

Dr. Barry continues on the subject of his so-called "proper membrane of the yolk in mammals."—

"I have observed a very interesting fact connected with the proper membrane of the yolk *post coitum*, not hitherto made known, which not only adds probability to the supposition that this membrane has a previous existence, but also accords in some degree with a change known to take place in birds. I find that in the rabbit, just before the ovum leaves the ovary, this membrane, previously so delicately thin, becomes perfectly distinct and very thick; and that the chorion, imbibing fluid into its interior, becomes somewhat distended, so that a minute space is visible between the membrana vitelli and the chorion. This thickening of the proper membrane of the yolk, and the distention of the chorion, subsequently proceed much further, as is proved by the state of the ova found in the Fallopian tube. I find, also, that the membrana vitelli is still visible, and has considerable thickness in minute ova, met with in the uterus. This subject will be entered into more fully in a future paper."

This future paper has been read before the Royal Society, but not yet published in the Philosophical Transactions. In the proceedings of the Royal Society (No. 38, 1839), however, there is an abstract of it, which concludes with the following short but very important remark:—"He (Dr. B.) has traced the chorion from stage to stage up to the period when it becomes villous, and shows that it is not, as he formerly supposed, the thick transparent membrane itself of the ovarian ovum, but a thin envelope closely investing that membrane, and not appreciable as a distinct structure until the ovum has been crushed * * * The chorion subse-

quently thickens, and imbibes a quantity of fluid, presenting a gelatinous appearance."

All this, if correctly interpreted, is nothing more nor less than a refutation of the leading doctrines deduced by Dr. B. from the whole preceding series of his researches, and a confirmation of my discovery of the mode of origin of the chorion in the ova of the mammifera, detailed in my second memoir.

§ 8. After this admission of error on the part of Dr. B., in regard to the chorion, I need scarcely take any notice of the section in his first paper, entitled, "*The true Chorion, a structure super-added within the ovary in the Class Mammalia*!"

§ 9. The remaining part of the first series of Dr. B.'s Researches is occupied with the consideration of structures of secondary importance in the economy of the ovum—structures which had on that account been less carefully studied. Dr. Barry has, therefore, here found something to glean, but the value of some of his observations on this part of his subject is necessarily depreciated by the inaccurate view he first took of the nature of the vitellary membrane and chorion. I shall only take notice of one assertion:—

At p. 322, in speaking of the granulous matter which immediately surrounds the ovum in the ovary, and which he proposes to call *tunica granulosa*, Dr. B. says, "Should the existence of this structure, as a *tunic*, be confirmed by the observations of others, it will no longer be surprising that the outer line in the double contour of the thick chorion* remained so long unseen, and that this thick membrane was regarded as a 'zone,' 'halo,' or 'pellucid space.' For the same reason it will be obvious why it has been found so difficult to free the ovum from the surrounding mass of granules; though I find that these granules do not adhere to the chorion (?) they invest, so closely as to each other."

As to this *tunica granulosa* of Dr. B. I believe it to be the same substance as that described by Krause, under the name of *zona pellucida*, which I notice in my second paper as being, in the ova of the rabbit, a gelatinous substance, inter-

persed with grains, a substance which, it is not unlikely, is converted, after impregnation, into the chorion which I discovered. But that the outer line in the double contour of the thick chorion* did not remain unseen by me at least, and that I never regarded it as a "zone," "halo," or "pellucid space," is, I think, proved by the figures and description I gave of the ovum in my first paper. I have already given extracts bearing on this point; here I would only add the following:—"To examine the ovum properly, it is necessary to separate entirely the proligerous disc from around it. A separation sometimes takes place spontaneously, particularly if the ovary has lain a day or two in water. It may, however, always be effected by careful manipulation with fine instruments under the microscope. I am surprised that Baer says he only succeeded once in doing this."

§ 10. Having found the allegation, that the subject of embryology is one to which the attention of physiologists in this country has scarcely begun to be directed, made by Dr. Barry, in the paper containing the first series of his Researches in Embryology so ill supported†, I confess I was not prepared to read in the abstract of his second series such a statement as the following:—

"The knowledge at present supposed to be possessed of the early stages in the development of that ovum (the mammiferous ovum), consists chiefly of inferences from observations on the ovum of the bird."

"But there exists a period in the history of the ovum of the mammal, regarding which we have hitherto scarcely any direct or positive knowledge."

For a perfect and unqualified contradiction of this very bold assertion, I would refer to my memoir, contained in the Philosophical Transactions, Part II. for 1837, page 339, already alluded to.

With an abstract of the leading points contained in that memoir I will conclude this communication, already, I

* Vitellary membrane.—T. W. J.

† My first paper was read before the Royal Society two years before, and my second paper during the time Dr. B. himself tells us (p. 302) he spent in Germany, preparatory to the commencement of his own researches, "for the purpose of becoming acquainted with the known facts on animal development, and other objects of microscopic research."

* Really the vitellary membrane.—T. W. J.

fear, too long. I would, however, notice, first, a point in the abstract of Dr. B.'s second paper. I have already shown that he retracts what he said in his first about the chorion; but if I understand the abstract right, his former erroneous notions are in some degree still mixed up with his more recent views. Thus he says, "The ovum enters the uterus in a state very different from that in which it leaves the ovary; hence the opinion, that 'in their passage through the tube, the ova of mammalia undergo scarcely any metamorphosis at all,' is erroneous. Among the changes taking place in the ovum during its passage through the Fallopian tube, are the following, viz.: 1. An outer membrane, the chorion, becomes visible. 2. The membrane originally investing the yolk, which had suddenly thickened, disappears by liquefaction; so that the yolk is now immediately surrounded by the thick transparent membrane of the ovarian ovum," &c. &c.

This appears to me so inconsistent in itself, and with what is said at the conclusion of the same abstract (which I have already quoted), that I must suppose some mistake has been made in the preparation of the abstract. I will therefore make no further remark on the second series of Dr. B.'s Researches until they appear in a more complete form.

§ 11. The abstract of my paper On the First Changes in the Ova of the Mammifera in consequence of Impregnation, and on the Mode of Origin of the Chorion, as given by Müller in his "Jahresbericht" for 1837, in Archiv, &c., vol. for 1838, being very concise, I shall translate it, at the same time taking the opportunity to correct a slight misconception of my meaning.

"Wharton Jones examined the internal organs of generation of a rabbit, killed three (not two, as Müller says) days after impregnation. The ova in the tubes were surrounded with a thick gelatinous layer, so that they were 1-70th of an inch in diameter. The germinal vesicle could not be detected. That this envelope of gelatinous substance is acquired in the ovary, was proved by further observations. In a rabbit examined forty-one hours after impregnation there were *no ova* in the Fallopian tubes, nor in the uterus. On the ovaries were several Graafian vesi-

cles, which were prominent, and filled with coagulated blood. At the most projecting point of each there was a small mammillary elevation, within which was the ovum, surrounded by the gelatinous substance, less swollen, however, than in the preceding case. The germinal vesicle was not remarked. Forty-eight hours after impregnation much the same appearances presented themselves. This substance appears to the author not to present itself before impregnation as a proper envelope; he asks, however, whether this layer be not that described by Krause. Seven days after impregnation the gelatinous-looking envelope constituted the sole covering of the yolk, which possessed only a spherical blastodermis. The cavity of the gelatinous-looking envelope was much larger than the spherical blastodermis; and on the inner surface of the former the author saw the remains of the vitellary membrane, which, according to his opinion, disappears in the same manner as in the ova of the ovipara. According to the author the chorion is developed, not from the vitellary membrane of the ovum, but from this gelatinous-looking envelope. A very young human ovum* agreed in what has just been related in regard to the rabbit, viz. that the vitellary membrane had disappeared, or been resolved into a gelatinous cellular tissue, which filled the chorion. Imbedded in the gelatinous cellular tissue, towards the extremity of the ovum, was a small round body—the spherical blastodermis†."

* Dr. Allen Thomson (Contributions, &c. already quoted, in Edinb. Med. and Surg. Journal for July, 1839, remarks (p. 122) of this ovum—"In a paper on the early condition of the ova of mammiferous animals, published in the Philosophical Transactions of London, Mr. T. W. Jones has described a very small human ovum, sent to him by Dr. Mackenzie, of Glasgow, and which I am inclined to regard as one of the earliest, if not the very earliest, human ovum, that has been accurately described, the record of which has come under my notice."

† Müller has transposed, in his abstract, the account of the human ovum,—a circumstance which makes it appear as if I supposed the point of its resemblance to the ovum of the rabbit consisted in its chorion being filled with a gelatinous cellular tissue. The disappearance of the vitellary membrane, and the chorion remaining the sole envelope, are the circumstances of agreement between the ovum of the rabbit seven days after impregnation and the human ovum. What is here called a *gelatinous cellular tissue* was evidently no other than the *reticular tissue* of Velpeau, found in more advanced ova between the chorion and amnion.

TABLE I.*—*Figures which illustrated the paper on the Ova of the Mammifera before Impregnation.*

TABLE II.*—*Figures which illustrated the paper on the Ova of the Mammifera after Impregnation.*

* The measurements here given do not lay claim to any very great accuracy, as they were made with a micrometer glass under the simple microscope.

Description of figures in Table 1.

Fig. 3 represents the human ovum as seen under the microscope by transmitted

light; it is magnified forty-five diameters. On one part of its surface a small spot is seen, which is the elevation on the side of the germinal vesicle.

Fig. 4 is the ovum still surrounded by the proligerous disc, magnified fifteen diameters.

Fig. 5 represents the outer envelope of the ovum lacerated, and the granularly membranous sac composing the yelk drawn out.

Fig. 6 exhibits a human ovum magnified forty-five diameters, in which the granular sac is so much contracted, that it does not fill up the whole cavity of the external envelope*. The spot on the surface of the granular sac, which may be considered as the cicatrula, is the elevation on the side of the germinal vesicle.

Fig. 7 represents, within a square area, the human germinal vesicle, magnified forty-five diameters. On one side of it is seen the small elevation.

Fig. 8, a human ovum, magnified forty-five diameters. In it the grains composing the granular sac were in such small quantity, and adhered so little together, that the whole germinal vesicle is seen shining through the outer envelope.

Fig. 9 is a diagram of a section of an ovum, representing the thick external envelope, within which is the granular sac, and connected with the inner surface of the latter the germinal vesicle.

Fig. 10 represents a human ovum, which I found in the ovary of a married woman of about 30. It is somewhat like two joined together, but there is only one germinal vesicle.

Description of figures in Table 2.

Fig. 1, an ovum found in the Fallopian tube of a rabbit the third day after impregnation, magnified forty diameters.

Fig. 2, the ovum of the frog when recently laid, magnified two diameters.

Fig. 3, the ovum of a water-newt, in which development has commenced, magnified rather more than twice.

Fig. 4, a diagram shewing the embryo of the newt after the vitellary membrane has given way, contained only within the cavity of the substance, which is added to the ovum in the oviduct.

Fig. 5, a diagram shewing the embryo of the frog still surrounded by the vitellary membrane, as well as the gelatinous substance, which is added to the ovum in the oviduct.

Fig. 6, an ovum found in the horn of the uterus of a rabbit seven days after impregnation, magnified forty diameters.

Fig. 7, a human ovum thrown off at the third or fourth week; natural size.

A CASE OF

SECTION OF THE HAM-STRING TENDONS,

FOR THE

CURE OF CONTRACTED KNEE-JOINT.

BY BENJ. PHILLIPS, F.R.S.

Surgeon to the Marylebone Infirmary, and Lecturer on Surgery to the Westminster Hospital School of Medicine.

[For the London Medical Gazette.]

THE practice of cutting tendons for the relief or cure of many deformities is so widely spread, and every new application of the principle seems to be adopted with so much avidity, that I trust I shall not be deemed to be occupying time and space unprofitably, by a very few prefatory observations, previous to the statement of the case which is the immediate subject of the present communication.

The dictum of Hippocrates, "that tendinous structures cannot be cut with impunity," held almost exclusive sway over men's minds up to nearly the end of the last century. Some persons, among whom were Paul Barberette, Meekren, and Abraham Titsingh, however, denied their sensibility, and maintained that wounds of these structures produced no general reaction. Others, among whom were Paré and Petit, believed that such wounds were very dangerous, producing spasm and great general reaction. Others, such as Boerhaave, Cowper, Platner, who, adopting the opinion of Galen, that tendons arose from nerves, taught that injuries of tendons are as serious as those of nerves, producing tetanus and other spasmodic affections. It was the apprehension so entertained which, it would seem, prevented Marianus from using the knife, in making way for the stone to be extracted from the bladder, and induced him to prefer tearing those parts to a sufficient extent by means of his dilators. Indeed, except in the case of a few bold innovators, such as Tulpus (1641), Roonhuysen, who cut the tendon of the sterno-mastoid successfully for the

* I believe the distension of the external envelope, by the absorption of water, and not the contraction of the granular sac, may be the more correct explanation of the appearance delineated.

cure of a case of wry neck (1674), Blasius (1677), Meekren (1788), and Ten Haaf (1791), tendinous structures have been respected up to very late times; for the momentary resuscitation of the principle by Thilenius in 1784, by Michaelis in 1811, and by Sartorius in 1812, did not cause the adoption of the system.

Petrini, in his memoir, "*Sull' insensibilita ed irritabilita*," published in 1735, seems first to have demonstrated that tendons and aponeuroses might be "dissected" without fear; but certainly the prevalent opinion was opposed to him; and the memoir of Jacques Fr. Chat, seems to have been an epitome of the opinions of the time on the subject. He concludes by saying, "*On doit donc éviter la section des tendons*" (1742.)

No very clear conviction seemed to exist on men's minds with regard to the possibility of union in divided tendons until the time of Titsingh, who said that wounds of tendons were united by the interposition of callus, which is organised, and by which they are cured in a few days. Stalpart van der Wiel (1777) also states that they are united by callus, like bone. Duchanoy (1775) and Bezoet (1765) state that at first a nodosity is distinguished, which soon acquires considerable consistency, and constitutes a firm bond of union.

These opinions obtained more consistency when maintained by Moore, Prochaska, Gordon, Boyer, and Thomson, who stated that the fibres of regenerated tendons are not disposed parallel the one to the other; that they are less glistening; and that the cicatrix is thicker than the tendon. Murray (1787) said that he had seen divided tendons unite like muscles, by means of plastic lymph, which becomes organised and transformed into a very dense cellular tissue. Bichat, in speaking of union after section of the tendo Achillis, says, that from the two ends of the tendon a fibro-albuminous matter is exuded, which is gradually condensed, and unites one to the other; that this matter is endowed with a sort of "ductility," which allows of its elongation and extension.

No man sought more fairly and completely to work out this part of the subject than Delpech. To satisfy himself of the principles upon which he ought to act, he made many experiments upon brute animals; and the knowledge so

acquired he successfully applied to man; and it is to me inconceivable how his merits, as connected with this subject, have been so greatly overlooked. Some years afterwards Stromeyer, in conjunction with Günther, a veterinary surgeon of Hanover, went over the same ground with Delpech; he applied the principle successfully to man, and his success caused its general adoption.

The mode of union was carefully observed by Duval (1837), who says, "As soon as a tendon is cut, the extremities are separated by muscular retraction. Some hours after, the surrounding cellular tissue is inflamed; twenty-four hours after, this tissue is bathed in serosity, and looks cedematous. The skin participates in this turgescence. Sometimes we find a mass of red matter, not unlike a clot of blood, between the ends of the tendon. From the cellular tissue at the circumference of the extremities of the tendons, filaments set out towards a fibrinous matter, which, however, is not always met with; but the cellular tissue is always inflamed during the first seven or eight days. Thirty-six hours after the section, the substance between the extremities exists in the form of a ligamentous membrane, much more developed superiorly than inferiorly. The third and fourth day this intermediate tissue acquires much thickness, and becomes, as it were, fleshy, dark red internally, whitish at its circumference. From the sixth to the eighth day it offers the same form with the tendon: the tendinous organization of this substance proceeds from the exterior towards the interior, by the condensation of cellular laminae. From the fifteenth to the twentieth day this organization is complete, its red colour no longer exists, and this new-formed tissue is as solid and as resistant as the tendon itself, from which it differs only in colour, which is less white; and sometimes by a little less thickness." We may complete this part of the subject by a short quotation from the commentary of Ammon on the same subject:—"The tissue thus formed fills, by the end of a fortnight, the same functions as a healthy tendon, with this exception, motion is a little more difficult, in consequence of the new substance being a little less elastic than the old, and also in consequence of its ad-

hering, to a certain extent, to the surrounding structures."

One important question still remains to be discussed. We have ascertained that a divided tendon will unite firmly, and that at the end of a certain time the medium of union can scarcely be distinguished from the original structure. We believe that in fractured bones separation of the fractured extremities cannot be carried beyond a certain point without involving the danger of non-union; what the extent may be it is not easy to define. How far the extremities of tendons may be separated with impunity, is an important question in our subject.

If the section of the tendo Achillis be made, it will unite by means of a very fine dense medium, even though the distance between the cut extremities be considerable. Molinelli states, in the *Memoirs of the Academy of Bologna*, three cases, which are good evidence of this fact. In one the tendon had been cut at two fingers' breadth from the calcaneum; the superior portion was retracted, and the inferior portion, with the exception of two lines, was removed; yet the two portions were perfectly united without shortening. Clement, of Avignon, according to Heister, saw a case in which the separation of the two ends, in a similar case, was above two inches, and yet the union was firm and complete. But, as might be expected, there is a limit beyond which this separation is imprudent. What that limit is, in man, I do not know; but in dogs about three inches is the maximum point, at which the development of a proper bond of union seems to be practicable; at least, in all the cases I have known, it has failed when the separation has extended to four inches.

This is a point of great importance in deciding whether extension should be promptly and firmly employed after the section of the tendons or not. Some persons recommend the immediate application of the principle; and further, that it should be energetically employed. If the reasoning could be applied to the human subject which is derived from experiments on brute animals, it is clear that it would be imprudent to produce a separation between the cut extremities to the extent of four inches; that it is not easy to determine how much short of that, separation might be

employed with impunity. I have known a separation to the extent of nearly two inches to be made in the human subject, immediately after the section of the tendo Achillis, without any inconvenience; I have known a separation of four inches in a dog, without union.

In this state of the question I think a middle course best. Some men do not employ extension for many days—until, in fact, the medium of union is organized; others apply extension at once. In the one case, the medium may not readily yield to extension; in the other, the medium may not connect the cut extremities.

Such are the preliminary remarks which it seemed to me desirable to make, for the purpose of fully opening the question, and also to facilitate the comprehension of the subject: to prevent unnecessary apprehension on the one hand, to induce proper reflection on the other. Whether the recklessness with which, in the present day, these structures are attacked—which has caused the section of the tendo Achillis at least 500 times since 1836—will be productive of as much good as the advocates of the operation expect, is more than doubtful. The tide has set in strongly in its favour, but I apprehend a reaction is not distant; and for that reaction the indiscreet advocates of the operation will have to answer. Failure has already been not unfrequent; and it behoves us, therefore, to avoid bringing into disrepute a system from which much good has already been derived, by employing it in cases where its success would be at best problematical.

I will now proceed to state the result of the section of tendons, as a means of treating certain cases of what is termed false ankylosis. By this term I merely wish to convey that condition of an articulation in which its motion is very sensibly impeded, or almost entirely prevented, by rigidity of the soft parts connected with the joint. This rigidity may affect only the tendons destined to move one bone on another, or it may be accompanied by a similar state of the ligamentary tissues. This condition may be brought about by many causes; it may be occasioned by phlegmonous inflammation of the cellular tissue about the joint; that inflammation may be communicated to

the lubricating apparatus of the tendons, may disorganise the synovial sacs, and terminate by causing an adhesion between the tendons and their sheaths. It may be brought about by long inaction in bed-ridden people, the limbs being in a state of flexion; or by repeated attacks of gout or rheumatism.

In the case I am about to detail, the patient was a young woman, of the age of 29, whose general health was good. Five years ago she suffered much from rheumatism, which affected principally the knee-joints and the hands. From this affliction she suffered for two years and a half, during which the leg of either side became more and more flexed upon the thigh, and extension was impossible. A great variety of mechanical means were used, for the purpose of endeavouring to procure extension, but without the slightest amendment. She then proceeded to Bath, underwent the usual course of treatment there, combined with attempts to extend the limbs by means of certain modifications of Amesbury's apparatus, but returned home, no better than she was when she left it. On her return she was placed under the care of Mr. Crellin, of St. John's Wood, whose treatment dissipated the remaining traces of rheumatism; but the contraction of the ham-string tendons remained unchanged. During the succeeding two years and a half her general health continued good, and she experienced no further attacks of rheumatic pain.

In January 1839, Mr. Crellin consulted me in the case. I found her almost bed-ridden, the right leg presenting with the thigh an angle of 55 degrees; beyond that point extension could not be made, but flexion might be proceeded with until the heel very nearly came in contact with the buttock. The left leg was flexed to a much less extent than the right, though the heel of that side is two inches and a half from the ground: it was, however, three inches and a half longer than the right. The joint appeared on either side to be unaffected, and no thickening was apparent. At the first view it seemed as if the patella were slightly displaced laterally; but this was more apparent than real, for in the leg upon which I operated the patella is now perfectly natural.

When the hand was placed upon the

posterior part of the thigh, from the tuberosity of the ischium, the muscles were tense and hard, and in the ham the tendons were like extended cords.

Nine months ago, when the case was first mentioned to me, I had recently seen an account of an operation performed at Antwerp, for the purpose of overcoming the resistance offered by the flexor muscles; and when I consulted with Mr. Crellin, I at once recommended a somewhat similar operation in this case, and as the patient's health was good, and as suspense would not probably improve her condition, the operation was performed on the succeeding day.

The Antwerp case will be found detailed at the conclusion of the paper.

I saw possible inconveniences from performing the operation as practised by Lutens, of Antwerp, and I saw no difficulty which could attend the section, made by means of the smallest external opening which would admit of the introduction of a proper instrument—such as is used in the section of the tendo Achillis.

Accordingly, on the 10th of January, in the presence of Messrs. Crellin and M'Ilree, I effected, without much pain or difficulty, a section of the tendons of the semi-tendinosus and the biceps, which allowed of an immediate extension to the amount of between two and three inches, and caused the disappearance of the tension at the back of the thigh. The operation was performed in the following way:—The patient lay, as nearly as she could, upon the face, and extension was made as far as possible, so as to produce a very marked cord-like tension of the ham-string tendons. A very straight blunt-pointed knife, such as is used by Bouvier in the section of the tendon Achillis, was glided on its flat under the tendon of the biceps, between it and the bone; its cutting edge was then directed upon the tendon, a sawing motion impressed upon it, and the knife soon passed through it, without injuring the integuments. It immediately retracted, to the extent of an inch. A similar course was taken with the semi-tendinosus. No blood was lost, and strapping was employed to bring together the lips of the two small incisions. All went on very satisfactorily, and I proposed to begin extension on the third day; but, in preparing for this, I found I had still resistance to

overcome: the semi-membranosus would not yield, and I at once decided to make a similar section of its tendon. The same means were employed as before, but the different portions of this muscle are not so easily cut; however, I continued to incise so long as I found this muscle offering resistance. This was soon accomplished, with comparatively very little suffering; its section allowed of our increasing extension by another inch. All went on very well, and in two days more extension was commenced, with a modification of Amesbury's apparatus. For some days matters seemed to proceed propitiously, but then she complained much of pain on the internal surface of the tuberosity of the tibia at the point of insertion of the cut tendons; this was subdued by small doses of morphia, and the screw was very sparingly used. When the screw had been used for some days, to the amount of a single evolution daily, she complained of pain at the patella; this was borne for a few days, but at last increased in severity, though there was no tumefaction nor much heat about the joint. I now divided the knee-cap of the instrument into two portions; one of which was applied above, the other below the patella. Gradually all pain and discomfort ceased, and soon I had the very great comfort of finding that the turns of the screw were nearly exhausted—that extension was almost complete. In a few days I removed the instrument, and discovered that there was scarcely any tendency to contraction; that the muscles were capable of extending and flexing the leg at will, though at first very slowly. Every day the power increased—every day the extension was more perfect; and as much more rapidly produced as she bore more weight upon the affected limb. At this time the foot of the affected leg, and particularly the tarsal portion of it, became the seat of subacute rheumatism, which still affects and prevents her from using it; but happily there is no disposition in the knee-joint to relapse into its former condition.

Some time since, I obtained a Thèse sustained at Paris, by M. Duval, brother of the orthopedist of that capital; in which are detailed seven cases upon which his brother had operated.

The first was treated in October 1837. The patient was a boy of eleven, who,

at the age of five, suffered from phlegmonous inflammation around the knee-joint, with abscesses, which were followed by sinuses which continued open during the next four years. Motion at the joint was obscure. On the 10th of October he divided the tendons of the biceps, the semi-tendinosus, and semi-membranosus muscles. At the end of three weeks, the leg was extended on the thigh, and the boy was able to walk without crutches.

His second patient was a boy of twelve. At five, he hurt the left knee. The injury was followed by inflammation and abscess, which continued to affect the neighbourhood of the joint for five years and a half, when the sore cicatrized. The leg was at that time so flexed upon the thigh, that a strait line, drawn from the middle of the posterior part of the thigh to the heel, was removed nearly six inches from the ham. The tendons of the biceps, the semi-membranosus and tendinosus, were cut through, and in six weeks he was enabled to walk pretty well.

The third patient was six years old. At two years and a half he had symptoms of meningitis, which paralysed the left side of the body. The paralysis of the lower extremity was accompanied by contraction of the ham-string tendons. The same tendons were cut as in the former cases. At the end of twenty days complete extension could be made, and at the end of seventy-three days he could extend it himself; but the paralysis interfered with progression.

The fourth case was that of a boy, who, at two years old, had a large boil in the ham; suppurative inflammation extended around the joint; fourteen or fifteen abscesses had been opened during the succeeding five years. At the expiration of this time all the abscesses closed, and the articulation became sensibly smaller and less painful; but the leg was flexed so as to describe with the thigh a right angle. A section of the same tendons as in the former cases was made, and allowed of immediate extension to the amount of two inches. An extending apparatus was employed, but eight months was required to restore it to its natural direction.

The fifth case was that of a young woman of twenty, who, seven months and a half before, had great itching at the knee. It swelled, and presented

ampullæ almost like those in superficial burns. The vesicles disappeared in a single night, but the swelling increased. Leeches, blisters, and caustics, were applied with benefit, but a certain portion of tumefaction persisted. During the whole of this time flexion had been more and more marked, and at the time of the operation the limb described a right angle. A section of the biceps and tendinosus was made; an extending apparatus was employed, and in thirty-two days she began to walk.

The sixth was a man, aged 35, who had paralysis of the right inferior extremity; his was accompanied by considerable flexion of the leg on the thigh, and the ham-string tendons were tense. In this case, the impression produced on M. Duval's mind was, that the contractions depended upon the muscles of the calf, which are also flexors of the thigh upon the leg. A section of the tendo Achillis was made, and in six weeks the cure was complete.

The last case was that of a patient, aged 20. Three years ago he fell on the right knee, which became inflamed; and while he kept his bed the leg became flexed; it remained so many months, and when he got up, the toe alone rested on the ground. Many means were ineffectually tried to restore the limb to its natural condition. The three tendons of the ham were like tense cords; they were cut, and at once the limb could be extended to the amount of two inches; extension was employed, and in twenty-five days the limb was perfectly straight, and the patient could walk on it. Three or four days after the operation acute inflammation was developed at the knee; twenty-five leeches and emollient cataplasms were applied, and in eight days it was dissipated.

In the month of February, 1837, M. Lutens divided the ham-string tendons at the hospital at Antwerp. The case was that of a man named Brilet, a sailor, who, in July, fell from near the mast-head to the deck of a ship, the back of his right thigh coming in contact with the jib-boom; the contusion was great, the extravasation of blood considerable. In October he was placed under the care of M. L.; he found no trace of inflammation remaining; but the back of the thigh, from the ischium to the knee, felt as if cords were tightly drawn along it. The leg flexed upon

the thigh, and extension impossible. In the attempt to make extension, the tendons became extremely tense, and no plan which was adopted produced any relaxation. If he tried to walk, the toe rested alone on the ground, and was turned outwards.

The articulations of the hip and the knee were free from disease. All means of procuring extension failing, M. L. consulted with M. Gougué and M. Decondé, who at first thought nothing could be done to relieve this condition. Afterwards, M. Decondé concluded with M. L. that it might be well to make an incision through one or other of the muscles near the ischium. Two months elapsed, when M. L. decided to make an incision on either side of the knee. A bistoury upon its flat was glided under the semi-tendinosus tendon, about two inches above its inferior attachment; the edge was then directed upon the tendon, which, with the aponeurosis and skin, was at once divided. On the outer side, the sheath of the biceps was exposed, and the muscle cut through. The next day all hardness at the back of the thigh had disappeared, and the leg could be made perfectly straight, and an immoveable bandage was applied to maintain extension. He now moved about in the ward, and on the thirtieth day the wounds were dressed with dry lint; cicatrization proceeded slowly. Three months afterwards he could walk pretty well, and without a stick; some little difficulty was experienced even then in flexing the leg upon the thigh, but still it could be accomplished.

Once the operation has been performed by Dieffenbach, but I am not in possession of the particulars of the case; once by Mr. Liston, without success; once by Dr. Little, with very partial success.

I know of no other case in which the operation has been performed; but those which I have detailed present a sufficient variety of causes of contraction; the operation has not been attended by any unpleasant consequences, and the results have been extremely favourable.

Towards the autumn of the present year I propose to make a section of the tendons in the left ham of my patient; and I shall probably lay before the profession the result of that operation.

AGENCY OF SOUND ON THE EAR.

To the Editor of the Medical Gazette.

SIR,

IF I have in any measure been fortunate enough to elicit truth, by aiming at simple facts, this may in some degree aid the more able physiologists, on whose experiments and opinions I have presumed to animadvert in a more perfect analysis of the human ear; which considerations will, I trust, induce you to indulge me by continuing my subject in your able work.—I am, sir,

Your obedient servant,

W. SHAND.

Aberdeen, 28th June, 1839.

In comparing the physical properties of the ear with the operations of sound in external bodies, every part and principle to be met with oppose the idea of intelligent and predominant sounds entering by the meatus externus and the temporal cavity.

I have already explained why, according to understood principles, the external surface of the auricle cannot collect the sonorous atmospheric undulations with consistency.

Treviranus* is of this opinion, but could not bring himself to believe that the phenomena operated by the vibration of the solids in reference to aerial action; and yet the mode of communication by the stethoscope affords sufficient proof of intelligent sounds entering by the solids. Philosophers have so long and uniformly impressed on the minds of successive generations for many centuries, that sounds are collected on the surface of the auricle, and must make sonorous impressions on the membrana tympani, that all reasoning and all experiments are based on these erroneous hypotheses. They sever bodies from each other, and divest them of their original characteristics, in order to coerce nature to their will.

Savart†, in his experiments on the membrana tympani (believing it to be powerfully sonorous), severs it from the temporal bone, divests it of extraneous matter (cerumen and moisture), by which, in my mind, he changed its properties, because we cannot in any manner change the form, texture, or surface

of any material without altering its sonorous properties. If this membrane be sonorous, it must be much more so when connected with the temporal bone than apart from it. If the pelt of the military drum were separated from the other parts, would not vibratory action and sound be impaired? Were the strings of the violin separated from the body of the instrument, would any musical sounds be produced? The sounds produced by the tuning fork are exceedingly more intense when the stem is in contact with another hard body, than if held between the finger and thumb. The principles are the same in all these cases, and yet M. Savart not only separates the temporal bone from this membrane, but he separates the membranous parts; for the external fold of the membrana tympani is a continuation of the cuticle which lines the meatus.

One part of the same string or membrane cannot be sonorous and the other non-sonorous.

I have already adverted to many of the obstacles which are in the way of atmospheric undulations reaching the tympanic membrane in a sonorous state, and consequently with their original character; and these obstacles multiply as we advance. If it be admitted that the cerumen which covers the cuticle of the meatus is soft, yielding, and has a tendency to damp sound, it cannot have this effect on the skin which lines this canal, without producing the same effect in the tympanic membrane, so intimately connected with the cuticle, were not a portion of the cerumen found throughout the whole of the internal parts of this cavity. In any case, the experiments of M. Savart, by separating these bodies, and removing the cerum, is a dereliction of nature, and cannot exhibit any satisfactory results. It may, then, be observed, that, according to the opinions of Professor Young and Dr. Neil Arnott, an elliptical tube, such as the meatus externus, cannot produce musical sounds, because of the irregularity of its inflections. For the same reason, it cannot consistently conduct speech; and similar objections exist to the elliptical form of the membrana tympani. Were this membrane perfectly sonorous, as supposed, it would produce prolongation of sound inconsistent with speech, because no repetition of sound from a single impulse can be permitted. Where do we find that articulate sounds

* See Prof. Todd's Cyclopædia, vol. ii. p. 574.

† Ibid. p. 573.

are communicated to the sense of hearing through a flat sonorous body, resembling the head of a drum, or the membrane alluded to? In every case, externally, speech must be reflected by a body of certain solidity and peculiarity of texture, not yielding a second reflection of which the ear is sensible. There could not be a more unhappy contrast than that of the central ear with the musical drum, for the following simple reasons:—There can be no repetition of external reflection of a single letter, in speech, upon the ear without a conflict and confusion; but a musical drum must give out a succession of sounds from a single impulse.

The cavity of the tympanum, and the chain of bones in it, possess no consistency of character analogous to any external bodies which conduct sound without change from its original nature, the walls of this cavity being indescribably irregular, and the chain of bones not pointing uniformly towards their connecting parts between the membrana tympani and the fenestra ovalis, but diverging in various directions.

Where is it found that sound passes through an aerial medium, surrounded by solids, without its character being modified by the nature and form of the solids? After the human voice has been produced in the wind-pipe, and passes through the larynx, and over the epiglottis, is not speech or song modified by the form and motion of the mechanism of speech, which must be lubricated by saliva, a peculiarly glib material, in order to produce a clear and agreeable sound; but if this mechanism be dry, and deficient of this glib slimy property, the surfaces over which sound passes being dry and rough, the sound produced is also rough and harsh; and shall it pass through a variety of bodies in the ear previous to reaching the auditory nerve, which are comparatively dry and rough; some hard, soft, and flexible; some adhesive and yielding, without partaking of the nature of these? Similar causes and effects, such as I have just alluded to, are exemplified throughout nature. In every apartment that we enter, sounds are found to partake of the nature and form of the surrounding bodies, and according to their proximity to the ear. I have pointed out the effects of hard asperities on the walls of an apartment by what is experienced from this cause, in St. Andrew's

church, in Glasgow, in a short paper published in the *Scottish Guardian*.

The difference of effects alluded to may be understood by experimenting on a piece of thin deal board, which produces rough harsh sounds, if used as it comes from the saw; but, if planed on its surface, it gives out a clear and distinct sound.

Sound operating upon an uneven surface is reflected in conformity to the position of that surface: it is divided in a certain ratio by a single hair in the ear, and by a square pillar in an apartment. The principle is the same, and the influence of external bodies is greater in all cases as they approximate to the ear; and it must be still more so in the ear, according to the number and extent of diverging surfaces.

I would here again revert to the remarkable facts, that the tympanic membrane, and the mechanism of bones in the tympanum, may be taken down without material injury to the sense of hearing; but neither the organ of hearing, nor the mechanism of speech, can be deprived of any considerable portion of moisture, without deprivation of the power of speech and hearing. It may also be remarked, that most physiologists attribute little conducting power to water, and have, in regard to its influence in these organs, said little; but in order to show the sonorous property of water at the temperature of the human body, I have, in the *MEDICAL GAZETTE* of the 9th Feb. last, adverted to the singular intensity of sound in the river Cobra, in Jamaica. That it is an indispensable agent in the human ear cannot be doubted, when we consider the place which it occupies in the labyrinth, and that it is the last medium in connection with the acoustic nerve, where its influence must be more uniform and delicate than by contact with any hard body. Whether the transit of sound be by the aerial passages, or by the surrounding solids, it must necessarily be communicated to the acoustic nerve through the fluid in the labyrinth.

I must, in the meantime, conclude, but shall hereafter recur to this interesting subject, and make such observations as may occur to me in relation to the physical properties, and the operation of sound, in the labyrinth and the Eustachian tube, and perhaps make some remarks on the organic parts by which sound is produced and speech formed.

CASE OF

DISLOCATION OF THE FEMUR
INTO THE ISCHIATIC NOTCH,

WITH FRACTURE.

The Dislocation reduced after the lapse of six weeks.

BY CHARLES THORNHILL, ESQ.

Read before the Hunterian Society, June 26, 1839.

[For the London Medical Gazette.]

THE great disappointment and annoyance which have frequently resulted from the attempt to reduce dislocations of some standing, induce me to draw up the following history, as it appears to my mind to present some instructive points, not altogether undeserving the notice of the practitioner. It is true it may be said that there is nothing novel either in the case itself or in its mode of treatment; but when the length of time during which the patient was subjected to the relaxing power of the pulleys, together with the hindrances that occurred to thwart our purpose, are taken into consideration, we have at least one useful lesson afforded us, that we ought not, under similar circumstances, to content ourselves with mere ordinary efforts, but should steadily persist in the employment of means, to the extent that is consistent with prudence and safety. Here it will be seen that we had begun to regard our attempts as fruitless, and, in despair, were just on the point of removing our apparatus, when, in a happy moment, the bone was distinctly heard to re-enter its natural socket. Had we been influenced by the desire of the patient, and yielded to his entreaties but a few moments earlier, the poor fellow would, in all probability, have remained a cripple for the rest of his days, and we should have had to deplore, as often as we met him, the imperfection and uncertainty of our surgical art.

Sir Astley Cooper has observed, that of the various dislocations occurring at the hip-joint that into the ischiatic notch is the most difficult to reduce; and it is readily conceived that this difficulty must be proportionally increased with the length of time it has been allowed to remain. This distinguished surgeon, in his great work on the subject, has recorded a case where the reduction was easily accomplished after the lapse of fifteen days; but certainly the cases are rare in which a satisfactory

result has been obtained after so long a period as *six weeks*. Indeed I am not aware that there is even another case on record where a successful attempt had been made after such a lapse of time. Besides, in the present instance, we had to contend against the difficulties arising from a recently fractured thigh; and this rendered it necessary that the pulleys should be applied with extreme caution, lest any sudden or undue extension might occasion a separation of the parts so newly united.

It requires no apology for having stated so fully the particulars of the case, because I am convinced that, although the proceedings that were adopted are perfectly familiar to the generality of practitioners, we all stand in need of being frequently reminded of the first principles of our profession, as well as of being encouraged in the prosecution of our arduous duties.

Samuel Sheldon, æt. about 40, of short stature, but strong muscular make, was at work as usual at Tibbington Colliery, on the morning of the 6th of February, when a large fragment from the excavated roof of the pit became disengaged, and fell upon him. The portion that struck him was supposed to be about five or six hundred weight, which, coming in contact with the lower part of his back and right hip, while he was in the act of leaning forward, spent itself out upon the thigh of the same side. He was nearly stunned by the violence of the shock, but was immediately drawn up out of the shaft, and conveyed in a chair to his residence in this parish—a distance from the colliery of between two and three miles.

Mr. Roberts, the surgical attendant of the colliery, having at the time some pressing engagement, sent a note to request that I would take the charge of the case. Accordingly, in somewhat more than two hours after the occurrence of the accident, my brother saw the patient, and, on examination, discovered a slightly oblique fracture of the right femur, at the upper third of the bone. Several severe scratches and bruises were visible about the loins and pelvis, and it was evident that the hip also had sustained some considerable injury; but in consequence of the great tumefaction of the soft parts it was impossible to ascertain accurately the extent of the mischief. The fracture being reduced, the limb was dressed and secured in the

usual manner, and afterwards placed in the straight position. I had not an opportunity of seeing the patient until a week or more subsequently, when the swelling around the hip had so far subsided as to enable me clearly to distinguish a dislocation of the head of the femur from its appointed acetabulum. No attempt, however, could at present be made for the accomplishment of reduction, on account of the want of necessary firmness and stability in the shaft of the bone; and it was resolved to wait patiently until reunion between its fractured extremities should become firmly established, and then to adopt such means as might be deemed most desirable to meet the urgency of the case. Every thing continued to progress in a very satisfactory manner; but notwithstanding all our entreaties, the patient could not be prevailed upon to remain in bed longer than a month.

After the expiration of the fifth week it was proposed to endeavour to effect reduction; but at the suggestion of a neighbouring medical friend, who thought that the restorative powers of the system had hardly yet contributed sufficient strength to the limb as to enable it to offer resistance to the mechanical force which would necessarily be applied, the operation was deferred for another week. The day was at length fixed for the trial of our means; and Mr. Roberts, of Dudley, and Mr. Lees, of Wednesbury, were kind enough to render their valuable assistance on the occasion. We assembled for that purpose, therefore, on Wednesday morning, the 20th of March, exactly six weeks from the period at which the accident had happened.

The patient was directed to undress, in order that the limb might be minutely examined by the gentlemen present. When he stood upright, and allowed the left leg to support the weight of the body, the unsound limb was observed to be about one inch and a half shorter than the other; and from the great trochanter being felt rather in the rear of the acetabulum, and from the inclination inwards of the knee and the foot together, with the pointing of the great toe towards the ball of that on the opposite side, it was at once pronounced to be a luxation into the ischiatic notch. But independently of these diagnostic marks, the emaciation that had supervened upon the accident was so great,

that the head itself of the femur could be felt lying in that foramen. The muscles around the joint seemed remarkably flaccid; and as there was a greater power of motion than is ordinarily witnessed, it was anticipated that we should have but little difficulty in effecting reduction. The sequel will shew whether or not our expectations were realized. A door, with a blanket thrown thereon, was placed upon the bed, and two staples having been driven into the opposite walls, the patient was instructed to recline upon the door on his left side, with the right shoulder drawn one-third backwards. This latter precaution was deemed necessary, in order to prevent his being drawn forwards upon his face by the first application of the extension. A well-padded band was then passed between the thighs close upon the perineum, and this was affixed to the staple at the back of the patient, when the pulleys being secured to the opposite staple, as well as to the rings of the knee-belt which had been previously applied, extension was made in the usual manner in a line directly across the middle of the uninjured thigh. After this had been steadily and perseveringly employed for upwards of half an hour, without occasioning much relaxation in the muscles, it was thought advisable to administer the antimonii potassio-tartaras, in doses of a grain, repeated at intervals of a few minutes, until nausea should be fully obtained. When three or four doses had been given, the head of the bone began to advance towards the acetabulum, and I could distinctly feel it disengaging itself from its recently-formed attachments. At this stage of the operation, my brother having passed a strong band under the upper part of the thigh, got upon the door, and fastening the loop of the band over his own shoulders at the same time that he pressed firmly with his hands upon the crista of the ilium, endeavoured to lift up the head of the bone, while Mr. Roberts forcibly rotated the limb outwards by grasping it both at the knee and ankle joints. Whilst this was going on, one of the straps that secured the band between the thighs suddenly gave way; but as we had another band in readiness, it was applied over the other without loss of time, and without much reducing the amount of extension already obtained. As soon as this was

properly adjusted, similar efforts were again resorted to, and continued for some time without success. By this he had taken about ten grains of the tartar emetic, and the system began to be somewhat under its influence, as was manifested by the increasing pallor of the skin, and the comparative looseness and tremor of the muscles in general; but while we were employed in augmenting the extension, another difficulty presented itself, in consequence of the knee-strap gliding over the surface of the patella, although the precaution had been adopted throughout to keep the limb at right angles. This was replaced as speedily as possible, and our efforts were renewed as assiduously as before. After the patient had taken the twelfth dose of the potassio-tartrate he became very restless, and it was evident that nausea had been duly produced. He now implored us most earnestly to desist from the further use of means; and as extension had been carried as far as was justifiable, it was resolved, before we abandoned the case as hopeless, that another and a last attempt should be made. For this purpose my brother endeavoured once more to elevate the bone, while Mr. Roberts performed rotation outwards, as already described; and after these efforts had continued for two or three minutes, the head of the femur was forced into its socket with an audible crash, the poor fellow having been under treatment for an hour and three-quarters. On relaxing the pulleys and disengaging the apparatus, the limb was found to be of nearly equal length with the other; but the difference that existed might be wholly attributable to the effects of the fracture.

The empl. thuris comp., spread upon linen, was applied over the joint, and the bandage ordinarily used in such cases was passed round the waist, and closely bound over the unsound hip. The patient was then placed in bed, and ordered to remain there for the space of a fortnight. Before the expiration of this time, however, he got up, and went out of doors upon crutches, though as yet he was unable to bear weight upon the leg.

About this period he came up to my surgery to be dressed. On examining the hip there was considerable enlargement and disfigurement, arising from the thickened state of the muscles and

integuments, and also from a large mass of callus which had been deposited about the joint; and to so great an extent had coagulable lymph been thrown out, that it was extremely difficult to trace the characteristic prominences of the bony structures. Indeed, in no case that had ever fallen under my observation do I remember having previously witnessed such an immense deposit in the neighbourhood of the acetabulum: notwithstanding, the different motions of the limb, as far as they could be performed, were perfectly natural, and the man seemed highly pleased with the progress he had already made. The mercurial plaster was now substituted for the empl. thuris comp., and this was renewed every week for about a month or five weeks. But as absorption had taken place only to a trifling extent, and as the motion of the limb continued to be in a measure impeded by the callous mass, the size of a nutmeg of the iodine ointment, in the following proportions, was directed to be rubbed every night around the joint:—

R Potassa Hydriod.; Tinct. Iodinæ,
aa. 5j.; Ung. Cetacci, 5j. M.

On the 10th of May he walked on crutches to Dudley, a distance of five miles, where he was seen by Mr. Roberts, and also Mr. Badley, who concurred in the propriety of continuing the iodine preparation for a few weeks longer.

At the time of the present report (May 29th) he represents himself as rapidly gaining strength and power of mobility in the joint. He is able to bear his entire weight on the injured side, and he talks of substituting a stick for the use of the crutches. There has been considerable absorption of the morbid deposit, though it is still sufficient to occasion a slight disfigurement about the hip. Much of this callous mass, it is to be feared, will remain permanently; but this will not be of any great consequence, as even now it does not appear to interfere materially with the motions of the limb. These have already become very extensive; but some months must necessarily elapse before they are perfectly restored to their pristine condition.

Darlaston, Staffordshire,
May 29, 1839.

MEDICAL GAZETTE.

“*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*”

CICERO.

FRENCH AND ENGLISH SCHEMES OF HOSPITAL GOVERNMENT.

WE promised, in a late number, to contrast the condition of the objects of hospital charity in France and England, with the view of showing that whatever may, in some instances, be the errors in the government of such institutions in this country, they are as nothing in comparison with those of which the evils fall, not on physicians and surgeons, but on the distressed objects whose welfare is the ultimate professed end of all such establishments.

For the extent of assistance afforded by the voluntary system of England, it is sufficient to refer to the many thousands who are annually supplied with medicines, food, and shelter, and very often with clothing, by the donations of private individuals or public bodies (under the guidance of what motives it matters little, for the worse they are, the better for our argument). But the opponents of such voluntary charity urge, or at least suspect, that benevolence will too often stop at providing the means, without looking into the mode of its expenditure; that ostentation (the other chief motive) will care but little for the almost hidden details of the scheme of relief, if it can but be prominently present to the public view; and that thus, in hospitals, the patients may be left to careless and cold-hearted superintendence, to misery and discomfort, under the guise and pretence of relief; or that at the best, in the desire to do some good to the greatest possible number, the better plan of doing great good to a few may be overlooked. It is imagined

that the objects of hospital charity are treated like those of Poor-law charity—supplied with the smallest life-maintaining quantity of help, at the cheapest possible rate, and taught that (according to the common expression) they “have no right to look a gift horse in the mouth.”

That all these evils exist, to their fullest extent, in a government scheme of relief for the sick, we will presently show; but that they are entirely absent from English hospitals, however managed, an inspection of such establishment will be at any time sufficient to decide. The comforts that are afforded in an English hospital, are probably in every case greater than the patient, even when in good health, enjoyed at his own home; far greater than it is possible for any labouring man, however frugal and industrious, to obtain when sickness visits him or his family; in many cases, more than those which the rich can afford. In all that regards the comforts of the patients, there is the least possible regard to expense, and the most scrupulous attention; there is no pinching economy, necessary to save the little earnings of the time of health from being totally dissipated, nor, on the part of the distributors, any grinding parsimony to obtain the credit of cheap management. The medical officers, indeed, receive no direct emolument for their services, but their places are objects of ambition for the best of the profession; and at their orders, medicines and food of all kinds, and of the best quality that money and care can procure, are administered without limit.

We appeal for confirmation of the general truth of what we have stated, to any one who is in the habit of visiting those of our hospitals or other houses of refuge in distress, that are supported by voluntary contributions. It matters not what are the motives that induce this liberal supply of the needs

of a great proportion of the sick poor; they are at least only those motives that would be engaged in any case of what is called voluntary relief; but whether it be that an hospital is established and maintained solely for the pleasure or advancement of any great man, or upheld to be the field of family and party contests, or whether it be (as a few are) the genuine offspring of philanthropy and charity, in every case the objects of the gifts receive in this country liberal and generous treatment; and so far as we know, the motives of the bestowers have no influence whatever on the treatment of the recipients.

Now let us contrast this with the scheme of relief under the guidance of the French government, for the details of which we are indebted to the recently-published Report of the Medical Commissioner of 1838, on the Hospitals and *Hospices Civils* of Paris.

The bread supplied from the general bakerey (it is said) is badly baked; the crumbs might be made into dough again. But it is especially in the flour which is prepared by those who furnish it, and not regularly bought, that the reasons for not making good bread are to be found. The wine, made of a mixture concocted in the general depository, is a drink as disagreeable as it is injurious; its taste is sweetish; its odour alcoholic; it very soon becomes turbid, and grows acid as soon as it is exposed to the air. The meat cannot be subject to the same adulteration as the other food; but the animals that are bought are not always in a state fit for affording good food; and the low price at which the meat has to be furnished, prevents the conditions that are imposed on its suppliers from being strictly fulfilled. The soup (*bouillon*), which is often the only aliment of the patients, is never substantial and well

flavoured, for want of employing the proper quantity of meat in making it; and, to conceal this fraud, there is an article in the rules ordering the *bouillon* to be sweetened with treacle, &c. The dry pulse are remarked in every establishment as of the worst quality; they contain insects which disgust the patients, and the greater part of the beans, lentils, peas, and haricots, are damaged, and deprived of their nutritious parts. The milk, which ought to be considered as at once an aliment and a remedy, is one of the provisions that is the least attended to; and the suppliers have no hesitation in adulterating it in the most disgraceful manner to obtain a profit, which the low prices imposed upon them will not permit them to obtain legally. The sugar was already employed with much parsimony, when a recent order arrived to reduce the quantity to a still smaller allowance, and to substitute liquorice in its place. Lastly, the cooking of the food is still worse than the quality of the provisions, and this not only from want of proper care, but also from the bad quality of the butter, the fat, and all the other appliances.

Such is an abstract of the complaints, not of the patients only, who might be called fastidious and discontented, but of the medical officers of the charitable institutions for the sick in Paris. Only imagine such a state of things in London! What an outcry would there be against those who, under the pretence of voluntary charity, offered a sick man sour beer, and stale maggot-eaten vegetables! There may be similar practices in the treatment of the healthy paupers who fall under the patronage of our Commissioners, as the sick do under that of the French Council of Administration; but in a privately-governed hospital such things would justly be scouted as disgraceful to the

name of charity and unworthy even of ostentation. We remember once the astonishment with which a Polish physician surveyed the business of the kitchen in one of our large hospitals, and expressed with evident sincerity his wish that he himself were always as well fed in Poland, as the patients seemed to be in England. But such coldness and indifference to the wants of the afflicted as exists in the French administration will always exist in those whose *business* it is to *manage* the poor; when their feelings of kindness and pity are (as they must be in time) blunted, and when they have no reputation at stake, and no credit to be gained unless for rigid economy, no wonder that they lose sight of the only real end of their office, the administration of comfort as well as of necessary assistance to the needy.

The Report, in continuation, says that the bad quality of the food is not all that is complained of, but that there is positively not a sufficient supply of it, such as it is. The physicians of the Maternité declare that the children placed there have not enough food for their support, and that they frequently die of hunger. The physicians of the Bicêtre complained, in 1834, of the inadequacy of the regimen allotted to the old and infirm; and in 1837, their complaint being disregarded, the same demand for more food was renewed by them, and by the physicians of the Salpêtrière, and is repeated in the present Report, with the declaration that the mortality in both these establishments is considerably greater than in others of the same kind, in which a more liberal diet is allowed!

The cause of the patients has been warmly espoused by the medical attendants, who constantly find their orders and their requests alike disregarded or countermanded by higher authorities. They are often disappointed of their

anticipated success in treatment by the mean and parsimonious management of their patients' diet. They are now in hot dispute with the administering council, who will yield them nothing, and by whom their Annual Reports—all as condemnatory as that from which we have quoted the most striking parts—are completely set at nought. We shall content ourselves with noticing only this part of their complaints, which relates to the objects of the charities; there are plenty more, in which they detail the inadequacy of the present accommodation for as many as would resort even to this miserable assistance; the unjust and unequal remuneration of the different officers attached to the institutions; the favours shown to those who are appointed by the government; the comparatively small portion of the grants which is devoted to the positive relief of the sick; and so many more abuses, that the reader might be tempted to imagine the English scheme to be veritably Utopian.

The comparison of the results of the English and French methods of hospital management affords very important evidence on the long-agitated point of the comparative merits of the compulsory and the voluntary systems of general relief for the poor. Not that the relief of the sick poor can be considered as exactly analogous to the permanent or temporary maintenance of the healthy poor, whose poverty may be the result of indolence, or many faults which sickness would not immediately follow; yet there is sufficient similarity between the two cases, to make them deserve attentive consideration. In France, where all the people are taxed for the relief of the sick, and where the management is governmental, the results are most discouraging; the sick are not all provided for, and those who are, are ill treated and half starved. In England, where private donations and pri-

vate management are bestowed upon the same class, they enjoy the greatest comfort. But in England, also, the poor generally are maintained by public taxation, and are managed by government servants, and the result is the same as among the hospital patients in France. It is unfortunate that the labours of Commissions of Inquiry are confined to the accumulation of evidence from our own country alone; facts of great importance, though requiring more caution in their application, are of daily occurrence in other nations, which are constantly overlooked or neglected; and among these, we have lately met with none more important than those of which we have quoted but a small part from the present Report.

UNIVERSITY OF LONDON.

EXAMINATION FOR HONOURS.

No candidate presented himself to be examined for honours in Anatomy and Physiology, and only one in Chemistry and Materia Medica. This paucity of candidates may, we believe, be attributed to the Senate having decided that candidates for honours in subjects above mentioned must not have attained their twenty-second year, and we understand that only one of the nine who occupied the first division at the "pass" examination was eligible.

It may be proper to state that the prizes to be adjudged where the Examiners deem the candidates worthy of them, are in each of the three subjects above referred to;—an exhibition of 30*l.* per annum, for two years; two gold medals value 5*l.* each.

We subjoin the questions for honours in Chemistry and Materia Medica.

BACHELOR OF MEDICINE. 1839.

FIRST EXAMINATION.

EXAMINATION IN CHEMISTRY FOR HONOURS.

Wednesday, July 10.—Morning, 10 to 1.

Examiner, Professor DANIELL.

1. Is there any, and what, difference in

the law of expansion by heat, between water and alcohol?

2. Explain the phenomenon of dew.

3. Explain the principal phenomena of electrical induction, and the construction and action of the Leyden jar.

4. What are the principal phenomena of a simple voltaic circuit?

5. Describe the construction of the voltaic battery, and explain the origin of its power.

6. What is electrolysis? and what the principal laws by which it is governed?

7. What is Isomerism? Illustrate the subject by examples.

8. Describe the process for the production of sulphuric ether, and explain the changes which take place during its production.

9. What is the constitution of urea? Explain by chemical notation the relation which it bears to cyanate of ammonia.

10. What is oxalamide? What relation does it bear to oxalate of ammonia?

—
Wednesday Afternoon, 3 to 6.

MATERIA MEDICA AND PHARMACEUTICAL CHEMISTRY.

Examiner, Mr. PEREIRA.

1. Describe the method of preparing hydrochlorate of morphia according to the London Pharmacopœia. Explain the successive steps of the process and state how morphia is directed to be extracted from the hydrochlorate. What is the primary form of the crystals of this vegetable alkali? By what chemical characters is morphia distinguished from narcotina, codeia, strychnia, brucia, and quina? What is the atomic constitution of morphia?

2. What are the symptoms, for the relief of which opium is used in inflammatory diseases; and what are the circumstances which permit its employment? For what purposes is this remedy administered in continued fever, and what are the symptoms which forbid its use?

3. What are the botanical characters and prevailing medicinal qualities of *Stannulaceæ*, *Umbelliferae*, and *Solanæ*? Enumerate the officinal species in each order.

4. Describe the digestive apparatus (including the mouth) of the officinal leech. Explain how this animal perforates the skin and draws blood. Mention in what cases leeching is to be preferred to cupping.

5. What change does sulphate of iron suffer when mixed with the *Decoction Aloë compositum*? What soluble ferruginous salts are compatible with this decoction? What substances are incompatible with the *Mistura Ferri composita*?

6. Describe the method of preparing *Antimonii Potassio-tartras*, PH. LOND.; and

explain the chemical changes which occur during the process. What is the composition of this salt in the crystallised state?

7. In what inflammatory diseases, and under what circumstances, would mercury, given so as to affect the mouth, be admissible and advisable? How would the existence of syphilis, serofula, or local malignant disease affect its use?

8. What are the effects, uses, and doses of *Lobelia inflata* and of *Chimaphila corymbosa*?

9. Describe in botanical language the fruit of *Conium maculatum*.

10. What pharmaceutical crystals have the square prism for their primary form?

ON

A RECENT CASE OF SUDDEN DEATH.

WITH REMARKS.

By HENRY SAVAGE,

Lecturer on Anatomy, at the Westminster Hospital School.

WE can scarcely take up an ordinary newspaper without meeting with an instance of sudden death. Yet, notwithstanding the apparent frequency of its occurrence, we look in vain for properly authenticated cases in our medical periodicals. The deficiency in this part of our records it is not easy to explain; it cannot arise from a want of common interest respecting so fearful a calamity; for where is he who does not shrink back with horror at the bare idea of meeting his death in this terrible form?

The case under present consideration deserves more than ordinary attention, from the circumstances under which it took place; and I have therefore ventured beyond a mere detail of its history and the appearances discovered at the post-mortem examination.

Joseph Hall*, by trade an ornamental picture-frame-maker, was induced to apply to Dr. Turnbull, about two months before his death, with the hope of being cured of slight deafness, and during this time he frequently submitted himself to the use of the acoustic air-press, an instrument of modern invention. The operation sometimes made him feel faint and sick, but it generally occasioned no feeling of inconvenience. On Saturday morning he rose as early as usual, and repaired to the residence of Dr. T. He was not ill that morning. A fellow-workman, who slept in the same room with him did not perceive any change in his appearance. His health was generally very good; in

fact, his strength exceeded that of the majority of young men of his age, and in consequence of his superiority in this respect he was called "strong back," under which name Dr. Turnbull was accustomed to employ him in charging the instrument, both for himself and for others. On this occasion he charged the air-press as he had before done. Mr. Lyon, "a partner in the eye department," then introduced the catheter into the Eustachian tube, and discharged the condensed air into the tympanum. This proceeding was repeated five times (taking the two tympani together.) The first time he turned the stop-cock himself; but subsequently this part of the process was entrusted to Charles Spadhow, an intelligent deaf lad, who "turned it on strong, but not so strong as he could." Immediately after the fifth discharge Mr. Lyon proceeded to withdraw the catheter, and whilst in the act of so doing the patient sank gently against the back of the chair, his eyes closed, his hands dropped by his sides, he fell into perfect deliquium, and ceased to breathe.

Under the impression that he had merely fainted, stimulants were applied to his nostrils; but as the real nature of the case revealed itself, this treatment was followed by artificial respiration and the warm bath. The brachial and jugular veins were opened, and blood was obtained, the bleeding even continued for a greater part of the day, at intervals, but life had irrecoverably fled; not the slightest sign of returning animation attended the employment of any restorative medicine.

The post-mortem examination.—On Tuesday morning, at seven o'clock, 68 hours after death, I opened the body, in conjunction with Dr. Reid, of Bloomsbury Square, and in presence of Mr. Richard Quain and Mr. Liston.

The body was that of a robust muscular male, about five feet eight inches in length, and without the slightest appearance of deformity; on the contrary, the features, although slightly puffed up by incipient decomposition, were good-looking, and the trunk and limbs remarkably well proportioned. The skin of the face, upper part of the chest, and arms, was changed to a greenish hue, but the epidermis was not in any place detached. Narrow dark bloody streaks ran down the neck and arms from the punctures in the veins; the flow had ceased, but the blood was still fluid. *Head:* hairy scalp, thick; when cut across poured forth from numerous venous orifices, small quantities of dark fluid blood. The calvarium moderately thick, and quite smooth, inside and out. Diploe not more vascular than usual. Dura mater and its processes perfectly healthy, but the sinuses contained (not dis-

* Mann's Notes of Inquest.

tended) grumous semi-fluid blood. On removing the dura mater on a line with the detached calvarium, a stratum of grumous dark fluid, resembling that in the superior sinuses, was seen resting on the arachnoid. In quantity, this fluid might amount to about three fluid drachms, certainly not more. The stratum was less than a line in thickness at the vertex of the hemispheres—the most dependent portion, according to the position in which the body laid for three days—and gradually thinned off to an imperceptible film at a circumference radiating half an inch from that point. It appeared to me to cover an equal surface of each hemisphere. The superficial veins of the brain were distended with the same kind of dark fluid and air. A yellowish transparent fluid (cerebro-spinal) lifted up the arachnoid from the pia mater, especially at the sulci, with each of which, and with the ventricles, it communicated freely. The nerves at the base of the brain were perfectly sound, the cerebro-spinal fluid ran freely between pia mater and arachnoid, which was not ruptured at any point. The substance of the brain and cerebellum (both rather softened) was of the usual colour, presenting no bloody points at the surface of the sections made of it, nor any trace of extravasation. The thoracic and abdominal organs were, with the exception of the heart, in a healthy condition. The state of the heart and blood-vessels resembled that described by Mr. Chevalier*, in three cases of sudden death, and termed, by him, idiopathic asphyxia, viz. the former very flaccid and perfectly empty, and the latter were also destitute of blood for an inch and a half of their cardiac extremities.

State of the ear.—The tympanum and outer portion of the organ were examined at the time, but the temporal bones were removed for subsequent and more careful inspection. Pinna and external meatus perfectly natural and healthy, the dermoid covering of the memb. tympani could be withdrawn like a blind sac, leaving that membrane glistening at the bottom of the meatus.

Tympanum.—Chain of small bones unbroken; handle of the malleus still attached to the membrana tympani, and the base of the stapes to the fenestra ovalis: they had not escaped unaffected by the process of decomposition, for at a touch the little bones separated from each other, and all, save the stapes, fell loose into the tympanum. The fenestra rotunda and mastoid cells sound.

The lining membrane of the tympanum and Eustachian tube showed by evident signs that it had been the seat of inflammatory

action during life; thus, instead of being delicate and transparent, as it is in a healthy state, when its existence as a continuous membrane hardly admits of demonstration, in the right tympanum and Eustachian tube, it was red, and half a line in thickness, and in the left upwards of a line thick, and covered by a tenacious bloody mucus.

The Eustachian tubes.—The condition of these tubes was particularly interesting, inasmuch as it pointed towards the real cause of the deafness. The lining membrane was so much thickened and villous, that, although a probe could be carried through them without the least difficulty, yet during life this thickening must have been sufficient to oppose the passage of air considerably in the right tube, and to obstruct it entirely on the left.

The membranous and nervous structures of the labyrinth were soft, and could not be well made out, but it was satisfactorily ascertained that no preternatural opening of communication with the cavity of the skull existed, nor was any part of the organ broken, or in any way injured by mechanical violence. The base of the skull was in every respect sound; the internal meatus had its usual contents, which were healthy. The petrous sinuses contained air and dark-coloured blood; and the thin film of bone which covers the canal leading from the tympanum to the mastoid cells, presented no appearance of abrasion or decay.

Upon reviewing the above statement, the reader will perceive that little or no evidence which will assist in accounting for the sudden death of the unfortunate youth can be drawn from the post-mortem examination. The congestion of the scalp, the distension of the cerebral veins and sinuses with dark coloured blood and air, did not exceed what I have met with in almost every body brought to the dissecting-room. The state of the different portions of the ear, although indicating the cause of deafness, completely removes the idea of injury to the brain in consequence of rupture of the tympanum, and the escape of air into the cavity of the skull. The healthy condition of the viscera and blood-vessels generally, precludes the possibility of our assigning the cause to them; and thus we have only remaining the stratum of fluid found on the hemispheres, and the empty state of the heart and cardiac ends of the great vessels to take into consideration.

The stratum of grumous thin fluid, let it be remembered, merely occupied a round surface of the hemispheres, of about three inches in diameter; in quantity it did not exceed three drachms; it had collected around the vertex, on which the

* Med.-Chir. Trans., vol. 1.

head had rested for sixty hours, and it did not resemble blood. I cannot help thinking that it was an exudation after death; but supposing it to be the result of extravasation during life, it could not have produced death by pressure, the quantity was too small; but might it not be produced by a stroke of apoplexy? The post-mortem signs of this disease, it is well known, bear no proportion to its degree of rapidity and fatality. I beg to submit the following transcript of the best authors in answer to this question:—

“In apoplexy, blood is usually found extravasated in the brain, rarely on the surface.—It may take place at any age; but it is rare early in life; and when it does occur in the young, it usually comes on slowly, and not by a sudden stroke as in old age.—Interrupted circulation in the brain is the proximate or immediate cause of that suspension of the sensorial functions, which constitutes the apoplectic state.—In most cases, probably in all, if sufficient attention were paid, the apoplectic attack, if real, is preceded by a symptom.” The ordinary precursory signs are heaviness and somnolency; and in sudden cases, during the apoplectic state, those of deep sleep, with flushed countenance. These forms of apoplexy are generally attended by, or rather they are consequent on, extravasation of blood to some extent, although perhaps not proportionate to the severity of the symptoms. But there is another form—“nervous apoplexy”—which leaves no sign that can be discovered in the head, beyond what was found in Joseph Hall; here, however, the similarity ends, for nervous apoplexy is slow in progress: thus, out of many cases mentioned by Dr. Abercrombie*, death did not take place until the second day after the attack, “whilst the rapidly fatal cases presented after death extravasation, often considerable, in some part of the brain.” If this abstract from the best writers can be relied on, Joseph Hall’s death cannot be attributed to apoplexy. But now as regards the state of the heart and great vessels:—

The attention of the profession was first directed to this condition of the circulating organs, as explanatory of sudden death without apparent cause, by the late T. Chevalier, Esq., in a paper read before the Medico-Chirurgical Society in 1808. He there mentions three cases in which the heart after death was flaccid and empty, and the cardiac ends of the great blood-vessels also evacuated of blood for an inch or more. The author attributed death to a loss of power in the blood-vessels, particularly the smaller ones, to

propel their blood, the heart dying for want of its accustomed stimulus, “the flaccidity of the heart being probably owing to debility of its own blood-vessels.” Under the impression that this condition of the vascular system arose spontaneously, and that the short feeble breathing which characterizes this species of sudden death depended on a diminished flow of blood through the lungs, he made use of the term “asphyxia idiopathica,” which, as far as regards the primary cause of death, in reality leaves the question as he found it. It should be remarked, that death in these examples was not rigorously instantaneous, as half an hour elapsed between the attack and fatal termination.

There is a great resemblance between the death of Joseph Hall and the cases just alluded to, and we have as much reason to be satisfied with asphyxia idiopathica as the distinguished surgeon who invented the term. But asphyxia, although an apt term, will not get rid of the difficulty; it does not help us to get nearer to the real cause of death, and I confess myself unable to understand how the smaller vessels can become simultaneously debilitated, unless in reference to the nerves with which they are supplied, and under whose control they are strictly placed. It seems to me more reasonable to seek in the nervous system for information, and I am not sure that by so doing we shall meet with disappointment.

Let us take two extreme cases; viz. a case of sudden death from lightning, and a case of death under ordinary circumstances. It is well known that in ordinary death, every part of the body does not die at one and the same time: thus, the heart and blood-vessels are the last parts which lose vitality for a little time after respiration has ceased; the circulation is still carried on in feeble circuit; the heart’s expiring struggle is taken up by the arteries, and so the vital fluid is found accumulated in the large veins and primary venous trunks: it even gets back again as far as the ventricles and anricles, for a more or less fibrinous coagulum may in general be detected in them. In death from lightning, on the other hand, all the structures of the body are at once deprived of every mark of life; every organ is in a moment struck dead; the heart ceases to beat; even the blood refuses to coagulate, but, still in a fluid state, remains in the arteries as well as in the veins.

Between these two extremes there are many gradations. Sir B. Brodie showed by experiment that in animals killed by an explosion of a galvanic battery, the heart continued for some time to act feebly.

* Diseases of the Brain, &c.

Other grades are exemplified by the cases related by Mr. Chevalier, and by that of Joseph Hall. It is true they did not owe their death to electricity; but death was produced by a shock, which, although it differed as to its cause, was nevertheless powerful enough to annihilate the functions of the nervous system. Not else can we account for the debility of the smaller vessels, which did not complete the circuit began by the last beat of the heart; and I am inclined to think that the state of this organ and blood-vessel after death may be regarded as nothing more than a good criterion of its severity.

If I have succeeded in reducing the inquiry to one which regards the nature of the shock, it is merely necessary to discover the latter, in order to render the case complete. Cold, when applied to the ear for a short time, as in injecting cold water into the external meatus, very powerfully affects the system; two cases, which fell under my own notice, will serve particularly well to illustrate this observation. A young gentleman, accustomed, on rising in the morning, to syringe his ears with warm water, on one occasion used cold; at the third or fourth syringeful he fell insensible on the floor, and did not fully recover for twenty-four hours. He described his sensations to be those of fainting; he became dizzy, sick, faint, and finally insensible. A young lady experienced similar sensations, but not so severe, after the use of cold water in the same way: she did not recover for six or seven hours. These curious effects were surely the result of a shock on the nervous system; they could scarcely be produced in any other way. Now, it is well known that air, in resuming its former bulk after condensation, becomes a powerful refrigerating agent; and, therefore, when injected into the tympanum for an unusual length of time, may and will, as the following cases show, produce effects very much the same as those arising from the use of cold water.

A. W., an elderly gentleman, applied to an aurist for the cure of his deafness: at the second discharge from an air-press he fell insensible, and did not recover for four hours.

A. Y., a boy about 18 years, applied to an aurist, and was treated in the same manner: at the second or third discharge he fell into perfect deliquium, and did not recover for the greater part of the day. It is alleged that these two persons were subject to fits, but these fits were not characterized by insensibility, and if they were, it is plain that the remedy is dangerous where a nervous susceptibility exists.

I know of three other cases, but, as they resemble in every respect the two

just named, it is not necessary to detail them.

I would here ask the careful reader, who will take the trouble to review the circumstances attending the death of Joseph Hall, if he does not attribute the fatal result to the long-continued injection of air, rendered much colder on resuming its former bulk, into the tympani.

The Air-press as an Acoustic Instrument.

The air-press, although made of various shapes, in principle is precisely the same as the condensing syringe and reservoir of an air-gun. A flexible tube, with a stop-cock, is attached to the reservoir, and thus an unrelenting blast of air, in strength and duration, depending on the degree of condensation, is obtained. A Eustachian tube catheter, of silver or elastic gum, completes the apparatus.

An instrument of this kind, long ago suggested in this country, has lately been made use of for acoustic purposes in France and Germany, by several talented physicians; but in England, where its introduction is comparatively recent, it has fallen into the hands of a blundering few, who, instead of employing it as a diagnostic agent, with a view to the more rational treatment of diseases of the ear, make it serve as a vehicle for every species of quackery.

It is much to be regretted that those who have taught us, by their prudent example, to rely on them in matters of doubt or difficulty, do not undertake to test some of the many new remedies, particularly those which are backed by the recommendation of enlightened individuals of other countries. If this were the case, the public would cease to run, or at any rate they would pause, before they endangered their lives by running to every one professing to cure by a new instrument. Let us here compare the practice of ear medicine as it exists in France and in this country, and, in illustration of the former, take Delcau. "It is, perhaps, to the prognosis I give my patients that I owe part of my practice. Many patients are sent to me by persons whom I had pronounced incurably deaf, but who are not the less ready to recommend me than those I have cured. This is not surprising; for, indeed, it is as useful to humanity to prognosticate the impossibility of curing certain cases of deafness, and not to subject to treatment the numerous incurables, as to cure those who are curable. Consider how many wounds, blood-letting, and operations still more painful, one should practise, if he subjected indiscriminately to treatment that immense number of individuals who are constantly running about to consult all the medico-chirurgical notabilities, and all the inven-

tors of new nostrums!" He makes mention of various "bruits,"—as *bruit de pluie, de pavillon, de la trompe, de la cuivre*, &c.—which are only to be heard by considerable care and dexterity in using the air-press. The steam of the air should be allowed to enter the tympanum gently, and the catheter should be loosely engaged in the Eustachian tube to allow of its escape back again into the fauces. During the process, the operator listens at the outer ear, and judges by the kind of sound the air makes in thus circulating in the tympanum of the condition of its lining membrane; which may be so much thickened as to close the Eustachian tube, diminish the diameter of the fenestra rotunda, and thus prevent the due vibration of the tympanic membrane and the ento-lymph in the labyrinth. The propriety of this manœuvre is unquestionable, and it is obvious that one, or at most two, discharges of the press are sufficient to procure all the information that the instrument can afford. It is out of place to proffer any remarks on the use of the air-douche as a means of altering the condition of the lining membrane of the tympanum and Eustachian tube, or to inquire into the precise relation between this condition and the degree of deafness. I may perhaps, however, be permitted to say, that the effect of the air-douche, as applied in England, has not been successful in ten cases which have come to my knowledge, as the affection was considerably aggravated after from three to six applications.

How strikingly different is the practice of acoustic surgery with us! One would be inclined to suppose that diseases of the ear were considered by our best surgeons as utterly unworthy of their attention; for, with one or two exceptions, this department of our science is engrossed by a set of the most bare-faced quacks that ever the world produced. They not only steal from the fair rights of the well-educated professional public, but, like rats, only wait for an unfortunate brother to fall into a trap, when on they rush to eat him up, barely leaving the tail behind them. Who is not disgusted at the public advertisements which this case of Joseph Hall seems to have called forth. "That is not my plan," says one; and invites the public to witness the superiority of his process. "I have no such instrument as an air-pump," says another; and takes the same opportunity of expatiating on the beauties of an air-trumpet, by which even the deaf and dumb are enabled to speak as well as hear. Verily one turns heart-sick away from such effrontery, yet the public are every day gulled by a species of quackery which, if bad, indeed, when practised by the ignorant pretender, is

particularly abominable when boldly advocated by "M.R.C.S." or "M.D."

And what does the acoustic quack? I will pledge myself to bring forward more than one instance of the truth of the following statement:—The patient, whatever may be the cause of his deafness (malformation of the ear or otherwise), is first assured that he will be cured, and he is accordingly directed to take up his abode near to or in the residence of the operator. A fluid is poured into the outer meatus, and there follows a ramming and cramming with some preparation. The patient is now directed to apply again in a morning or two, when four or five pellets are extracted by the aurist, screwed up in paper, and banded to the deluded patient, for the inspection of his friends. The legerdemain is repeated, but the patient, unless the cause of deafness be of a temporary description, ultimately finds himself in the same state as at first, and does not return. Or suppose the air-press is made use of: the catheter is, with much display, thrust into the Eustachian tube; the press, charged by the untutored hand of a sturdy by-stander, is now affixed, and the operator, instead of intently listening to the murmur in the tympanum, retires to some distance, as if fearful of the instrument so unskilfully prepared. Endless would be the task of recounting cases of this species of imposition; indeed I ought to apologize for having so far exceeded ordinary limits. I will, therefore, conclude with the hope that some more influential pen may employ itself on this subject, in order to induce the legislature to adopt such measures as will effectually put down a system which can exist only at the expense of public health.

7, Lower Southampton Street,

VELPEAU'S CLINICAL LECTURES ON OPHTHALMIA.

By J. HENRY BENNET, B.L. & B.S.
Sorbon.

General observations.—Comparison of German, English, and French ophthalmic writers.—School of Beer.—Division of ophthalmia into the serofulous, rheumatic, and catarrhal, erroneous.—Diseases of the eye divided into those affecting—1. the eyelids; 2. the inner canthus; 3. the eye itself.—Different forms of blepharitis, or inflammatory affections of the eyelids.

GENTLEMEN,—Before I enter at length into the examination of the subject of

which I am about to treat, I wish to make a few remarks respecting the history of this branch of surgical science, principally with the view of dispelling some erroneous opinions which seem to prevail, not only among foreigners, but even among many of our own countrymen: I allude to the reproach often made to France, that she has contributed but little to the advancement of Ophthalmology—that she has allowed other nations to take the lead, and has shewn indifference to a class of diseases which has been cultivated with the greatest interest in neighbouring countries.

A cursory survey, however, of the history of ophthalmology will show clearly that there is no real foundation for such an opinion, and that, although a much smaller number of special treatises on this subject has been published in France, during the last few years, than in England or in Germany, we are not at all behind these countries in our knowledge of this division of pathology. We must never forget that in medical science, as, indeed, in all others, it is not the number of authors, but the accuracy of their ideas, that ought to guide us in forming an opinion.

In all ages, diseases of the eye have attracted great attention; nor, indeed, can we be surprised at this, when we take into consideration the extreme importance of its functions, and the numerous maladies to which it is subject. No other organ of the animal economy, indeed, offers to our observation so many forms of disease; and this is at once accounted for when we consider the extremely complicated nature of its texture. In the eye we find nearly all the elements of our organization. In it we meet with cellular, muscular, vascular, fibrous, and nervous tissue. In it we find an apparatus for secretion and excretion; also tissues not to be observed in any other part of the body, such as the choroid membrane, the retina, the crystalline lens, and the vitreous humour. Each of these tissues must necessarily be subject to peculiar affections, manifesting themselves by peculiar symptoms, as is the case in all other regions of the body.

In Galen's time, a great number of diseases of the eye were already known. He says that many persons specially devoted themselves to this branch of the healing art; nor need we think this extraordinary, for then nearly every branch of medicine had become a prey to specialists. There were oculists, aurists, lithotomists, physicians for the chest, physicians for the abdomen, &c. &c.; and this is the state of things into which some would now wish us to return.

From Galen up to the sixteenth century we find no important work on diseases of the eye. At that epoch France

gave the signal—France opened the path of modern improvement. Guillemeau is the first who classed the different affections of the eye; this he did in an interesting treatise, in which he describes as many as one hundred and thirteen diseases, designating them by names mostly taken from the Greek authors.

It is not, however, until the end of the seventeenth and during the eighteenth century, that we see those works appear which constitute an era in science. It was then that the writings of St.-Ives, Maitre Jaen, David, Brisseau, Guerin, Janin, Pellicier, Wenzel, Demours, appeared in France; that of Scarpa, in Italy; those of Richter, Beer, Schmidt, Ilmly, in Germany; those of Woolhouse, Wathen, Ware, and others, in England. Hitherto France has, you see, her representatives among ophthalmologists, and their labours will bear comparison, in every respect, with those of foreigners. Even those who speak the most lightly of French surgery, yield to France the superiority during the eighteenth century. But where, they ask, are the men of our times whom you can compare with Jüngken, Ammon Røsas, Jæger, in Germany; with Saunders, Wardrop, Travers, Mackenzie, in England; with Fabini, Quadri, Flarer, in Italy?

We cannot, I confess, bring forward so many pure ophthalmologists; but I appeal to your reason, is it necessary to be decorated with the name of oculist to have exact notions respecting diseases of the eye? Do not these affections belong to pathology in general? and ought not every good surgeon to be acquainted with this branch of his profession, as well as with all others? Absolute specialties ought not, in our days, to meet with the favour they met with formerly. Indeed, public opinion seems to be gradually becoming more enlightened in this respect; and we may still hope to see the time when specialties will fall entirely into the domain of charlatanry. You are aware, I presume, that I only allude to specialties as practised by those whose knowledge is confined to the branch of pathology they have embraced. I am far from wishing to cast any blame on the preference a practitioner may give to some branch or other of his profession. It would, I think, be difficult to find a man of science who has not some favourite subject to which he more particularly directs his attention.

If we look over the French periodicals, and the different works on surgery that have appeared in our own times, we shall certainly find many articles which the most celebrated ophthalmologists would not disown. Had we not a few years ago Demours junior and Forlenze? Have we not now M^r. Wenzel junior, Guillet, Faure, Gondret, Bourgot, Andrieux, Stæ-

ber? MM. Carron du Villard, Furnari, Rognetta, although of Italian extraction, profess among us French doctrines. Again, are Boyer and Dupuytren—are MM. Ronx, J. Cloquet, Sanson, Laugier, Marjolin, inferior to those surgeons of Great Britain or Germany? May I be allowed to say, that I myself have for many years paid great attention to diseases of the eye. In 1820 and in 1825 I published several articles on this subject. In 1831 I gave a series of special lectures on ophthalmology at La Pitié, some of which appeared in the periodicals of the day.

This I say, merely with the view of proving that France has done as much as any other nation, towards the advancement of this branch of pathology. Were I to say more I should be obliged to enter into details which would carry me too far. I will, therefore, only add, that providing justice be rendered to France, I am perfectly willing to be generous to other nations.

In the course of these lectures my opinions will often be at variance with the doctrines professed and adopted in other countries; I think it necessary, therefore, to announce, as briefly as possible, the doctrines to which I allude.

I shall occasionally find myself opposed to men of science, whom I esteem, some of whom I number among my friends. This consideration, however, cannot deter me from making my opinions public; every other feeling must give way when we are prompted by the interests of science and the welfare of humanity.

The school which reigns at the present time is that of Beer. Even M. Stæber has not escaped its influence. The doctrines professed by the pupils of this oculist repose on two principles, which must detain us for a few moments.

The first of these principles—the one which forms, as it were, the basis of the system—is, that diseases of the eye ought to be classed according to the natural system; that is, according to their physical symptoms. This mode of classification, which is the one adopted by botanists, appeared novel in its application to medical science; but were you to peruse the nosology of Sauvages, you would at once see that it is not necessary to go to Vienna or Berlin to meet with such an application of the natural system. The same may be said of Pinel. Is not this also the system of all the solidists—of the Broussaian school itself. Beer, it is true, only applied this principle to diseases of the eye, but M. Jäger extended it to pathology in general. This is the system he opposes to that of the French physiologists and organicians.

The second principle is, that the classification should also be founded on the

nature of the disease; it may be considered the consequence of the first.

Such are the principles which have given birth to scrofulous, rheumatic, and catarrhal ophthalmia. Those of you who have followed my visits for any length of time, must have perceived that these denominations are founded on erroneous views. I do not mean to assert that a scrofulous constitution, or a syphilitic taint, will not exert great influence over diseases of the eye. The eye is no more shielded from such influence than any other organ. But I must be allowed to differ entirely from those who maintain that a disease of the eye assumes peculiar symptoms because the patient's constitution is modified by a general affection; and from those who pretend to judge of the constitution of persons from the ophthalmia presenting this or that symptom. Attentive observation of disease renders me every day more and more convinced, that such opinions are entirely without foundation. Examine the patients now in our wards; many will offer you all the symptoms which the German school considers pathognomic of a special affection of the eye; yet you will find but very few among them under the influence of the general affection on which so much stress is laid by Beer. Those whom these cases might not convince, have it in their power to perform an experiment which would perhaps carry with it more weight than what is seen here. Nothing, indeed, is more easy than to give rise in the healthy eye, by artificial means, to an inflammation assuming the symptoms of the scrofulous, the rheumatic, or the catarrhal form of ophthalmia.

Anticipating here the ideas I intend to develop in the following lectures, I will, in a few words, tell you my opinions on this subject. I believe the division of ophthalmia into scrofulous, rheumatic, and catarrhal, which the school of Beer is now attempting to establish, is altogether erroneous. These general affections exercise the same influence over diseases of the eye that they exercise over all other diseases. The error of Beer, and that of his followers, is simply this: they judge of the constitution by the appearance of the eye, whilst you ought to judge of the eye by the constitution. They shew us the image inverted, if I may use the figure; I wish to place it in its proper position.

Scrofulous or rheumatic ophthalmia, &c. as understood by one of the representatives of the German school now among us*, does not, then, in my opinion, properly

* M. Sichel, a private professor of ophthalmology, of high scientific attainments. M. S. has lately published a work, in which he entirely adopts the views of the German pathologists.—J. H. B.

speaking, exist. The doubts which some of you may feel on this subject will, I think, have vanished before we have brought our examination of these affections to a close. I shall endeavour to overthrow the opinions of the German school, not only because they are false, but also because they only serve to render more intricate a subject which is already extremely difficult.

To conclude these observations, I will say, that after having meditated frequently and seriously on the subject—after having made an immense number of observations at the bed-side of the patient—I think I am warranted in asserting, that the study of diseases of the eye ought to be directed by the same laws as that of all other branches of pathology.

Diseases of the eye may be divided into three classes:—

1st. Diseases of the eyelids.

2d. Diseases of the inner canthus.

3d. Diseases of the eye itself.

The diseases of the inner canthus having been sufficiently investigated during the last few years, I shall not enter into any details respecting them, referring you to what I have already published on the subject in my work on Operative Surgery, and in the *Dictionnaire de Médecine*.

With regard to diseases of the globe of the eye I shall lay aside every thing relating to degenerations of tissue, confining myself to what authors have designated under the general term of ophthalmia.

Inflammatory Diseases of the Eyelids.

The different inflammatory diseases of the eyelids are known under the general term of *Blepharitis*. Blepharitis presents several varieties determined by the nature of the tissue primarily affected, and by the variable intensity of the inflammation. I must again remind you, that, for the present I do not take into consideration the constitution of the patient, or the different specific causes of disease.

The eyelids, considered in a general point of view, present an external or cutaneous surface, an internal or mucous surface, and a free margin. Between these you find a tissue, the structure of which must be well known before you can form an exact notion of the inflammatory affections of the palpebræ. The most important anatomical feature is the laxity of the cellular tissue, uniting the muscular and cartilaginous portions, &c.

The anatomical structure of the eyelids might induce us to recognize an external, a median, and an internal blepharitis, as also a blepharitis of the free margin. Pathologists have, however, very justly excluded the two first from the list of inflammatory affections constituting ophthalmia: nevertheless, as inflammation here assumes a peculiar physiognomy which it does not present in any other part of the

body, the prepuce and scrotum excepted. I feel bound to say a few words on the subject.

When the inflammation is limited to the external surface of the eyelids, it offers, as I have already stated, the same characters as when it attacks the prepuce or scrotum. It is merely an erysipelatous or erythematous affection, which is to be treated by the means usually resorted to in these diseases. In the simple form, without any complication, the affection is so slight, that it is only necessary to point it out to you.

When, however, the intermediate layers are inflamed, the malady becomes more serious. The connection between these tissues and the inner surface of the eyelids is so intimate, that generally the inflammation, passing from one to the other, gives rise to blepharitis, properly so called. Thus, as we have not only to fear the consequences of the inflammation in the part primarily affected, but also its extension to the palpebral conjunctiva, we ought at once to adopt every measure likely to arrest its progress.

This kind of blepharitis may assume two forms; it may be circumscribed or it may be diffuse. When diffuse, it constitutes what is called phlegmonous erysipelas. In both cases, the best plan to extinguish the disease, and to avoid the usual consequences of phlegmonous erysipelas, is to scarify the parts, regulating the number of scarifications by the extent of the inflammation. These affections do not, in reality, deserve to be comprised under the head of ophthalmia. I shall not, therefore, enter into any further details respecting them, but at once commence the examination of blepharitis, properly so called—that is, of the inflammatory affections of the internal surface and of the free margin of the eyelids.

Blepharitis, strictly so called, presents four principal forms, which are determined by the consideration of the structure of the parts primarily affected. Thus, when the inflammation is limited to the conjunctiva, I call it mucous blepharitis; when it occupies the Meibomian glands, glandular blepharitis. This second form admits of a variety, diphtherical blepharitis. The third form is not yet well known; the inflammation appears to be concentrated in the mucous follicles. This latter circumstance has induced me to give it the name of granular blepharitis. Lastly, I have called ciliary blepharitis that form in which the inflammation is situated at the base of the cilia. To these four principal forms we may add purulent blepharitis. We have therefore to study—

Mucous blepharitis.

Glandular ditto.

Granular ditto.

Ciliary ditto.

Purulent ditto.

Although I thus distinguish several forms of this disease, you must not suppose that they are always separate—always perfectly distinct from one another. This is by no means the case; they are, on the contrary, nearly always combined. Thus you will generally find two or three, sometimes even the whole four, present in the same eye. Each form, nevertheless, offers symptoms and characters peculiar to itself, which ought not to be confounded. We shall also find, shortly, that these distinctions are of great importance with regard to the prognostic and treatment of blepharitis, considered in a general view.

LIVING WORMS UNDER THE CONJUNCTIVA OF THE NEGRO.

Blot, of Martinique, has, like Bajon, of Cayenne, and Mongin, of St. Domingo, seen two worms in active motion under the conjunctiva, which he removed by incision. One of these, which was sent to M. Blainville, was thread shaped, thirty-eight millimetres long, with a black protuberance adapted for suction.

Bajon remarked (1768) a serpentine motion of a worm in the eye of a negress, which, without giving pain, caused constant epiphora. When an incision was made, the worm went to another part, and was obliged to be secured with a small forceps. In a second case (1771) the conjunctiva was more inflamed; the patient refused to submit to operation. In Blot's case (1828) the worm lay on the outside of the eye, and sometimes turned round a portion of the corner, causing stinging pains and nervous symptoms, arising probably from fear. The patient, an African negress, was unable to tell where she came from, or whether her fellow-country people were subject to this disease. A surgeon at Mompox (New Grenada) offered to extract this worm, but his services were refused. The worms found by M. Guyon were not of the species termed *Filaria Medinensis*, which are found in abundance amongst Africans, and could not be secured by the forceps.—*Zeitschrift für die gesammte Medicin*, Feb. 1839; and *Dublin Journal of Med. Science* for July.

ROYAL COLLEGE OF SURGEONS.

At a quarterly meeting of the council of the Royal College of Surgeons in London, on Thursday, July 11, Robert Keate, Esq., was elected President; and John Painter Vincent, and George James Guthrie, Esqrs., were elected Vice-Presidents of the college for the year ensuing.

BOOKS RECEIVED FOR REVIEW.

Diary of the Rev. John Ward, A.M. Vicar of Stratford-upon-Avon; extending from 1648 to 1679; from the original MS. preserved in the Library of the Medical Society of London; arranged by Charles Severn, M.D. Member of the Royal College of Physicians, Registrar to the Medical Society of London. pp. 315. Colburn, 1839.

A Treatise on the Medical Jurisprudence of Insanity. By J. Ray, M.D. Clark, Edinburgh, 1839.

The Analysis and Medical Properties of the Tepid Springs of Buxton; with Cases and Observations, by Sir Charles Sendamore, M.D. F.R.S. Churchill, 1839.

APOTHECARIES' HALL.

LIST OF GENTLEMEN WHO HAVE RECEIVED CERTIFICATES.

Thursday, July 11, 1839.

Wm. Love Street, Exeter, Devon.—George Mayris Sylvester, Trowbridge, Wilts.—Francis James Bellingham, Windmill Hill, Sussex.—Wm. Donald.—Thos. Woollett, Usk, Monmouthshire.—Walter Edwin Chilcote, Brixham, Devon.—Charles O. Baylis, Liverpool.—Edmund Guest, 30, College Street, Chelsea.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.
By DR. VENABLES.

Pathology.—With respect to the proximate cause of this form of disease, Dr. Prout believes we may suppose it to consist in a diminished or suspended action of the usual acidifying powers of the kidney, and the formation, instead of lithic acid, of a greater quantity of alkaline matter than natural, as urea (equivalent to ammonia), and particularly of magnesia and lime. We have already seen that the urine in this affection often abounds in urea, and that it also contains a sort of muco-purulent matter, thrown off from the mucous lining of the bladder and urinary passages. Now this must arise from some peculiar irritable condition of the mucous surface, not absolutely inflammatory, but partaking more of the congestive character*. When the triple crystals are deposited, the bladder, generally speaking, is not yet much engaged in the affection; but when the fusible phosphates appear, then the whole mucous linings may be considered as suffering, and secreting more

or less of this tough ropy mucus. This mucus is generally alkaline. It contains two saline principles, the one carbonate of soda, and the other phosphate of lime. From the carbonate of soda which it contains, it derives its alkaline reagency, and power of reddening turmeric. Here is some of this mucus and distilled water slowly filtered from it, as you see, has a strong alkaline reaction. The phosphate of lime we can easily demonstrate, by burning it and examining the ash, or by dissolving out the phosphate by a diluted acid, and reprecipitating by a neutralizing agent. This mucus sometimes so abounds in phosphate of lime that it appears in white streaks; in others, in which it is more abundant, it appears in irregularly-shaped white masses, and plastic, like mortar.

Urea, by the action of fixed alkali, is converted into carbonate of ammonia, and thus one of the elements of the triple crystals is furnished abundantly. Therefore, if urine be alkaline, we may expect that the triple crystals will be formed. Alkaline urine is a source of irritation to the membrane lining the urinary passages, and produces that congested state which is attended with the formation of this mucus. If this begin in the kidneys or ureters, the congestion speedily extends to the bladder, and all the mischief is increased. But it would also appear that even phosphate of lime may be secreted in unnatural quantity by the urine; and if the excess of acid holding these principles in solution be neutralised by the generation of any alkali, as ammonia, the triple crystals, or the fusible phosphates, according to circumstances, may appear. However, neither affection probably prevails long without inducing the other; and the joint result may originate from either as the primary affection.

Treatment.—There is no occasion to consider the treatment of each of these forms

* "This inflammatory action, however, if it be worthy of the name, must differ from common inflammation; for in one instance in which a small calculus was contained in the bladder, and in which a large quantity resembling that passed in the present affection had almost constantly for years been secreted by the inner coat of that organ, this entirely disappeared when acute inflammation of the common kind was excited in the bladder, owing to the patient having imprudently taken a long journey in a rough carriage."—Prout on Diabetes, &c., p. 245.

separately, since the principles are the same, and differ only in the degree and extent in which they are applicable. One of the primary indications is to reduce the general and unnatural irritability of system, to invigorate the frame, and to give tone to the digestive and urinary organs by tonics, astringents, and other appropriate remedies. The next indication is to correct the morbid conditions of the urine, so as to counteract and prevent those results which must inevitably take place from the uninterrupted continuance of such morbid conditions.

With the view of diminishing the unnatural irritability of system, nothing is superior to opium; indeed, Dr. Prout states that in severe affections of the second class (the amorphous fusible phosphates), opium is the only remedy that can be employed with much advantage to fulfil the first indication; and all who have had occasion to try the several sedatives in these affections must yield the palm to opium. It must, too, be given in large and repeated doses to prove effectual; for instance, from one grain to five three or four times a day; and, indeed, the system bears such large doses well, for the relief experienced counterbalances, or rather counteracts, the injurious effects which would otherwise result from such large quantities of opium. Smaller doses, from their stimulating agency, would do harm by exciting the system, and inducing a low degree of fever, which would prove highly distressing.

The form or preparation in which opium may be best administered must depend upon circumstances; for in someone preparation will agree, and in others a different. The *pilula saponis composita* of the London Pharmacopœia is a very good preparation, and often agrees well; but when we wish to give large doses, as this preparation contains but one grain of opium in five of the pill-mass, it will be better to select some less bulky preparation; but in all cases we must select that which agrees best with the patient's constitution. Thus I have known individuals with whom no other preparation would agree, or at least so well, as the *liquor opii sedativus*. But when the salts of morphia agree, they are by far the best and by far the most efficacious. Of these, the hydrochlorate and the sulphate—as more permanent in their composition, and consequently more uniform in their strength and operation—are the preferable. Of these, from one grain to two or three may be given three or four times a day, according to the urgency of the symptoms; and it is astonishing what quantities of opium patients of this sort will sometimes bear, not only with impunity,

but, indeed, with decided benefit and improvement of the health. When the gravel is crystallized, consisting of triple phosphate, the treatment is the same, but less energetic; but in the fusible phosphates, opium not only may, but of necessity must, be pushed to the utmost extent. By these means the patient, if not completely relieved, will soon find his sufferings greatly alleviated; and this alone would be quite adequate to the improvement of the general health.

Having effected so far an improvement, we may begin to alter and improve the chemical condition of the urine. It has been stated that the urine, if not alkaline, is at least neutral, and soon becomes alkaline; and therefore it is necessary to use those agents which will correct this tendency, or counteract its effects. Therefore with the opium or morphia we may combine some of the mineral acids, as the hydrochloric, nitric, but perhaps still more advantageously the phosphoric, as the one adopted by nature for holding the earthy salts in solution, and for the preparation of which a formula has been introduced into the New London Pharmacopœia*. The acid of the strength of that of the Pharmacopœia may be given in doses of from ℥xx. to fʒj. The hydrochloric, nitric acids, &c. sometimes disagree, and it has been then proposed to use the vegetable acids, as the citric; but they never answer so well as the mineral. The phosphoric acid, however, seldom disagrees†; and if it should, the probability is that so also will the vegetable acids.

In cases, however, where the acids disagree, and so far are objectionable, a solution of pure chlorine may be given; and, indeed, I have frequently given this with success. We have no formula for a solution of pure chlorine in the Pharmacopœia, but it is evident that such a solution may readily be prepared by passing the chlorine into distilled water, instead of the salines directed by the Pharmacopœia. The opium and the acids may be com-

* In a former lecture a process was pointed out for separating phosphoric acid from urine by lead. The process adopted in the Pharmacopœia for the preparation of phosphoric acid—the acidifying phosphorus by means of nitric acid—is, in my mind, an operose and unnecessary process, when phosphoric acid of any strength may easily be prepared by the decomposition of phosphate of lead by a current of hydrosulphuric acid gas. The obtaining of phosphorus is generally effected by the previous formation and subsequent decomposition of phosphate of lead; consequently the necessary precursory preparation of this salt would be no objection.

† Dr. Paris states that the phosphoric acid allays the insatiable thirst in diabetes better than any other drink. If apt to disagree, we might expect that this effect would be very likely to occur in the state of stomach predominant in diabetes.

bined, and at the same time colchicum, which appears to be a valuable remedy in almost every form of urinary disorder. Indeed, if the property of generating, or rather of promoting the secretion of lithic acid, attributed to it be just, there can be no question of its advantage.

With these, tonics, as the cinchona, but more particularly the preparations of iron, especially the sesquichloride, may be had recourse to. Likewise the urinary astringents, as the *ura ursi*, which is most advantageously administered in the form of extract, and may be combined with the extract of colchicum. Of the same description is the *alchemilla arvensis*, *pareira brava*, &c. These, though said to be diuretic, frequently by relieving irritation, produce a directly contrary effect.

At the same time we may adopt local measures to the loins, as plasters of pitch, galbanum, soap, ammoniacum, or the *emplastrum ammoniæ*. Any of these, by gently stimulating the surface, and at the same time affording mechanical support to the back and loins, afford great relief. I have found the belladonna plaster applied to the loins, after being previously irritated by some stimulant embrocation or plaster, highly beneficial, and procure comfortable and tranquil nights, when all other resources had proved comparatively inert. In some instances, however, setons or issues become necessary before any thing like permanent or effectual relief can be obtained.

The practice hitherto recommended is calculated to confine instead of to relax the bowels; and although diarrhœa, or any solubility of bowels approaching to this state, would prove highly prejudicial, by exhausting and debilitating the patient, yet a constipated state does great harm, by the irritation which fecal accumulations excite in the system in general, and in the urinary organs in particular. There is a great tendency in this disease to irregularity of the bowels; and it is very often difficult so to manage as to effect the due regularity in their action. More frequently, however, constipation is the prevailing irregularity, and active purgatives are almost invariably followed by diarrhœa. Thus Dr. Prout states that he has seen the most serious consequences brought on by a small dose of calomel, which induced severe diarrhœa, with consequent debility, aggravating all the symptoms, and endangering the patient's life. Saline purgatives, but more particularly those constituted of a vegetable acid—the tartrates, for instance—are literally little better than poison. The principles upon which these agents are so injurious have been already explained. The best remedy in such cases is castor oil; and if this be

not sufficiently active, a draught, consisting of infusion of rhubarb and a small portion of the powder, rendered a little more active by some purgative tincture, as of senna, will in most cases have the desired effect. But if not, the occasional recourse to a laxative enema will always, when assisted by the foregoing, produce a sufficient evacuation. Mercury in almost every shape is pernicious; and more have been sacrificed by the injudicious use of mercurials, under these circumstances, than perhaps would be imagined. I wish to impress this fact upon your attention, because the general symptoms and the sallow or half yellow countenance of the patient are such as apparently indicate the use of this mineral. But if the specific effects be once excited in the system, the devastation and ruin of constitution which immediately follow, though it may not, perhaps, convince you of the error, yet will speedily remove the unfortunate victim from the effects of his imprudence. However, there may be occasions in which a guarded use of mercury may be not only innocent, but absolutely necessary. When such do occur, the bichloride with hydrochlorate of morphia, and excess of hydrochloric acid (or even chlorine, as already mentioned, I believe to be the very best formula, and the least pernicious of all the methods of giving mercury. "Perhaps," says Prout, "the best mode of exhibiting it (mercury) in such cases is to combine it with opium, or with a purgative in some instances." In my opinion, however, the formula already alluded to presents by far the preferable method of giving mercury; and one advantage which it seems to possess is, that it is not apt, specifically, to effect the system, while in many cases it will effect the purpose intended by the exhibition of a mercurial. But there is a still further advantage, that while effecting the one object we are at the same time improving, or at least endeavouring to correct, the diseased states of the urine by the excess of hydrochloric acid—purposes which cannot be conjoined in any other form of mercurial; but, as stated by Prout, if possible, the use of mercury had better be dispensed with altogether, or deferred till the distressing symptoms have somewhat yielded, and the patient recovered a little strength. In urgent cases, the substitutes for mercury formerly mentioned may be tried till a more favourable opportunity for giving the mineral presents.

I need hardly caution you against any use of the alkalies, than which nothing can be more pernicious in this diathesis, for they do not favour, but absolutely greatly

aggravate the mischief already existing. Indeed, all diuretic remedies, and all remedies exerting any stimulating effect upon the urinary organs, should be most carefully avoided. The drinks should be of a soothing and demulcent character, and consisting of the softest and purest water, even distilled if possible: hard waters are highly pernicious in this diathesis, and therefore should be most carefully avoided.

We have been considering this affection in, perhaps, its most aggravated form; when, however, the symptoms are milder, and that the constitution has not suffered, or at least to no great extent, and that the irritation is chiefly local, in the urinary system itself, although the principles of treatment are essentially the same, still the means admit of some degree of modification. Here, perhaps, we shall not require so active a use of opium, or possibly it may be dispensed with altogether. For it we may substitute the extract of hyoscyamus, or the hydrocyanic acid, or both. Thus, the extract of hyoscyamus with that of *uva ursi* may be administered at intervals, and a strong infusion of the *alchemilla arvensis*, with occasionally a few drops of the hydrocyanic acid, will be found to give great relief. Here, too, purgatives may be given more freely, remembering, however, the tendency, and selecting always the milder, and least drastic.

In children, as previously stated, the triple crystals are sometimes very copiously deposited, and it is often very beneficial in such cases to purge freely, and even repeated doses of calomel and rhubarb produce the most beneficial results. The cases in which this practice may be beneficially employed are to be distinguished by the absence of the severe symptoms already noticed, and by the high specific gravity of the urine, which in some amounts to 1.020 or 1.025, and usually contains much urea. Purging, in such cases of diuresis, reduces the sp. gr. of the urine, and diminishes the quantity of the urea.

With respect to regimen, as air, exercise, diet, &c. they require to be properly regulated. When the symptoms are very severe, exercise, at least any of the severe exercises, greatly distress the patient and increase his pains. Indeed, he is totally unable to any exertion. But when the symptoms have been somewhat abated, then the more gentle exercises, and in moderation may be adopted with great benefit; but much of this must be left to the discretion of the practitioner, to be regulated according to the particular circumstances of the case. The diet, especially in the severe forms, should be light and nutritive, and in rather small quan-

tity at a time. The digestion is usually much impaired, and therefore the more indigestible articles of food should be shunned. Dr. Prout advises an animal instead of an acescent vegetable one, as usually recommended, and indeed, reason approves what experience has confirmed. Vegetables are much more difficult of digestion, and are likewise much more prone to fermentation. Hence the debilitated stomach is not only called upon to perform harder duty, but the extrication of gases and consequent over-distension of the stomach and bowels; for the evil extends throughout the whole length of the intestinal tube, produce the greatest distress, and aggravates all the symptoms. Therefore, the milder, and at the same time not over-stimulating animal foods, may be directed: such are, for instance, mutton, poultry, and game, not too rich, are the best, and are generally found to agree well with the patient. Such a diet will keep up the strength, and at the same time not produce any distressing distension of the stomach. But notwithstanding that the diet should be principally animal, yet it is not intended wholly to interdict vegetables, especially farinaceous matters, and, indeed, a due admixture is best suited, even to a weak digestion. The selection of vegetable matters should be made consistent with the strength of the digestive powers. Therefore, green, esculent, and acescent matters, will prove injurious; whereas, the more farinaceous, as bread, and this rather stale, will be best. Watery diets, as soups, &c. from the over-distension which they produce, tend only to weaken the stomach, and impair the digestive powers.

With respect to the drinks, some of the light French wines mixed with water, if the patient have been accustomed to wine, may be taken in moderate quantity; but it should be recollected, that over-distension of the stomach will at all times impair the digestive powers, and increase any existing debility. The drinks, therefore, should be in moderation. Cider and perry also, if they do not disagree. Also our own malt liquors in moderation often assist digestion, but contrary to what at first view might be imagined, they ought not to be hard. When malt liquors, as ale, porter, &c. for instance, become what is known by the term "hard," in contra-distinction to that expressed by the term "mild," they prove injurious. The former depends upon incipient fermentation, and the generation of acetic acid. In the other, they contain a little carbonic acid, which renders them more grateful. There are many who prefer these beverages when hard; but so far as I have had an oppor-

tunity of seeing, they disagree with a weak stomach, and, still further, impair the digestion. Thus it is, that a stomach which will bear an acid well, will not endure the process by which the generation and evolution of that is effected*.

Lastly, the mind of the patient must be kept as composed and tranquil as possible. If this be not attended to, every other means will prove abortive. There is nothing that exerts a greater influence upon the progress of this disease than mental anxiety. Therefore, the patient's mind should be detached from all kinds of business, and distressing or agitating reflections, and it should be quieted by every means of soothing, as pleasant society, agreeable pursuits, and such amusements as are most congenial to the patient's habits and disposition. Such is a summary of the principal means of cure in the different degrees of the phosphatic diathesis. For some interesting cases upon this subject I must refer to Dr. Prout's work. The second form, which is the more rare, when it does occur is, for the most part, complicated with stone in the bladder; still it does occasionally occur without this complication. I have, within the last four years, seen three cases at the dispensary uncomplicated with stone. They seemed to have arisen from sprains or injuries to the back. With respect to the result, such patients will seldom continue sufficiently long under treatment to effect a radical cure, even were such attainable. When relieved, they will draw themselves from medical superintendence, as was the case in the above instances.

Stone in the kidney and ureter.—In a former lecture some account was given of stony concretions in the kidney, bladder, &c. When the lithic acid, which is by far the most frequent constituent of renal calculi, is not discharged or carried off, it increases and gives rise to the formation of a renal calculus. The general symptoms have been already described. If the circumstances be favourable, the calculus, after fever, vomiting, bloody urine, and most intense suffering, arrives in the bladder, and a remission of the symptoms succeeds. But if, from the size of the stone or from any other cause, it should not be discharged, but is retained, it gives

rise to a number of very distressing symptoms. Thus there is a sense of weight and uneasiness, attended with dull pain, which is much increased by exercise, especially rough exercise—as on horseback or in a carriage over rough ground. Sydenham, who professed to be affected with stone in the kidneys, states, that when he walked much or rode over paved streets in a carriage, even though the horses walked gently, he passed bloody urine; but this did not happen when he rode on unpaved roads; the urine passed then, though it looked terrible when voided, almost like pure blood, yet, soon after, it became limpid at the top, the blood clotting to the bottom*.

The calculi found, or rather originating, in the kidney, are mostly composed of lithic acid; next to this, the oxalate of lime. Cystic oxide is so very rare, that there can be but little said upon the subject; however, from what is already known, there can be no doubt of their renal origin. Renal phosphatic calculi, however, are very rare, although instances of their existence have been unequivocally demonstrated. Their rarity, in all probability, depends upon various circumstances; but more particularly the increased diuresis which attends this diathesis; its being seldom an original source, and, indeed, the general circumstances attending the deposition of the phosphates.

When the symptoms of a renal calculus exist, as they may arise from disease of the kidney, we should examine the state of the urine to determine the nature of the diathesis, and endeavour to promote the progress of it along the course of the ureter, and ultimately its passage into the bladder. As this state of things is usually attended with some degree of inflammation, bleeding, if not otherwise useful, would be necessary on this account: but it favours the passage of the calculus by the exhaustion and relaxation which it induces. At the same time, leeches or cupping the loins will be necessary, and the immersion of the patient in a warm-bath will also prove highly beneficial, and afford great relief. The bowels should be opened by a dose of calomel, followed by castor oil; or if the urine indicate the lithic dia-

* The farmers and persons in the country all prefer malt liquor hard; but their digestive powers are usually much impaired, and I believe it is more owing to this, perhaps, than any thing else. One would also expect, that in such cases they would be much more liable to lithic deposits, and especially to gravel or stone of this composition. Gravel certainly is not very rare among this class of persons, but still not so common as from the above we should be led to suppose. But, however, they are more subject to other forms of urinary disease, especially irritation and disease of the kidneys and bladder.

* "Etinim cum bruma anni 1676, statim a soluto rigidissimo gelu diu multumque obambulassem, urinam mox reddidi sanguine pemitum; idque toties mihi usu venit, quoties vel multum itineris pedibus conficerem, vel in curru per platearum pavimenta veherem, quantumlibet lento equorum gressu; quod mihi tamen non accidebat, quoties per viam regiam, lapidibus non stratam, licet quam longissime, curru vectarer. Urina quam tunc excrebam tamen si terribili sanguinis tantum non sinceri specie prodiret, non ita diu post sanguine in fundo seorsim grumescente, in summitate limpida et sui similis conspiceretur."—Sydenhami Opera, p. 700.

thesis, the catharsis may be promoted by the Rochelle salts or soluble tartar, as before mentioned. In these cases, also, calomel and Dover's power may be given in alterative doses, till some effect has been produced in the system.

At the same time mustard cataplasms may be applied to the loins as counter-irritants. Blisters, generally speaking, are not useful in affections of the kidney; but when the severity of the symptoms has been abated, Dr. Prout asserts that their use is not only safe but beneficial. In most cases plentiful dilution is advantageous, and diuretics to a certain degree, and especially of the antispasmodic class. Thus for instance, I have found an infusion of juniper with nitric æther very effectual in such cases. In a word, the descent of the calculus along the ureter must be promoted by all the means compatible with the existing diathesis; and enough has been already said upon this subject. Hyoscyamus in large doses, so as to keep up a constant antispasmodic effect, ought to be exhibited.

Sometimes, however, the calculus is too large to pass through the ureter, and as its expulsion seems hopeless, then we can only endeavour to prevent its increase by palliatives and other preventives. The means, of course, will depend upon the existing conditions of the urine, and which have already been dwelt upon at sufficient length. As a means of counteracting the effects of the chronic form of disease necessarily induced, and preventing disorganization of the kidney, issues or setons in the lumbar region will be beneficial.

Stone in the bladder.—When the renal calculus has passed into the bladder under favourable circumstances, it is expelled through the urethra; but when retained, it becomes the nucleus for the further deposition of calculous matter. But, as already shewn, a nucleus may be any foreign substance introduced into the bladder—with which may be ranked clotted blood, hardened mucus, &c. When any of these occur, and that there is a calculous diathesis either existing or superinduced, a precipitation of the excess of this matter takes place, and thus the stone enlarges. A fluid is said to be saturated, when the temperature, remaining unaffected, it will not dissolve any other portion of a saline with which it is in solution. When, by an alteration of temperature, the solvent now takes up an additional quantity, or holds in solution an additional quantity, it may be said, in relation to the former condition, to be supersaturated. In such a case the solvent will let go such excess if the temperature be changed, or if there be a nucleus upon which it can deposit it,

even though there be no alteration of temperature. To illustrate this by an example, you see in this flask a transparent limpid fluid. It holds in solution an excess of sulphate of soda, with which, in fact, it is supersaturated; still, as yet, it has deposited none, and you see there is no disposition to let go a particle, nor indeed would it, if there were no evaporation of the water, if left at rest. But if I introduce a small nucleus—for instance, any solid matter—you see an immediate separation takes place, and the solution arrives at the point of saturation. Now this is, at least in part, what occurs in the bladder. The renal calculus may be considered as placed in a solution of various salines; and if any of these happen to be in excess, so that the urine, as in the instance of the solution of Glauber's salts before you, be in a state of supersaturation, the excess will be deposited upon the nucleus.

The point of saturation at the same temperature is fixed, but that of supersaturation depends upon a variety of circumstances. The urine does not always hold an excess of any of its salines in solution; but as circumstances arise so as to cause the generation and predominance of any of these principles, supersaturation will take place. Therefore, when the urine is supersaturated, it will deposit the excess; but when there is no excess, of course there will be no precipitation, and the bulk of the calculus will not be increased. Now this enables us to account for the different structures of calculi: for instance, some are laminated, shewing that the formation has been interrupted, and renewed again at distant periods, according as circumstances have arisen to modify the quantity of the saline in the urine, or, in other words, its saturation. When they have a homogeneous structure, then the deposition has been constant. Again, some consist of layers of different principles: this is owing to the diathesis changing, and the urine becoming supersaturated with the corresponding principle, and its deposition upon the nucleus, whatever its composition. Thus we can understand, not only the laminated structure of calculi, but also those laminæ consisting of different and distinct principles, and even the alternation of these with each other.

The general symptoms attending calculus in the bladder have been already enumerated, and therefore it is unnecessary to enter farther upon this subject; but it is evident that the calculus may consist of any one or more of the principles stated to enter into the different species enumerated. Therefore it will be necessary to make a few remarks upon each of these when in the bladder.

Description of the various forms of Blepharitis ; viz. the Mucous—Glandular—Ciliary—and Purulent of New-born Children.

Mucous Blepharitis.

Mucous blepharitis is the "conjunctivitis palpebralis" of authors. When the inflammation does not invade the entire conjunctiva, it shews itself under the form of regular or irregular patches, the colour of which varies between a deep and a pale red. In all cases, the principal symptoms are the following:—The patient at first feels a prickling sensation in the inflamed part. This sensation he compares to that which any extraneous body (such as sand, for instance) would produce, were it placed between the ocular conjunctiva and the internal surface of the eyelids. On evertng the palpebræ, you will perceive a great number of small vessels interlaced in every direction. The colour and size of these vessels are not uniformly the same. They appear gradually smaller as they approach the oculo-palpebral sinus; the redness also becomes less apparent as we recede from the free edge of the eyelid. Their mobility, the freedom with which they glide over the subjacent tissues, indicate clearly that they merely creep, as it were, along the surface of the mucous membrane. These three last characters must not be lost sight of; they will prove exceedingly useful towards establishing the diagnosis.

The functions of the eye are necessarily more or less modified by the inflammation. Generally the secretion of mucus is increased, and this, no doubt, is the reason why the Germans have given to this form of inflammation the name of "catarrhal blepharitis." I shall not, for the present, attempt to prove how futile are the grounds for such a denomination; I will merely observe, that I am perfectly at a loss to know why they should endeavour to render specific a symptom which we meet with in the most healthy patients, and which we can produce whenever we think proper. The mucus, generally clear and limpid, sometimes, however, of a grey purulent colour, is secreted in greater or less abundance, and accumulates in the

inner canthus of the eye. In some instances the mucous membrane, swollen and thickened, forms a kind of circular fold around the globe of the eye, thus constituting one of the varieties of chemosis.

Instead of increasing, the secretion from the conjunctiva may decrease, or even be entirely suppressed. When this is the case, the mucous surface becomes dry and shining, and we have what several authors have called "dry ophthalmia, or taraxis."

Such is the first and least severe form of blepharitis. Under judicious treatment, it is generally cured in five or six days, and left to itself, disappears in from ten to fifteen, providing, however, the cause be removed.

Glandular Blepharitis.

The seat of glandular blepharitis, as I have already stated, is in the Meibomian glands. Let us examine the symptoms, by which we may distinguish it from the other forms of inflammation.

The prickling sensation, already described, is but slightly felt, and that only towards the external part of the eyelid. The sensation itself is modified; it seems to the patient as if small grains of sand were adhering to the margin of that organ. The inner surface of the palpebræ does not present reticulated patches, as in the mucous form, but a kind of vascular band, extending transversely, close to the free edge, the convexity of which is directed towards the eye. The vascular band is peculiar, the vessels being fixed and immovable, and the redness gradually becoming more and more vivid as we approach the free margin of the eyelids. This appearance is at once accounted for, when we consider that the region presenting it is the principal seat of the inflammation. The most characteristic symptom, however, is the secretion from the Meibomian glands; this secretion, of a viscid nature and variable consistence, soon becomes concrete on exposure to the atmosphere, and collects between the cilia and the glandular edge. During sleep, when the eyelids are closed, the mucus hardens and glues them together in such a manner, as to render it nearly impossible for the patient to open his eyes, unless they have been previously moistened with warm water. If this precaution is neglected, some of the eyelashes are generally brought away by the efforts which are necessary, and this gives rise to small abscesses and ulcerations. The internal edge of the eyelid is nearly always rather swollen and prominent. Depending on the hypertrophy of the Meibomian glands, this slightly tumefied appearance of the inner margin will be detected at the first

glance by an experienced observer. There is neither photophobia nor epiphora, that is, when the glandular inflammation is unaccompanied by other forms of ophthalmia; indeed, although of more importance than mucous blepharitis, it is by no means a serious disease. It may exist during a lengthened period, and become even indefinite when not properly treated; this again may serve to distinguish it from the mucous form of inflammation. We must also keep in mind, when treating this affection, that the chronic form is extremely difficult to cure, and that, consequently, every effort should be made to get rid of the malady when still in the acute stage.

Sometimes the free edge of the vascular ribbon, which I have described as occupying the external part of the eyelid, becomes covered by a white concretion, of variable thickness. This constitutes the form I have designated under the name of diphtherial blepharitis. The nature of the affection is implied by the name I have given to it. The surface of this pseudomembranous layer occasionally presents small granulations of a silvery hue. This diphtherial appearance of the eyelids is worthy of attention, as it constitutes a most unfavourable complication. We may generally expect, when it occurs, the disease to prove long rebellious to the most judiciously directed treatment.

Granular Blepharitis.

Granular blepharitis has never been described by authors as a distinct form of inflammation; the granulations it presents having been merely looked upon by them as one of the consequences of catarrhal or purulent ophthalmia. It may, however, be met with both in the acute and chronic state, and easily recognised, the peculiar characters it presents rendering it nearly impossible to confound it with any other disease, once the attention has been directed to its existence. I cannot, indeed, see why the mucous follicles of the palpebral conjunctiva should not be subject to diseases of the same nature as the mucous follicles of similar membranes, as, for instance, those of the lining membrane of the intestinal canal. That the affection has its origin in the mucous follicles will, I think, be clearly demonstrated by the description of the disease; and I feel convinced that the enumeration of the symptoms will leave but little doubt in your minds respecting the seat of the inflammation.

On examining with care the conjunctiva, we find that it presents a great number of exceedingly small granulations. These granulations, from their arrangement, may

be compared to the papillæ of the tongue. At first they are perfectly distinct from one another; they soon, however, increase in number, and form a species of net-work extending over the entire mucous surface of the eyelid. On this granular net-work we also perceive a number of small vascular ramifications, of a pale red colour, interlacing each other in every direction. After a few days' duration, the vascular appearance sometimes disappears, the granulations alone persisting. When this is the case, we may conclude that the disease is assuming the chronic form. The patient suffers but little. The sensation of extraneous bodies between the eye and palpebræ is modified; it no longer appears to be caused by sand, as in mucous blepharitis, but by particles of finely pulverized dust. If the inflammation is severe the eyelids are generally more or less swollen; indeed, their volume may increase to such an extent as to conceal entirely the globe of the eye. When they present this appearance, we are often surprised on raising the eyelids to find the eye itself perfectly healthy. The disease may attack the upper or lower eyelid only, or both at the same time. When the upper eyelid is alone inflamed, and the inflammation is slight, it is not very easy to recognise the disease, owing to the difficulty experienced in raising the eyelid in such a manner as to examine it freely. This, however, may be attained by drawing the free margin of the eyelid towards the superciliary ridge, and then communicating to the tarsal cartilage a movement of *bascule*, whilst the patient is directed to look downward. There is scarcely any photophobia, and the secretion from the conjunctiva is not abundant.

This form of blepharitis resists with greater tenacity than any other the action of therapeutical agents; it is, indeed, exceedingly difficult, as we shall shortly see, to effect a cure.

Ciliary Blepharitis.

Ciliary blepharitis, known to surgical writers under the name of *psorophthalmia*, has been considered by some as a symptom of tinea. Such an opinion, however, is purely hypothetical, experience daily pointing out to us its fallacy. This disease is by no means rare, and must have become familiar to you, as we have continually cases in the wards on which you may study it. Although most authors have given but a short and imperfect description of this affection, it is, I assure you, worthy of all the attention you can bestow. Not only are its consequences often extremely disagreeable, when not well treated from the commencement, but

it may also give rise to nearly all the different inflammations of the eye. It is principally at the onset, when the symptoms are generally overlooked, that I should advise you to pay attention to this disease. At a later period, when the inflammation has existed for some time, it becomes extremely difficult to get rid of the complaint; indeed, it will often resist every means you may employ. In the first period there is merely slight itching and redness of the external edge of the eyelids. We have no sensation of an extraneous body, no photophobia or shedding of tears, nor are the natural functions of the eye in the least deranged; such are the forerunners of the malady. No one would suppose that this was the first stage of a disease which proves so rebellious to every species of treatment, and which may lead to most of the more serious affections of the eye. Generally, the persons thus affected pay no attention to these symptoms. Soon, however, the base of the cilia become covered with small yellowish scales, which the patient brings away on rubbing his eyes. These scales gradually become larger, more adherent, leaving behind them, when they fall, small ulcerations, on which there forms a thin incrustation. These incrustations are in their turn rubbed off, and are replaced each time by others. The small ulcerations furnish a kind of viscous, dark-coloured secretion, which adheres to the cilia, glueing them together in such a manner that several of the cilia uniting, form, as it were, small pencil brushes, giving to the eyelids a very peculiar appearance. If the disease be not then arrested, the cilia, whose roots are destroyed by the progress of the ulcerations, fall gradually, and the eye is sometimes entirely deprived of the protection they should afford. This state of the eyelids, as you may easily imagine, becomes a permanent cause of keratitis and conjunctivitis. The external edge of the margin of the eyelid is then of a dark red colour, and assumes a rounded, tumefied appearance. These are the symptoms ciliary blepharitis presents, when existing alone, without any complication. It is, however, generally combined with the glandular form of inflammation, and this combination gives rise to symptoms which vary according as the one or the other of the two affections predominates. When the inflammation of the ciliary glands is the more severe, the external free edge of the palpebræ being swollen, becomes slightly inverted, and the cilia are turned inwards, against the globe of the eye, thus constituting an entropion, which can only be cured by an operation. If, on the contrary, the inflammation of the Meibomian glands predominates, the

symptoms are reversed. It is then the internal free edge of the palpebræ which is swollen, and consequently more or less everted, the cilia are therefore directed outwards. The whole of the cilia will fall off occasionally, leaving a naked surface, in some instances nearly a quarter of an inch in width. It is not a rare occurrence to meet with old people, whose eyelids have been long inflamed, in this state.

Purulent Blepharitis of New-born Children.

This disease has been improperly confounded by ophthalmologists with purulent ophthalmia, properly so called. They describe three forms of purulent ophthalmia: ophthalmia of new-born children, Egyptian ophthalmia, and gonorrhæal ophthalmia. I cannot, however, admit this division. The Egyptian and gonorrhæal ophthalmia do not so much attack the palpebræ as the eye itself; whereas the purulent ophthalmia of children is mostly confined to these organs; nor is it only the part affected which varies in these diseases; the symptoms are also different, and the prognosis is much less unfavourable in the one than in the other two. I shall, therefore, for the present, confine myself to the description of purulent blepharitis, deferring that of the two other forms of purulent inflammation until treating of the eye itself.

Purulent blepharitis of new-born children has been thus called, from its generally attacking children within the first fortnight after birth. It, however, sometimes occurs several months or several years later. I have met with it, at La Pitie, in a child twelve years old.

The etiology of this affection is exceedingly obscure; and although, as I have already stated, I intend deferring the consideration of specific causes until the termination of these lectures, I shall on this occasion depart from the rule I have laid down. Some authors, looking upon the disease as contagious, attribute it to infection from the mother, whom they suppose to be labouring under gonorrhœa or leucorrhœa at the time of birth. Such an explanation of its production, if applied to every case, in my opinion is perfectly inadmissible. Do we not meet with many cases of purulent ophthalmia, although we cannot possibly entertain any suspicion respecting the health of the mother? Have we not already seen that children may be affected with this disease some years after birth? We should also bear in mind that when the child traverses the vagina, the palpebræ are closed, sometimes folded inwards, as it were, towards the eye, and consequently the mucous surface is protected from external agents.

Vitiation of the atmosphere, the aggregation of many individuals in the same

locality, bad living, uncleanness, &c. have been assigned as the causes of purulent blepharitis. They seem, indeed, well calculated to produce such an affection, but I can hardly admit that alone, they suffice to account, in every case, for its appearance. Do we not occasionally meet with this form of ophthalmia in the higher classes of society, although every law of hygiene has been observed. These considerations induce me to confess that in this, as in many other instances, the principal cause has hitherto eluded our observation.

Another question naturally presents itself to us. Are we to consider purulent blepharitis a contagious malady? The facts of which I am now in possession are not sufficiently numerous to authorize my giving a decided opinion on so important a subject. The disease is seen, it is true, in children who are not supposed to have been in communication with others similarly affected; but can we, in these instances, assert with confidence that no communication of any kind has really taken place? The subject deserves to be treated at length; but a serious examination of the different opinions which have been brought forward, would lead me too far. I shall, therefore, proceed to enumerate the symptoms which the disease presents.

The little patient seems at first to be inconvenienced by the light; the eyes are also evidently the seat of considerable formation, the child continually raising its hands to them. The free edges of the palpebræ are red, rather tumefied, covered by a thin layer of white glutinous matter, which unites and forms a kind of viscid mass in the inner angle of the eye. This is the first stage of the disease, and is the period in which the therapeutical agents that we possess against this complaint should be employed, in order to arrest its progress, which may yet be done. The practitioner must not, however, be deceived by the mildness of these premonitory symptoms. The inflammation soon attacks the palpebral conjunctiva, the secretion becoming, at the same time, more abundant. This secretion, at first liquid, transparent, and called by ophthalmologists *hydorrrhœa*, becomes of greater consistence in the course of a few days, and is then termed *phlegmatorrhœa*. At a later period it assumes a greenish hue, and, from its resemblance to pus, is called *pyorrhœa*. The palpebral conjunctiva now becomes considerably thickened. The eyelids are also tumefied, the upper eyelid covering the lower one, in such a manner as to render it nearly impossible to raise it. The tumefaction is sometimes very considerable, so much so that the eyelids

present the appearance of a large abscess. If you could see the inner surface, you would find it covered with granulations, which give it a fungus-like appearance. The purulent secretion, which flows copiously from the eyes, often produces considerable excoriation in the neighbouring parts. In the midst of these severe symptoms we are surprised to find that the eye is generally free from inflammation, and the cornea transparent. Indeed, it has been remarked by many surgical writers, that when the eye itself becomes inflamed, when there is purulent disorganization of the cornea, the patients are able to open their eyes; and that when, on the contrary, the eye remains healthy, the palpebræ are firmly applied to one another. Several attempts have been made to explain this circumstance. Might we not account for it by supposing that, in the first case, the cornea not allowing the rays of light to reach the retina, that membrane is no longer acted upon; whereas, when, on the other hand, the cornea remains transparent, the retina, from its increased sensibility, not being able to bear the impression of light, reacts on the muscles, which contract, and keep the eyelids in close apposition.

We have now examined the principal symptoms of the different forms of blepharitis. You must not however suppose, from my having described separately each of these forms, that they are always found isolated, perfectly distinct one from another. At the commencement, they often exist separately, but at a later period they are generally combined. Indeed, when we consider how limited is the seat of inflammation, we must acknowledge that it can hardly be otherwise. You will often meet with the mucous, the glandular, and the granular forms in the same patient. Ciliary blepharitis, when it has existed some time, is nearly always accompanied with inflammation of the Meibomian glands.

These diseases may also lead to local affections extremely annoying to the patient; they may even become the causes of much more serious forms of ophthalmia. Ciliary blepharitis, as we have already stated, is frequently followed, when of long duration, by the loss of the cilia; and their absence, besides disfiguring the patient, is a permanent cause of inflammation. Glandular blepharitis gives rise to the small tumors we often observe on the free margin of the eyelids—such as the hordeolum and the various kinds of cysts.

Granular blepharitis keeps up a permanent state of chronic inflammation of the cornea, and, when it presents the fungus-like appearance I have described, sometimes leads to different degenerations of

the eyelids. Even mucous blepharitis, the mildest of these affections, may invade the ocular conjunctiva, and give rise to conjunctivitis, properly so called.

GLEANINGS FROM THE NOTE-BOOK

OF A YOUNG PHYSICIAN IN ITALY.

[For the *Medical Gazette*.]

WALKING one morning in the Largo di Santa Brigida, at Naples, my attention was arrested by a miserable looking wretch across the way, in rags and tatters, who lay on the ground convulsed to all appearance in the agony of epilepsy. The distorted limb, the foaming mouth, and seeming physical distress of the countenance; every feature, indeed, of this inexplicable and mysterious disease was here painfully and faithfully portrayed; so I crossed the road in the hope of seeing her safely provided for, even should I be unable in my professional capacity to serve her. I was struck at once by the very little sympathy she met with from the surrounding crowd, not a few of whom were even diverting themselves with her affliction. But the fact was, mine heroine had cried "wolf" too often, and was no stranger to her own order. Whilst absorbed by a mingled feeling of pity and indignation busy within me, the sound of an approaching carriage drew off the attention of the crowd, who made way for it to pass. But judge of my astonishment, when I beheld the object of my commiseration released from the reins of her disease, and foremost in the ranks of the retreating multitude. I stood still myself, dumb-founded at what I beheld, and scarcely able to accredit the testimony of my own eyes. But, sure enough, there stood the fact stark naked before me, and there stood I also, now wholly alone, the dupe of my own sympathy and humanity; so I moved on my way, to muse on the depravity of human nature, feeling the force of what Juvenal, in one of his Satires, says of some people or other—"The nation is a company of players;" and of impostors, too, he might have added, if speaking of the Italians. I certainly had gained no-

thing in the matter—not even the poor consolation of a little gratitude.

Nothing can show in a stronger light the viciousness of the people, and the weakness of the government, than the regular system of wholesale imposture practised in different ways amongst the populace, and under the very nose of their sovereign, who, by the way, is the greatest impostor of all. But when public spirit is extinct, and the people feel no interest in the preservation of morality, there is no longer any security for the fidelity of individuals, and too little encouragement to be virtuous.

Now, another species of impostor—the members of that family in Italy (the father of which, in great humility, denominates himself the immediate representative of our blessed Saviour upon earth)—is the priesthood. The influence of this body over the treatment of the sick is not less extensive than it is pernicious. I was asked one day by the parents of a poor girl living hard by my hotel, to visit their child, who was ill of a fever. I accompanied them to their miserable cabin, and found their daughter far advanced in the worst form of typhus, but still, as I believed, not hopelessly beyond the reach of our art. I prescribed for her accordingly, laying down very strict injunctions to be followed in my absence, and promised to return in the evening. Some six or seven hours afterwards I visited the sick house again; but was surprised to find no part of my treatment had been enforced, whilst the unhappy girl was now *in articulo mortis*. As I had not intruded any advice, but been expressly solicited to attend their child, this conduct on the part of the parents seemed at first sufficiently unaccountable. Another moment, and the film grew less dim on my mind's eye. I had scarcely beheld at first the greasy figure of a priest in the room, intent as I was upon my dying patient. Regardless of the presence of a stranger, this holy man advanced at the same time with myself to the bed-side of the girl, and, inquiring if his medicine had been administered, unfolded a paper containing a black salve, a minute portion of which, with homœopathic sagacity, he placed on her tongue, and turning round to the parents, commenced an intemperate harangue against the abomination they had been guilty of in seeking assistance from a heretic, (as

every Catholic is in the habit of considering the poor Protestants, (who would be sure to administer poison in place of balm to their ills. I did not remain to be further edified by the "say" of this preacher of the gospel; nor did I attempt the herculean task of disentangling their minds from the thralldom they had been brought under by their priest, whose influence I well knew no lay ingenuity of mine could oppose. And, then, the dark curtain of futurity was about to close for ever over the last act of life's great tragi-comedy.

Notwithstanding the little encouragement I had met with in this instance, I still "bore it with a patient shrug," and set out the same evening, at the urgent request of my servant, to play the good Samaritan a second time. My patient was a young married woman, and happened to live not only in the same street, but also immediately opposite the abode of the last. I found her labouring under a low form of delirium, which had made its appearance somewhat suddenly, and without any very manifest cause to explain its origin. A closer insight into her history inclined me to look further for an explanation; so that I was presently able to refer every existing symptom to a neglect of the use of the catheter, her husband confirming the manifest diagnosis I had made, by informing me that the bladder had not been evacuated for upwards of eleven days. I explained all this to her attendants in a very few words, described the facility with which I should be able to remedy the evil and restore her to health, and, in short, infused apparent joy into the hearts of all around. But the devil was "up and doing"—bestirring himself to defeat the good work I had intended. One short five minutes I was necessarily absent, in search of the instrument, and on returning to the house, desecrated a priest again preoccupying my place, and superintending my work. I know not whether he may have been invited, or conducted hither by accident; but, be this as it may, I was received by these poor dupes of bigotry and ignorance with manifest symptoms of distrust and repugnance, whilst every effort I employed to prevail on them not to sacrifice their relative to the interested insinuations of the wretch before me was unavailing, and the husband resolutely refused any further interference

at my hands. I need not say a word in explanation of all this. The populace live in the utmost thralldom of body as well as mind; and whilst priest-ridden to a frightful degree, entertain so much reverence as well as fear for their powerful enslavers, that the artful machinations of the latter penetrate unopposed into their minds and understandings, and exercise a lasting influence over them. I represented, therefore, in peremptory terms, the certain fatality that awaited a neglect of the means I had recommended for her relief, and withdrew from the spot. I know not what followed; but samtering by the door next day at noon, I saw the bodies of both my patients occupying the centre of their respective homes, now no longer warmed by the breath of life, but arranged in the vain pomp and trumpery gewgawism which are the constant attendants of a Catholic funeral, howsoever humble in life may have been the deceased. The doors of both these houses of affliction were wide open, and occupied by children and beggars, crowding forward to witness the scene within. There was no material difference in either. In the interior of both all was still and subdued—

"An atmosphere without a breath—
A silence sleeping there;"

save that, at intervals, a suppressed and long-drawn sigh of latent anguish broke upon the eye rather than on the ear, so slight and gentle—so very slight, that

"Nothing lived 'twixt it and silence."

The members and friends of the family sat somewhat formally round the interior of the room, gazing fixedly at vacuity, and to all appearance dead to the uproar and curiosity of those who crowded round the door. The body lay at full length in the centre of the apartment, its face uncovered and bestrewed with flowers, whilst a row of five or six long wax-tapers, arranged in a line with the feet, threw out their cheerless illumination over the scene. The indifference with which the Italians regard the actual interment of their dead, when once removed from the place of mourning, is strangely contrasted with the anxiety they feel for a display of pomp and raree-show prior to the surrender of the body into the hands of those whose business it is to bury it. For the indulgence of this national feeling the mean-

est wretch in Italy contributes during his lifetime the sum of a few *grana*, or half-pence, monthly, towards a fund set apart for the provision of such paraphernalia as are deemed indispensable on those occasions. The description given by Matthews, in his beautiful Diary of an Invalid, of the funeral ceremony I am speaking of, is so faithful to the reality, and so correct an account of what I beheld on this occasion, that I cannot do better, perhaps, than give his own account of it:—"In my way home I met a funeral ceremony. A crucifix hung with black, followed by a train of priests with lighted tapers in their hands, headed the procession. Then came a troop of figures dressed in white robes, with their faces covered with masks of the same materials: the bier followed;" [Dr. Matthews might have explained, for the benefit of those who may not have witnessed such a scene, that this bier is the principal attraction in the train. It is an elegant-looking mausoleum, supported on purple velvet, richly carved in itself, and ornamented at every point with massive gilding. On this the body is usually exposed more or less naked] "on which lay the corpse of a young woman, arrayed in all the ornaments of dress, with her face exposed, where the bloom of life yet lingered. The members of different fraternities followed the bier, dressed in the robes of their orders, and all masked. They carried lighted tapers in their hands" (which are of wax, about four feet in length, and not thicker than one's ring finger), "and chaunted out prayers in a sort of mumbling recitative. I followed the train to the church, for I had doubts whether the beautiful figure I had seen on the bier was not a figure of wax; but I was soon convinced it was indeed the corpse of a fellow-creature, cut off in the pride and bloom of youthful maiden beauty. Such is the Italian mode of conducting the last scene of the tragi-comedy of life. As soon as a person dies, the relations leave the house, and fly to bury themselves and their griefs in some other retirement. The care of the funeral devolves on one of the fraternities, which are associated for this purpose in every parish. These are dressed in a sort of domino and hood, which, having holes for the eyes, answers the purpose of a mask, and completely conceals the face. The funeral of the very poorest is thus

conducted, with quite as much ceremony as need be." After this point in the mournful ceremony, the Italians are wholly indifferent as to the disposal of the body itself, which they regard "as no more a part of the departed spirit than the clothes which it has left behind." It is surely a comfortable religion which can instil this sort of feeling into the mind—which assures us that our departed brother or sister has been transported at once into a place of eternal happiness, there to continue whilst an occasional mass is offered up for his soul.

As soon as the funeral service is concluded, the corpse is stripped, and consigned to those who have the care of the interment. Those who can afford it, or whose condition requires it, are deposited in vaults, erected in the churches for the reception of the dead, being previously laid in a wooden shell before they are cast into these Golgothas. But how fares it at Naples with the people, strictly so speaking—the great bulk of the population? After this fashion: at the still hour of night, when nature is reposing from her labours, and the city at large in a deep slumber, the "dead carts" parade the streets, to pick up at the different chapels the bodies which have been deposited there during the day. Into these they are tossed indiscriminately, "heads and tails," men, women, and children, most of them in general without a rag to cover them. As soon as the churches have vomited forth their contents, the dead carts move off slowly towards the Campo Santo, the public cemetery of Naples, a spot which lies two miles without the city, on the brow of a hill skirting the road to Capua. So I joined in the wake of this interesting freight, and followed the dead to their home.

The Campo Santo is a quadrangular space, inclosed within four white walls of considerable height. The area is clean and well paved, and subdivided into three hundred and sixty-five compartments, signalized by square slabs of stone, into the centre of each of which a heavy iron ring is inserted. And here the dead carts brought up at length, wheeling heavily over the pavement, until they arrived at the particular pit to be opened. I need not mention what is now pretty generally well known, that each of the square stones above mentioned is the roof of as many vaults

or pits, one of which is opened afresh every day in the year, for the reception of that day's dead. The men in attendance fixing now a moveable lever into the ring in the stone, raised up this superstructure, and exposed the hidden secrets of its interior. As a year had elapsed since it had been opened, there was only to be seen a mass of corruption and decomposition, from which an intolerable effluvia burst forth to tell the tale of what poor human nature must come to. The carts having been brought to the extreme brink of the vault, the head-pin was removed, the tail-board displaced, and all that was left of "the weary and the wicked" hurled without compunction into the deep abyss beneath. Some slack lime was then thrown in, the slab replaced, and would be cemented up on the following day, to continue untouched till the following year. Adjoining this lay the pit in which the dead of the preceding night were entombed. The *custode* of the place obligingly opened it at my request, when I beheld the outline of the bodies which had been deposited there the day before. The moon peered down in liquid splendour on the revolting spectacle, and exposed about thirty carcases to my eye. Uppermost lay a dead infant, half concealed by the head of a woman that rested on it. The latter was without shroud, and had been young—perhaps, too, beautiful. Her hair depended over her bosom in matted tresses of gore; whilst the arm of one side appeared, from the unnatural position it maintained, to have been completely dislocated or broken, the effect, perhaps, of some violence done it during the savage mode adopted for interment. Somewhat more in the background, my eye encountered a couple of bodies, evidently brought hither from the dissecting-rooms, the arm of one bearing evidence of recent amputation, whilst the decapitated trunk left no doubt on the subject. The other was not less mutilated; the limbs were variously disfigured in the line of the great arteries, which had probably been "taken up" by the students of one of the schools in the city.

I have indulged in no exaggeration in the above picture—added no superfluous varnish to the tale—plain and unadulterated it stands to speak for itself, and to speak to the sympathies of the world. Can the conception of man

conjure up aught more revolting, more indecent, more humiliating, than such a consummation. For man—I should particularize, perhaps, my fellow-countryman—in whose breast there always resides a prejudice, is sensitively alive to every circumstance which can tend to rob him of the least portion of those little household comforts and attentions which he lavishes on the dead body of what he has loved. They are called—perhaps they are—weaknesses here; but they are weaknesses incident to humanity. What was the elegant and gentle Matthews about when he could extol this state of things? Not, I believe, that he was in love with their mode of interring their dead; but with their advantage over us in the indifference they are able to feel about the real value belonging to the body after death. It reminds me of what a famous critic has said on the sentimentality of poor Sterne—"That a dead donkey was of more consequence in his eyes than an indigent mother." Hear, too, how the classic Eustace delivers himself on the subject of Neapolitan interment. We find him positively enamoured of this foul charnel-house—this Campo Santo! "It stands," says he, "on a rising ground, and the road that winds up the hill to it is lined with cypresses. A vault is opened every day in the year, and the bodies to be interred deposited in order. All is done gratis, and the expenses requisite supplied by public charity. It is to be regretted that this method of burying the dead has not been adopted in every hospital and parish in Naples, and indeed in every town and city, not in Italy only, but all over Europe." "It would be difficult to discover one single argument, drawn either from the principles of religion, or the dictates of reason, in its favour" (*i.e.* in favour of *our* mode of burial), "while its inconveniences and mischiefs are visible, and almost tangible." I am willing to believe the distinguished writer, whose words I have here quoted, had not familiarized himself with the details of the history of the Campo Santo; certain it is, he could not have witnessed such a spectacle as I have described above.

"The disposal of the dead (says a beautiful writer) is as true a test of civilization in a community as the social relations of the living;" and I am sure that much of a people is learnt from

this. Not that I pretend to decide whether an Englishman loves his father and mother better than other nations do, because more decency is observed in their funerals. "One" the oldest illustrations (I quote, I think, from Bulwer) of national prejudice, is to be found in Herodotus: the Greeks, in the habit of burning their fathers, were wonderfully indignant at the barbarity of the Callatii, who were accustomed to eat them. The Persian king summons the Callatii before him, in the presence of the Greeks. 'You eat your fathers and mothers; a most excellent practice!—pray, for what sum will you burn them?' The Callatii were exceedingly disgusted at the request. The Callatian and the Greek experienced filial affection in an equal degree; but the man who made a dinner of his father would have considered it the height of atrocity to have made a bonfire of him."

How different this Italian mode of burial from almost every other—even from their own, of remoter ages; for we read of a certain Roman emperor having spent a fortune and a life time in the erection of a pavilion of eastern splendour, for the reception of his body after death. The attention of the Egyptians to their dead is strongly contrasted with this modern feeling in Italy; although it is certainly offered, in explanation of their disposal of the body, that they believed the soul to live as long as the former continued undissolved, and therefore tried this method of embalming to elude death: and yet the Italians have the greatest and most touching philosopher that ever lived on their side here, contending for the utter worthlessness of "this vile body" after death, and hallowing, by his own example, a form of interment which dogs would turn cravens at, could they know such were destined for them.

"It concerns me not," says Socrates to Crito, "what is done with me when I am dead; *facilis jactura sepulcri*: I care not, so long as I feel it not. Let them set mine head on the peak of Teneriffa, and my quarters in the four parts of the world,

— 'cælotegetur qui non habet urnam;'
the canopy of heaven covers him that hath no tomb."

FATAL CASES

OF

OBSTRUCTION AND ENORMOUS DISTENSION OF THE BELLY,

Arising from a peculiar Conformation of the Colon.

BY ANDREW BUCHANAN, M.D.,

President of the Glasgow Medical Society*, and one of the Senior Surgeons to the Glasgow Royal Infirmary.

[For the London Medical Gazette.]

I PROPOSE, here, to lay before you some observations upon a very rare disease, of which it has been my fortune to meet with three cases. This disease is attended with symptoms which are quite peculiar and distinctive. It produces as much acute suffering as any of the most formidable diseases to which the human species is subject; and, notwithstanding the most powerful means employed to arrest its progress, it has invariably gone on to a fatal termination. It is, farther, interesting to the medical inquirer, from being a disease not generally known, and of which the true nature has not, as appears to me, been hitherto understood.

It will be seen, from the remarks which follow, that the disease in question is always attended with, and, according to my view, is necessarily dependent upon, a peculiar primordial formation of the colon, which, to avoid interruption hereafter, I shall commence by describing.

The colon is more subject than any other part of the intestinal canal to vary in length and in mode of disposition; or, which comprehends both, in the course which it follows through the abdomen. Upwards of twenty examples of such variations will be found recorded in the works of Morgagni. The most common of these variations is that observed in the transverse arch of the colon, which, instead of running straight from right to left, immediately under the liver and stomach, is incurvated downwards, so as to reach the umbilicus†, or even the urinary bladder‡. Morgagni has recorded an example of the right colon not running

* Read before the Society, 6th Nov. 1838.

† Morgagni de Sedibus et Causis Morborum, Epist. xxxiv. art. 2, 3; iv. 16, 30; xix 19; xx. 16; xxi. 33, 35; xxix. 12; xlviii. 3s; lii. 12; lix. 12; lxii. 7, lxx. 7.

‡ Id., xvi. 8; xxxiv. 2; lvii. 12.

straight from the iliac to the hypochondriac region, as it usually does, but instead, being so much inflected that the cæcum was in contact with the transverse arch of the colon under the liver*. The same author likewise describes a case in which the colon, after observing its usual course as far as the stomach, passed thence right down to the sacrum, in front of the small bowels†. A case will be narrated hereafter, in which the colon, after arriving by the usual route at the left kidney, passed thence to the umbilicus, and from that point right downward, between the tract of the recti muscles, to terminate in the rectum. A double variation in the course of the colon was, in one instance, observed by Morgagni, the transverse arch being inflected downwards; and, further, the left colon, after reaching the kidney, returning to the left hypochondrium, and passing thence obliquely towards the sacrum‡. Instances are not unfrequent of the sigmoid portion of the colon deviating from its usual course. It sometimes passes from the left groin across the fundus of the bladder to the right groin, and thence ascending and turning to the left, it goes over the top of the sacrum to form the rectum§. This is, indeed, described by Glisson as the usual course of this portion of the colon||. A case is described by Morgagni, in which the sigmoid flexure of the colon lay almost completely in the umbilical region of the abdomen¶.

These examples are here adduced, not merely to show how much the colon is liable to vary in its course, but because a knowledge of such varieties is of high importance to the physician, who, if ignorant of them, would, as has been remarked by Morgagni, be apt to fall into error in estimating the seat of many affections of the intestines. There is, however, only one of the varieties enumerated above which has been known to produce a disease at all analogous to that which I am about to describe.

The only variety of conformation in the colon which remains to be men-

tioned, is of the same kind as the two last enumerated; but I have kept it separate, from its constituting the most common predisponent cause of the disease to be here treated of. That it is a rare variety must be obvious from the circumstance of its having escaped the diligent research of Morgagni*. While, however, it is very rare in Italy, it may probably be much more common among the inhabitants of the British isles: at all events, within a period of little more than seventeen years, seven examples of this variety of conformation have been observed in Scotland; five of them in Glasgow, and two in Edinburgh; but the individuals in whom they were observed were not all natives of Scotland. Of these seven cases, I have myself seen four. The first I saw was in the year 1819; but in it, and in the two next cases which occurred to me, the peculiar disease arising from this formation of the colon had been induced, and I shall not, therefore, anticipate the history of them. In the spring of the year 1832, in examining the body of a patient who died of cholera, I met with an example of the same formation of the colon, which had not excited any similar disease.

A case of exactly the same kind occurred to Dr. Hunter, Andersonian Professor of Anatomy, in 1831†. The colon observed its usual course as far as the left groin, when it again ascended as high as the transverse arch immediately under the liver, and then, turning to the right side, it descended into the pelvis. This was exactly the disposition of parts observed by myself, in the case occurring in 1832; and, in both of these cases, it is worthy of remark that the colon entered the pelvis upon the right side of that cavity. In other cases, however, as will be seen hereafter, the colon descended into the pelvis, as usual, over the promontory of the sacrum; and, in one very remarkable case, the colon, crossing from the left to the right groin, ascended parallel to the right colon, and then, turning to the left, descended near the mesial line of the body into the pelvis.

The following more particular account of the form and connections of the colon in the patient carried off by cholera, I extract from my note-book, where

it has for title, "Anomalous Distribution of the Sigmoid Flexure of the Colon." The sigmoid flexure of the colon, instead of lying in the left iliac region, and having its meso-colon attached to the left side of the pelvis, stretched obliquely across in front of the small bowels, in the direction of and nearly as high as the gall-bladder. It then turned so as to form an acute angle, and, passing down parallel to the ascending colon, it entered the pelvis on the right side to form the rectum. Where the colon entered the pelvis, it was attached to the right side of that cavity by a fold of the peritoneum, exactly as is usually seen on the opposite side: the remaining portion of it was kept *in situ* by a very unusual attachment, the omentum supplying the place of meso-colon. The left side of the omentum lay free, as usual, on the surface of the small bowels; but the part arising from the right half of the transverse arch, and also that coming from the right colon, embraced the contiguous portion of the sigmoid flexure, and, descending from its inferior edge, terminated, by a well-defined margin, at the brim of the pelvis. In consequence of this disposition of parts, the omentum did not admit of being lifted up, as usual, except on the left side; its attachment to the sigmoid flexure prevented it from being raised on the right side, but the hand could be passed between these parts and the small bowels, showing that there was no adhesion of any kind between them.

Of the deviations from the usual conformation of the colon described above, those occurring at the proximal or middle portions of the intestine do not appear to be productive of any disease or inconvenience to the individuals so constituted*. On the other hand, the deviations which occur at the distal extremity of the colon have been, in several instances, found to accompany a very severe disease, which, so far as I know, has never been observed when the colon was of the usual conformation, and of which, therefore, the abnormal conformation of the colon must be considered as most probably the cause. Of this disease, the first example which I had an opportunity of witnessing occurred in the spring of 1819, and was treated by Dr. Andrew Duncan, jun., in the clini-

cal wards of the Edinburgh Infirmary. The next case occurred about two years afterwards, at the Glasgow Infirmary, where I was, at the time, house-surgeon. This case, in the absence of the attending physician, was chiefly treated by Dr. Lawrie, then one of the physician's clerks. The third, and only other case which I have seen, came under my own care in the year 1825.

In all of these cases I believe the disease to have been essentially the same; the leading symptoms and appearances on dissection, being very little different, although, as will be seen hereafter, there is some room for difference of opinion as to the precise mode in which the disease originated.

In attempting to sketch the history of this affection, I shall chiefly refer to the case last-mentioned; as I am more intimately acquainted with it than with the other two, in consequence of my having attended the patient during the whole course of his complaint, and examined his body after death.

James Connel, apparently from forty to fifty years of age, residing in Stockwell Street, came under my care towards the end of June 1825. He had been long subject to constipation of the bowels, but never to such a degree as to injure his health, which had been tolerably good. For some time previous to my seeing him, his bowels had been more confined than usual, and he had been troubled with flatulency and swelling of the belly. On examining the belly, I found it to be very much distended, and the swelling had all the characters of tympanites, being soft, elastic, and resounding on percussion. His pulse was not affected, and he complained only of the uneasy sensation occasioned by the flatulent distention of the belly. He was ordered a dose of calomel and jalap, which produced no effect. Castor oil, Epsom salts, senna, aloes, colocynth, scammony, and elaterium, were all tried successively, or in combination, but all to no purpose; not a particle of *fæces*, nor any flatus, was discharged. Injections, both simple and medicated, were alike unavailing. Among the latter employed were a strong solution of sulphate of magnesia, in an infusion of senna, and a solution containing six grains of tartar emetic. Not the least difficulty was experienced in throwing up the injections, but they came away, either im-

* Morgagni, Advers. iii. Animad. 14.

mediately or soon after, without any admixture of feces. On examining the rectum, it was found quite empty, as far up as the finger could reach, and very large in diameter. The patient's friends, of their own accord, introduced a common candle into the fundament, and pushed it as high up as they could get it to go; but not the least relief was procured from it. Meanwhile, the swelling of the belly went on increasing, till it was truly terrible to behold, being carried seemingly to the utmost possible point which the animal tissues could endure, without actually giving way. In this miserable condition the patient lay on his back, with his legs bent, and his knees drawn up, to avoid all stretching of the integuments of the abdomen. The only other posture he could endure was resting on his knees and elbows. When questioned, he complained only of the violent stretching of his belly, the pain of which seemed to swallow up all other feelings. His mental faculties continued unimpaired to the last. The respiration was slow, and as if impeded, most probably from the elevation and immobility of the diaphragm. His pulse was slow, and with a full steady beat. These characters of the pulse continued the last time I visited him, the day before his death, which took place about eight days from the time I first saw him, and about twelve from the last evacuation of his bowels.

The body was examined the day after the patient's death. On opening the cavity of the abdomen, the colon, enormously distended, and occupying an unusual situation, was the first, and indeed the only object which presented itself, all the other viscera being concealed behind its convolutions. Four immense bags were seen running nearly parallel to each other, and in the direction of the length of the body; while another similar one ran, at right angles to them, at the upper ends. So extraordinary was this appearance, that, notwithstanding my having seen two similar cases previously, it was only after tracing the colon from end to end that I became satisfied that I had, as yet, seen no other part of the intestines. The colon observed its usual course, till it reached the left iliac region, when it made a sweep to the right, passing behind the pubis, and returning across the lowermost lumbar vertebrae; it then

ascended, till it came in contact with the transverse arch, when, turning to the right, it descended to the sacrum; thus forming the two middle bags above described. Every part of the intestine was greatly enlarged in diameter, but the enlargement was greatest at its lower end, where it was not less than from five to six inches in diameter. The upper part of the colon contained chiefly wind, the lower part only feces of a yellowish white colour, and of the consistency of very soft mortar. On lifting up the folds of the colon, the small bowels were found inflated to the utmost: the stomach was empty, and of its usual size. There was no effusion of fluid in the cavity of the abdomen, and the peritoneal covering of the bowels exhibited no traces of inflammation, although there was a good deal of engorgement in the veins of the mesentery. The prostrate gland was much enlarged, and the dilated neck of the bladder contained upwards of twenty small angular calculi, consisting of uric acid.

It will naturally be asked, whether the examination of the body did not afford any explanation of the obstruction of the bowels? This subject I have deferred to the last, both on account of its importance, and because the obstruction in this case was ascertained to proceed from a cause quite different from that which has been assigned for it in all the other cases of this disease upon record.

In all these cases it was supposed that the obstruction proceeded from a twist of the colon, at the lower end of of its sigmoid flexure. In the present case there was no twist, but there was a cause of obstruction more powerful than if the intestine had been (which I believe to be impossible) twisted completely round. To understand the nature of this obstruction, it is necessary to call to mind the description of the colon given above. After leaving the left iliac region, the colon crossed the mesial line of the body, behind the pubis: immediately returning, it ascended on the left side as high as the transverse arch, and then it descended on the right side, keeping in front of the inflated small intestines, till it turned back over the promontory of the sacrum, to be bound down to the anterior surface of that bone by the peritoneum. Now, just at the point where it turned backward, and was most pressed upon by the in-

flated small bowels from behind, it was crossed in front by the beginning of the ascending portion of its own sigmoid flexure. This last part of the intestine was very heavy; the whole lower part of the colon being, as stated above, filled with feces, and containing nothing else. The infarction commenced somewhat below the middle of the descending colon, and extended to within three or four inches from the end of the sigmoid flexure, farther down than which the gut was completely empty. Now, what was it that arrested the descent of the feces at this point? It obviously was the compression of the lower end of the colon, between one of its own massy convolutions passing it in front, and the distended small intestines and inferior end of the vertebral column lying behind it. The compression was exactly of the same kind as though the gut had been pressed in a vice, or between two fingers placed parallel to each other, one before it, and the other behind. At the compressed part the two sides of the intestine were in contact; immediately below, it was quite empty; immediately above, it was more than five inches in diameter, and gorged with feces; and, on lifting up the anterior compressing portion, it left the mark of a quarter of a circle impressed upon the soft feculent mass in the portion behind. This quadrant was exactly the measure of the distance between the completely distended and the collapsed part of the intestine. It was this remarkable impression upon the end of the colon that first attracted my attention, and, by leading me to examine how it was produced, discovered clearly the cause of the obstruction.

In the case which occurred while I was a student in the clinical wards of the Edinburgh Infirmary, in May 1819, the patient was a female, forty years of age. She had been long previously of a costive habit of body. During nine days preceding her admission to the hospital, nothing had been passed through her bowels, and the obstruction continued complete till her death, five days afterwards, notwithstanding the administration of the most powerful cathartics and injections. As in the case last detailed, no difficulty was experienced in throwing up the injections, and, on examining the rectum with the finger, it was found quite empty and unobstructed. The abdomen was dis-

tended to the uttermost, and the seat of a constant and most distressing pain: the swelling was of the tympanitic kind. The sufferings of the patient were much increased by whatever posture put the parietes of the abdomen upon the stretch, and some relief was obtained by relaxing them.

The appearances after death were very similar to those described above. The colon was enormously dilated, and so disposed as to conceal all the other abdominal viscera behind its convolutions. It exhibited two deviations from its normal course. As, in the last case, after reaching the iliac region, it ascended as high as the transverse arch, and, turning to the right, descended nearly in the middle of the belly to form the rectum: this was the portion of the intestine most dilated. The other deviation consisted in an incurvation downward of the right half of the transverse arch. What added much to these remarkable appearances was, that the colon was in many places of a green colour, like the surface of stagnant water, owing, as was conjectured, to the contents of the intestine being visible through its attenuated coats. About a pound of sanguinolent serum was found in the peritoneal cavity, and there were marks of inflammation both on the large and small bowels. At the termination of the colon in the rectum, the intestine was observed by Dr. Duncan to be twisted from left to right, and this he supposed to be the cause of the obstruction of the bowels.

Of this case an account has been published, with permission of Dr. Duncan, in the 16th volume of the *Edinburgh Medical and Surgical Journal*, p. 384. To that account I am indebted for some of the particulars stated above.

The last case of this disease, of which, as above-mentioned, I can speak from my own observation, occurred in the Glasgow Royal Infirmary in the year 1820 or 1821. I am unable to give the date with precision, having myself preserved no notes of the case; and, although Dr. Lawrie was kind enough to cause a diligent search to be made for the hospital journal, in which the history of it is recorded, his efforts were unsuccessful. The patient was a man of the name of Graham. His bowels had been in a state of obstinate constipation for some time before his admission into the hospital; the most powerful purgatives

produced no effect in moving them: injections, and every other means which Dr. Lawrie could devise, were alike unavailing. Of these means, one deserves more particular mention, from its being singularly well adapted to the treatment of cases of this kind, and because it was many years afterwards brought forward as a new discovery in practical medicine. An œsophagus tube was introduced into the rectum as far up as it could be passed, and along this tube injections were thrown into the bowels, but no discharge of feces followed. The patient died after being in the hospital about eight days, and having suffered terribly from the pain in his belly, which was tympanitic, and distended to the utmost degree.

The dissection was performed by Dr. Lawrie and myself, assisted by our common friend, Mr. Robert Smith, then apothecary to the infirmary. We found the colon much dilated along its whole extent, and more especially towards its lower end. The sigmoid flexure exhibited the same abnormal formation as in the two preceding cases, being much longer than usual, and lying chiefly in the umbilical region of the belly, in front of the small bowels, having its ascending portion on the left side, and its descending portion on the right. The only cause of the obstruction of the bowels which we could discover was a twist or rather fold of the intestine to one side, where the colon terminates in the rectum. I did not feel satisfied of the adequacy of this cause to produce the effect ascribed to it, but I could discover none other. The small bowels were much inflated; there were no traces of peritoneal inflammation.

[To be concluded in our next.]

SUSPENDED ANIMATION IN STILL-BORN CHILDREN.

To the Editor of the Medical Gazette.

SIR,

IN the year 1818, I published in the Edinburgh Medical and Surgical Journal some cases of suspended animation in still-born children, in which success had attended a long-continued perseverance in the process of artificial respiration. The impression produced upon my mind by those cases has never

been lost: I have, in every instance which has since occurred to me, used vigorous efforts to save still-born children, and in many cases I have had the gratification of success; but I have never before met with a case quite so striking as that which induces me to trouble you with this communication, and which occurred in my practice but a few days ago.

I think it has happened in all my former cases that I have been present at the birth of the child, and the process of artificially inflating the lungs has been commenced immediately; but, in the present case, the expulsion of a still-born child was rapid, and almost instantaneous. It happened at two o'clock A. M., when I was at home, and in bed; and the nurse stated, that before the servant who was sent to call me had left the house, to her great consternation the baby was born. I took no particular notice of the exact time it took me to get up, dress myself, and arrive at the house, but I think it must have been at least from a quarter of an hour to twenty minutes. I found a still-born child, and was informed that there had been no crying, nor any sign of breathing whatever. It appeared that death had been occasioned by a faulty position of the funis; it had encircled both the neck and body of the child; the former the nurse had with some difficulty removed, but the twist round the body was so tight that she could not undo it. The body of the child did not present the slightest appearance of life, and I thought the prospect of restoration was feeble in the extreme. It was right, however, to attempt it. Having set the funis at liberty, I hastily wiped the child's mouth, and at once began breathing into its lungs. I have various tubes for this purpose, but I never use any one of them: I find, or at least fancy, that nothing is so efficacious as my own mouth, and for this purpose I usually have with me a bit of leno or coarse muslin to place over the child's mouth to render the work a little less disagreeable. I continued breathing, with the child in this situation, for a minute or two, and then, observing the funis quite cold and collapsed, I hastily separated it, got the child into hot water, and gave myself a more convenient and agreeable situation for continuing the process. It seemed un-

fortunate that I was twice obliged to leave my baby, though but for a moment, on behalf of her mother, as my patient at her last confinement, after a favourable expulsion of the child, had very nearly lost her life from flooding, caused by the retention of a portion of the placenta in an hour-glass contraction of the uterus, in consequence of which the utmost anxiety had affected the minds of herself and her friends respecting the present labour. I was, therefore, twice obliged to attend to the placenta, and endeavour to satisfy her mind, that although it was not come away, all was perfectly safe. I am accustomed to keep the baby up to its chin in hot water, if the vessel will admit of it; if not, I cover the upper part of the body with flannels kept continually hot and wet with the water. I support the head with my left hand, and compress the chest after each inflation of the lungs with my right hand, employing an attendant to hold the child's nose, if I find it necessary. In about ten minutes a very faint sob or slight attempt at inspiration took place, and shortly after this I found a feeble pulsation of the heart. The process was now persevered in with the pleasing assurance of success, and at the end of about twenty or five-and-twenty minutes there was sufficient respiration to admit of my service being discontinued. It was an hour or two after this before the child made any attempt to cry, and still longer before the hands and feet had a proper warm circulation. Of course I did not wait for these changes; but the placenta having been at last safely expelled, I went home much gratified with the happy termination of the case. The child is now perfectly well and healthy.

In concluding these remarks, I would beg leave to direct the especial attention of those who may do me the honour to peruse them, to a very interesting and important paper published, by Dr. Cape, in the *MEDICAL GAZETTE* for October 7th, 1837, in which he adduces instances of artificial respiration successfully applied, not only in cases of suspended respiration at birth, but also in the state of asphyxia sometimes attending convulsive fits. I have never met with cases in point, but I entirely concur in Dr. Cape's observations respecting them, and am of opinion that artificial respira-

tion may become more extensively useful than it has hitherto been.

I have the honour to be, sir,
Your obedient servant,
H. TERRY,
Surgeon to the Northampton
General Infirmary.
Northampton, July 16, 1839.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Tea; its Effects, Medicinal and Moral.
By G. G. SIGMOND, M.D. &c. London, 1839. Small 8vo. pp. 144.

THE author of this little work is Professor of Materia Medica to the Medico-Botanical Society; and having delivered an introductory address upon tea at the opening of this year's session, he has compressed it into a popular treatise for the general reader. Nevertheless, we fear it is not likely to become popular, nor to supply the obvious blank which exists on this subject in medical literature; for the greater part of the book is devoted to the botanical and commercial history of tea, and a very insufficient space is consequently left for the discussion of its medicinal and moral effects.

The treatise, small as it is, is not very well arranged: surely the following lists of substitutes for tea ought to have been in juxtaposition, not separated by an interval of eighteen pages:—

“As a simple and salutary diluent, no fluid is to be compared with the infusion of tea; although milk, milk porridge, gruel, broth, cocoa, coffee, infusion of sage, of balm, of juniper berries, of aniseed, of fennel, of hay, of coriander, of betony, of rosemary, of ginger, and even sugar and water, have all had their advocates, and have all been tried, they none of them form so grateful and useful a diluent with the ordinary meal, and they none of them are so uniformly agreeable; and though there may be peculiar idiosyncrasies, in which it may not altogether agree, yet it is innocent beyond all other drinks with which we are acquainted.”—P. 112.

“That tea is the most agreeable and the most salutary diluent that has yet been introduced into Europe, would ap-

pear from the general improvement that has followed upon its use; and although many plants have been used as substitutes, none have so long maintained their character. The common sage, *Salvia officinalis*, the wild marjoram, *Origanum vulgare*, the Arctic bramble, *Rubus Arcticus*, the sloe-tree, *Prunus spinosa*, the goat-weed, *Capraria biflora*, Mexican goose-foot, *Chenopodium ambrosioides*, common speedwell, *Veronica officinalis*, wild germander, *Veronica Chamadrys*, have been tried; but the most sanguine commenders of these herbs have soon become tired, and have abandoned their use"—P. 130.

Is tea a real good, or merely the least of evils? This is one of the most important questions in diet, but one to which we find no satisfactory answer in Dr. Sigmond's essay. We readily acknowledge that the constant drinking of tea is far better, that is to say, far less bad, than the constant ingurgitation of wine and spirits; that it is also better than the liberal use of coffee and chocolate, which are too stimulating for ordinary drink: our doubt is, whether it is good absolutely as well as relatively. After teaching certain comfortable persons how much wine they may drink at and after dinner, our author says—

"About two hours after this a diluent may be advantageously taken; then it is that tea imparts a grateful glow of warmth, assists the stomach to unload itself from the digested food, which it gently propels. Soon after it has been taken, the languor which is usually attendant upon a full meal disappears, the propensity to slumber so apt to prevail is dissipated, the body feels light, and the mind capable of either gathering fresh information, or of indulging in the recreation which society affords."—P. 109.

If tea is beneficial here, it seems to be as a medicine to a gorged feeder—a substitute for temperance, a good cook, or a cheerful companion*; but is it

advantageous to the bulk of our population, who have no wine and no loaded stomachs, yet drink more of the diluent than their well-fed superiors? What, too, is to be said of the numerous persons of the middle class, who are frequently heard to say, that they cannot do without their tea—that their tea is the best meal they have, &c.; is this passion for the infusion the cause, or only the effect of their weak lackadaisical state? We do not propose these questions as if by asking we answered them, but with real doubt. At present we take leave of the subject; but we must state, in justice to Dr. Sigmond, that the historical part of the work is far better than the one from which we have made our quotations.

On the Enlisting, Discharging, and Pensioning of Soldiers; with the Official Documents on these branches of Military Duty. By HENRY MARSHALL, F.R.S.E., Deputy Inspector-General of Army Hospitals. Second edition. Edinburgh and London. 1839. 8vo. Pp. 259.

THIS is a capital work: eminently useful to army surgeons, to whom it ought to be a vade-mecum, and well worth the perusal of civil practitioners. For, in the first place, *malingering*, or shamming sickness, though brought to the greatest perfection in the army, is an accomplishment by no means uncultivated in schools and colleges, hospitals and dispensaries; and, in the second place, so many patients, from negligence or other motives, conceal half their infirmities, that it is desirable for every one to have the *coup-d'œil* of a military practitioner, and detect much more than the sick man confesses.

The first part of the work is on the enlisting of soldiers, the second on discharging, and the third on pension-

to be cheerful if his fellow-diners are sad? Some faces make good digestion certain; while others, more potent than Medusa's head, would turn the best cooked meat into stone. Suppose, for instance—to take extreme cases—you sat down day after day opposite to Tetricus, with discontented looks and short answers; Ude or Beanvilliers might toil in vain, for the choicest morsels could hardly be swallowed. Again, imagine the fellow-diner was Callipareia, with a smile such as eye has not seen, and a voice such as ear hath not heard; does not the youngest student know that cucumber would become digestible, and that dry bread (as in the Tale of a Tub) would be converted into partridge? Let the writers on diet look to this.

* We have often thought that one might apply to medicine what Napoleon said of war, "That the morale was to the *physique* as three to one." In the matter of digestion, especially, this holds good; let the mind be at ease, and the cook may do her worst. There is a Spanish proverb which says, "Tell me whom you keep company with, and I will tell you who you are." We would propose as a supplement, "Tell me with whom you dine, and I will tell you how you digest." Cheerfulness at meals, quoth Bacon, is a great promoter of long life; but how on earth is a man

ing them. At page 10, Mr. Marshall says—

“The army is unpopular, and will ever continue to be so in this country, not in consequence of the severity of the punishments of military service, but on account of the necessary restraints upon the habits of the man who becomes a soldier, and the severity of the service and duties which he has to perform, namely, service for life at moderate pay, in unwholesome climates, at great distances, and incurring enormous risk to health and life.”

We think this very doubtful, though backed by the authority of the Duke of Wellington. Of the recruits inspected at the Dublin Depot, 8269 out of 12,835 were husbandmen and labourers, and these, at least, would not be likely to complain of their pay or style of living as soldiers; and it is clear, from what our author says elsewhere, that a great part of the disgust to the service felt by those who are actually in it, arises from its unlimited duration. It is obvious that this disgust cannot be concealed from the mass of the population, and therefore must operate as a strong check upon enlistment. The following anecdote illustrates this topic:—

“In countries where the armies are recruited by conscription, the mutilation of young men who may be enrolled for military service is not unfrequent; but, as far as I know, the following circumstance, which marks the popular dislike to the army, is unique in this country:—

‘A dissolute son of a widow, at Long-ashford, some time since enlisted as a soldier, to the great grief of his parent, who with much difficulty succeeded in obtaining his release. He has since frequently threatened to take the same step, with the view of obtaining from his mother any object he desired. On Monday he came home intoxicated, and his mother, believing that he intended to carry his threat into execution, had recourse to the following extraordinary expedient for its prevention. With the assistance of her daughter, while her son was asleep, she bandaged his wrist to prevent hæmorrhage, and the daughter having placed the fore-finger of his right hand on a block, the mother actually chopped it off with a hatchet, a little beyond the first joint.’—*United Service Gazette*, 12th Nov. 1837.

And, then, the flogging! How can we doubt that thousands and tens of thousands of fine young men are prevented from enlisting, by the dread of their errors being punished by long-drawn torture, arrested within a few lashes of death by the nice tact of the presiding surgeon? “The ulceration which follows flogging,” says our author, “sometimes leaves extensive unsound cicatrices, which prevent a man from carrying his knapsack, and consequently he becomes permanently disabled and unfit for the service.”—P. 37.

Just imagine a discharged soldier with “extensive unsound cicatrices,” going back to his native village, like a heretic escaped from the Inquisition, and telling the story of his torments. If the villagers have some small remains of common sense, the back of their old friend will be equal to a volume of practical discourses against soldiering, and prevent any of the inhabitants of Barleythorpe from carrying *their* knapsacks.

It is often disputed whether soldiers, who are unable to bear the whole of their punishment at once, are brought out, after recovering from the first infliction, to endure a second; Mr. Marshall, whose authority must be first-rate on the subject, says—

“The custom of inflicting second punishment prevailed more or less till within a few years; but it has been gradually falling into desuetude since Mr. Manners Sutton stated in the House of Commons, in February, 1813, his opinion of its impropriety and injustice.”—P. 130.

Impropriety is rather a tender word for such a monstrous practice, whether it belongs to Mr. Manners Sutton, or to our author; we must confess that the latter seems on this point to have a little of the old school in him, and talks, without a blush, of punishments of 500, 700, and 1000 lashes!

These enormous punishments—these relics of a darker age—have, indeed, been clipped and pared down of late years, but have by no means been brought within reasonable bounds; for though flogging may in itself be preferred among a choice of evils, yet flogging till sinking nature can bear no more is unnecessary, abominable, and unrecommended by the practice of any other civilized nation. It is gratifying to see, by the table at p. 252, that the

number of punishments inflicted has also diminished most considerably. Thus, in 1825, one man out of 59 was flogged in the British army; whereas, in 1833, the proportion was 1 in 111, and the same in 1834.

Perhaps the most singular fact in military statistics is the large number of suicides among soldiers. Only look at a troop of cavalry defiling through the streets of London, with all "the pomp and circumstance of glorious war," the admired of all the women, the envied of all the men; how gay and gallant their appearance! With what manly ease they sit their horses, and how superior seems their condition to that of us poor creatures, who creep along as well as we can, that is to say, not very well! Yet of these stout cavaliers, who ruffle it so bravely among your ordinary townsmen, among every twenty who die, one dies by his own hand! And this, of course, does not comprehend the attempted suicides. (Marshall, p. 141.) What an unutterable amount of despair must be concealed beneath those handsome uniforms! Truly has it been said, *Fronti nulla fides*.

The following very curious passages are the only selections we can afford to make from the sections on Feigned Diseases:—

"*Deformity of the spine.*—Of all disabilities which disqualify men for military service, personal deformity would appear to be the most unlikely to be feigned, as the imposture is so easily detected. Malformation has, however, been frequently simulated by recruits, and in some instances with success.

"E. Brady, a recruit for the 58th regiment, was approved by Mr. McLeod, lately surgeon to the 42d regiment, and acting district surgeon in Dublin, in August 1819. He was forwarded to the army dépôt, Isle of Wight, where he feigned malformation so effectually, that a board of medical officers, which was assembled on the 4th September, to report on his case, found that he was unfit for the service, on account 'of deformity of the spine and chest—strong inclination of the body to the right side—defective motion of the right arm and leg—pain on pressure upon the spinous processes of several of the dorsal vertebrae.' In compliance with the finding of the board he was discharged; he returned to Dublin, where he was minutely examined on the 22d September,

by Dr. Peile, Deputy-Inspector of Hospitals, the late Dr. Thomas Brown, and the late Mr. Todd, professor of anatomy, who found his spine and chest well formed, no inclination of the body to the right side, or defect in the power of motion of the right arm or leg; and that he did not complain of pain on pressure upon the spinous processes of the dorsal vertebrae. But, previously to the latter examination, the object for which deformity had been simulated, was obtained. In January 1822, Brady enlisted for the 89th regiment, and was approved at Newry, by staff-surgeon R. J. Brown. The above case is by no means a solitary instance of success in this variety of imposition. T. Darby, a recruit for the 59th regiment, was approved by Dr. Thomas Brown during the autumn of 1821, and transferred to the dépôt of the corps in the Isle of Wight. The nature of the farce he acted there may be inferred from the subjoined copy of a report made on his case, by a board of medical officers:—'The board have minutely examined recruit Timothy Darby, 59th regiment, and find a curvature of the upper part of the spine, with deformity of the chest and shoulders, the left shoulder nearly two inches higher than the right, and the body slightly bent forward, with the head inclining to the left side. He has been in hospital upwards of two months, under observation and treatment; large caustic issues have been made on each side of the spine, and the cough and pain he complained of on admission are removed; the board are of opinion, that the deformity is incurable, and recommend his removal from the service.' This report is dated 10th December, and Darby was discharged on the 13th of the same month, 'in consequence (as his discharge stated) of a deformity in the spine and chest.' Dr. Brown having been furnished with a copy of the above report very naturally inferred that there must be some fraud in the business, as it was morally impossible that he would have approved of so deformed an object as appeared to be described by the board. Darby was intercepted on his return home through Dublin; and on the 21st January, 1822, he was inspected by three eminent surgeons, Messrs. Colles, Todd, and Cusack, an extract from whose report I shall subjoin:—'We have this day minutely inspected Timothy Darby, and we are of opinion

that he does not labour under any disease or deformity of the spine or chest; on the contrary, he appears to be remarkably well formed.' On the 2d of November, 1825, Darby enlisted for the 87th regiment, but apparently presuming that he would be rejected, on account of the cicatrices of two large issues on his back, he refused to accept of a smaller sum than five shillings as enlistment money from the recruiting sergeant. He was brought to me for inspection, and I found him fit for the service, being perfectly aware at the time that Darby had been found unfit by a medical board. He was soon after transferred to the dépôt of the 87th regiment, and finally approved."—P. 134.

"Dr. Fallot relates an account of a Swiss soldier who feigned St. Vitus's dance. The symptoms were a little exaggerated, but in general they were exceedingly well imitated. The man appeared to suffer much by the complaint, and anxiously begged for medicines to relieve him. He was about to be discharged, but Dr. Fallot's suspicions being excited, the man was then requested to give a minute account of his feelings, which, aided by the promptings of the doctor, were obviously very absurd. The fraud was by this means discovered. Although this man was quite an adept in imitating the symptoms of the disease, he could not give any thing like a satisfactory history of the progress of the affection. Dr. Fallot afterwards discovered that the impostor had been tutored in the art of imitating St. Vitus's dance, by a relation, who was a medical practitioner. The man deserted from the hospital when he found that his imposture was discovered."—P. 160.

These cases are remarkably instructive; but we cannot quote them without cautioning our younger readers not to overlook real diseases in their zeal to detect feigned ones—a painful and unjust mistake which has often been made. Thus Mr. Marshall says—

"Other instances might be quoted where mental alienation was mistaken for feigned disease. From the report of a coroner's inquest held on the body of Joseph Godfrey, it appears that he belonged to the 83d regiment, and served with that corps at the Cape of Good Hope eleven years. During this period he evinced symptoms of derangement on five different occasions; was five times

tried by a court-martial for pretending insanity with a view to his discharge; and was, on each occasion, sentenced to receive corporal punishment, which was uniformly inflicted. Maniacal paroxysms continued to recur after he was discharged, and during one of the accessions he committed suicide, by drinking a quantity of sulphuric acid."—(*Times Newspaper*, 22d February, 1826.)—P. 162.

Two other examples are given by Beck; in one a soldier "was treated as a malingerer, and sent to drill, until a lumbar abscess appeared, of which he died;" in the other, a patient complaining of pain along the whole outside of the thigh was dismissed from the Edinburgh Infirmary as an impostor; in about a fortnight afterwards, he died of apoplexy, and on inspection, the cartilage covering the head of the femur was partially destroyed, and there were two ounces of pus in the cavity of the joint. — (*Beck's Med. Jurisprudence*, 5th edit., p. 33.)

Again, we recommend Mr. Marshall's excellent treatise to both classes of our readers, the civil as well as the military.

MEDICAL GAZETTE.

Saturday, July 27, 1839.

"Licet omnibus, licet etiam mihi, digressum
Artis Medicæ tueri: potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

SUCCESSFUL PHYSICIANS AND SURGEONS.

IN our article on Successful Physicians (July 13th), we found fault with the enormous and indiscriminating praise which the author of "Physic and Physicians" has lavished upon a great number of our London practitioners. Almost all the physicians, indeed, whom he calls eminent, in fact, are so, though there are some two or three who, if "blush lives at them," as Miss Jane Okey phrases it, must colour up to the ears at seeing themselves in the catalogue. But though the majority are

really eminent,—though they emerge from the crowd, either as scientific thinkers, or practical physicians,—still the overwrought panegyric with which the author bespatters them, does not produce the effect which he intends; but instead of making them all first-rate stars, reduces them to a sort of milky way, where individuality is lost in one general blaze. This, certainly, is not the style of those whose praise is fame; they do not lose individuals in classes, unless when there is nothing to characterize them singly, and when we read of *fortemque Gyan, fortemque Cloanthum*, we feel assured that though stout warriors, they were not able generals.

It must be confessed, moreover, that as in a picture the lights require to be set off by shadows, so the varied merits of the sitters for medical portraits, even if drawn by a delicate hand, would appear false and unnatural unless contrasted with their defects. Sketches of this kind of the members of the bar were executed twenty years ago, and most admirably too, by a writer who assumed the signature of "Amicus Curiae." He was well acquainted with the essential rules we have laid down, and knew how to praise with discernment. When he extolled, for instance, the powers of Scarlett, Brougham, or Denman, as advocates, he did not cry them up as black-letter lawyers; unlike the author of "Physic and Physicians," who constantly throws away the epithet *scientific*, as if science were common as a diploma. Yet we must candidly allow, that in taking medical likenesses, the painter labours under a disadvantage not shared by the legal limner. The barrister is a public man; and if his delivery is confused or hesitating, his law bad, or his cross-examinations rapid, the fact is open to all who attend the courts, and may be published without any breach of faith. Whereas,

if it were said of one physician that his manner was not really courtly, but laboriously polite; of another, that he had a cabbed, ungenial air; of a third, that he too much resembled the president of an eccentric club; they might complain, and with justice, that they had been watched by the malignant eye of some caricaturist in their hours of private confidence and social relaxation. Hence we must not only excuse, but praise, the author for the absence of all those nicer touches which acquaintance with the object of the sketch can alone give.

When he talks, however, of his "stern sense of duty," says that "medical men are, in every sense of the word, public property;" and asserts, that "it is for the advantage of society that the physician's and surgeon's character and intrinsic worth should be properly weighed, in order that the public may be enabled to make a selection of those in whom the most implicit confidence may be placed," we certainly expected something more than a dull stream of undiluted praise. Such promises made us fear that the critical scourge was about to be wielded with terrific severity. What will become of Dr. Alexander Turnbull, we ask? Assuredly the author's knout will reduce him a state of insensibility for veratria alone, and his friends will have to carry him away long before "a stern sense of duty" has got through the alkaloids. There will be no time to touch him up for the ear. Instead of this, to our unspeakable amazement, we find that "Dr. Alexander Turnbull is a physician who has contributed much to the alleviation of human suffering."

Even in these days of hurried writing, when authors scribble while the printer's devil is waiting in the passage for "copy," we are somewhat struck with finding Dr. Turnbull praised for the "absence of all mystery," in the same

page where an apology is offered for his making a mystery of the remedies he uses for the cure of deafness.

In his account of Dr. Elliotson*, the author says that he, "in measure, owes his reputation and present position in the medical world, to the publication of his lectures in the *Lancet*." And to this he immediately adds, "Do not let it be supposed that we wish, for one moment, to detract from the intrinsic abilities of Dr. Elliotson, or wish the public to believe, that, without the co-operation of Mr. Wakley's medical journal, the Doctor could not have risen to his present rank in the medical profession. This is far from our intention. We are convinced, from our knowledge of the talents and character of Dr. Elliotson, that he would have attained high eminence as a practical physician, had no such publication as the *Lancet* been in existence." This seems self-contradictory in form, but perhaps is not so in substance. The author probably means to say, that although the publication of a physician's lectures must hasten the diffusion of his fame, still a man whose lectures are worth publishing, must take rank in his profession, even if the lectures are not printed. If he means this, we agree with him: and we can readily understand, not only the effect which such a diffusion of a physician's opinions must have, but the foregone conclusion which it denotes;—for it is scarcely conceivable that one editor, far less two (for the lectures also appeared in this journal), should persist, month after month, and year after year, in publishing the effusions of

mere mediocrity. Half a dozen lectures on some small subject may be admissible, though of only average merit; but a series of sixty flat discourses would be intolerable. Hence we may conclude, and the history of medical journals confirms our deduction, that when a periodical gives an entire series of lectures on any subject, the author is a distinguished teacher. But granting that a man has delivered a satisfactory course, and can keep together a class of a hundred or a hundred and fifty pupils, does it follow that he must be a successful physician? Almost to a certainty; at least we do not recollect any instances to the contrary. The same qualities which draw pupils, and make lectures worthy of the press, will form the popular practitioner. In the first place, the good lecturer, instead of having to hunt for materials to fill up an hour, has only to select from his stores what is most apt and most instructive. As he has had a large hospital practice, and has known how to profit by it, his lectures do not consist of mere compilation from other writers (for these, however ingeniously dovetailed, will want force), but of the results of his own observation, and the experience of former physicians, so fused into one harmonious whole, that a break can seldom be perceived. Of course, on some occasions, such a teacher will dissent from established opinions; but if this is too often done, lectures will not be very instructive, unless we suppose their author to be a Sydenham or a Boerhaave. One thing is quite certain: a lecturer of the best kind will give due prominence to essential points, unlike those dullards who are ignorant of the *perspective* of science, and attempt to bring every object into the fore-ground. It is unnecessary to say that the lecturer must be a man of talent and industry, and thoroughly in earnest in his profession. No one can mistake him

* He calls him Thomas, though his real name is John; but literal accuracy is not the author's strong point. Thus he calls Dr. Copland, Copeland; changes Pereira into Periera; A. T. Thomson into A. T. Thompson; and Marcet into Marat (p. 244). Among errors of another kind, we may mention his enlisting Dr. Alexander Marcet among living physicians, though he must have been dead a good dozen of years; and devoting more than nine pages to Faraday, supposing him to be a physician.

for a mere physiologist or botanist, or dry historian of disease; he makes every thing subordinate to the practice of physic. Every one does with pleasure that which he does well; and he is therefore ready in teaching physic by short hints, as well as formal lectures, so that he must be good-humoured and facile of access. Such are the chief qualifications of an eminent lecturer; if to these we were to add great fluency and elegance of speech, enabling him to lecture with ease from the most scanty notes, he would be a first-rate one. At all events, the talent, industry, skill in arranging materials, tact in bringing out prominent points, and facility of access, which constitute the able lecturer, will make up a successful physician, even if no medical journals should be in existence.

It is almost incredible that any one should talk about Sir Charles Bell for two mortal pages, and yet not mention a word about the famous pamphlet, printed for private distribution in 1812, and the double roots of the nerves; yet so it is; no hint is given that Sir Charles Bell has made a discovery which is the subject of discussion wherever physiology is studied. He asserts that Sir C. Bell practised midwifery for two years—an assertion contradicted by Sir Charles in one of his clinical lectures some ten years ago.

Sir Anthony Carlisle is highly praised, like every body else. On one occasion he fell into a discourse on the importance of attending to trifles, in which he is represented by our mistaken author to have adduced as an example, the story of a surgeon who went some distance to perform an amputation, but forgot to take a saw with him. We should have imagined a saw at an amputation to be any thing but a trifle.

Mr. Liston is specially honoured, for nearly eight pages are consecrated to a discussion of his merits and peculiari-

ties. Who loves me loves my dog; so that the author naturally asks, "Who has not seen Liston's favourite cat, Tom?" We are ashamed to own that we have not, though it would seem that not to know Tom might almost argue oneself unknown!

On the whole, it must be granted that the author of "Physic and Physicians" has executed the delicate task of criticizing living practitioners harmlessly, though often with extreme inaccuracy. This, however, will very likely affect the popularity of the work out of the profession but little, for we observe it is praised to the very echo by those irrefragable arbiters in literature—the Sunday newspapers.

METROPOLITAN HOSPITALS.

VARIOUS changes have lately taken place in the medical department of some of the London hospitals.

At Charing Cross Hospital, Mr. Hancock has been elected assistant-surgeon. This, we believe, was a new appointment.

At London Hospital, Dr. Little has been elected assistant-physician, in the place of Dr. Davies, deceased.

At St. George's, Dr. Chambers has retired, after 23 years of active and honourable service. Dr. Hope has succeeded as physician; and Dr. Nairne has been elected to the office of assistant-physician, vacated by Dr. Hope.

At North London Hospital, Dr. C. J. B. Williams is to succeed Dr. Elliotson.

UNIVERSITY COLLEGE.

THE Professorship in Medicine, recently vacant, has been keenly contested;—Dr. M. Hall, Dr. Craigie, and several others, well-known physicians, being among the candidates. The choice has fallen upon Dr. C. J. B. Williams, whose valuable lectures on the Chest appeared in our volumes of last year.

LECTURES ON THE EYE.

WE beg to direct attention to Velpeau's lectures on the eye, now in course of publication in this journal. They will be found to contain views and opinions considerably different from those which prevail in the English and German schools.

LONDON UNIVERSITY.

WE subjoin the papers for the second examination, which complete the set:—

BACHELOR OF MEDICINE. 1839.

SECOND EXAMINATION.

PASS EXAMINATION.

Monday, July 15.—Morning 10 to 1.

PHYSIOLOGY AND COMPARATIVE ANATOMY.

Examiner, Dr. ROGET.

1. Enumerate the component parts of the blood; specify their physical and chemical properties, and describe and explain the phenomena of the coagulation of the blood.

2. Describe the course of the blood in its circulation; state the proofs that such is its course, and give a general account of the powers by which its motion is maintained.

3. Describe the general plans of the organs of circulation in the four classes of vertebrate animals, and also in the mollusca, with reference more especially to their different modes of respiration, and to differences in their temperature.

4. What effects ensue from the extirpation of the kidneys?

5. Describe the forms, and explain the office of the air-bladder of fishes.

6. State the purposes which are answered by the ganglia and the plexuses of nerves.

7. Describe and explain the effects of a section of the pneumogastric nerve.

8. Describe the characteristic forms of the nervous system in each of the four great divisions of the animal kingdom, viz. vertebrate, molluscan, articulated, and radiated animals.

9. Describe the mode in which images of external objects are formed in the human eye; and also the provisions in that organ for different focal adjustments, and for correcting the spherical and chromatic aberrations.

10. Enumerate the anatomical differences between the eye of the ox and that of man; and state generally the peculiarities of structure in the eyes of birds and of fishes.

Monday, July 15.—Afternoon, 3 o'clock.

CLASSICAL EXAMINATION.

Examiners, Dr. BILLING and Dr. TWEEDIE.

Translate the following passages into English:—

Celsus de Re Medica, lib. ii. cap. 4.

Celsus de Re Medica, lib. iii. cap. 20

Celsus de Re Medica, lib. iv. cap. 20, sect. 2.

Tuesday Morning, July 16, from 10 to 1.

SURGERY.

Examiners, Sir STEPHEN HAMMICK and Mr. BACOT.

1. Define common acute inflammation, its characteristic symptoms and causes.

2. State the various terminations of inflammation, with the treatment of each respectively.

3. How do you class wounds arising from external violence? Describe their nature, symptoms and treatment.

4. What is the process by which union is accomplished in a simple fracture of a cylindrical bone?

5. Give the different dislocations of the shoulder-joint, their symptoms, and mode of reduction.

6. What is hydrocele—its palliative and radical treatment?

7. Enumerate the different situations and names of herniæ, with the various conditions in which they may be found.

8. Describe the operation for popliteal aneurism.

Tuesday, July 16.—Afternoon, 3 to 6.

MEDICINE.

Examiners, Dr. BILLING and Dr. TWEEDIE.

1. Describe the general symptoms, anatomical characters, and physical signs of pleurisy. Give an outline of the treatment.

2. What are the different forms of scarlet fever? Specify the symptoms which characterize each variety, and its appropriate treatment.

3. What are the principal lesions which induce ascites? How is it distinguished from pregnancy, ovarian tumors, or tympanites?

4. What are the symptoms of laryngitis? Describe its anatomical characters, diagnosis, and treatment.

5. Give the anatomical characters of cerebral hemorrhage, and the changes which subsequently take place in the coagulum and in the nervous tissue.

6. Detail the symptoms, morbid appearances, and treatment of dysentery. Mention particularly the circumstances which determine the propriety of blood-letting, and those which contra-indicate its employment.

7. What are the symptoms of nephralgia calculosa? State its diagnostic signs, and the curative and prophylactic measures to be employed in the treatment.

8. Detail the measures to be adopted when an individual is seized with cerebral apoplexy.

Wednesday, July 17.—Morning, 10 to 1.

MIDWIFERY AND THE DISEASES PECULIAR
TO WOMEN AND INFANTS.

Examiner, Dr. LOCOCK.

1. What are the signs of pregnancy? Which are doubtful and which are decisive?
2. What are the changes which take place in the fœtus immediately after the first act of respiration?
3. What are the circumstances under which it may be desirable to bring on premature labour, and what are the various modes of effecting it?
4. What are the nature and causes of hæmorrhage before parturition, and the modes of treating it?
5. With what may polypus of the uterus be confounded, and what is the diagnosis?
6. What are the signs of the death of the fœtus?
7. What is the order of the first dentition?
8. What are the symptoms of laryngismus stridulus—the causes—and the treatment?

Wednesday, July 17.—Afternoon, 3 to 6.

FORENSIC MEDICINE.

Examiners, Prof. DANIELL, Dr. LOCOCK,
and Mr. PEREIRA.

1. What are the symptoms and chemical proofs of poisoning with opium?
2. How are blood stains on metal and linen to be distinguished from other stains?
3. What are the proofs that carbonic acid gas is a *positive* poison? What are the morbid appearances which it produces in the body?
4. What are the symptoms of arsenical poisoning? How may the presence of arsenious acid in organic mixtures be ascertained?
5. What condition of the ovary is a test of impregnation having formerly existed, and how much is such a test to be relied on?
6. Describe the signs of recent delivery, —those distinguishable during life—and those proved by dissection.
7. In suspected infanticide, what are the proofs that respiration has taken place, and how much are they to be depended upon?

REMOVAL OF A THORN

WHICH HAD BEEN FIVE YEARS IN
THE EYE.

To the Editor of the Medical Gazette.

SIR,

Should the following case be deemed of sufficient interest for the perusers of your

well conducted and widely-diffused journal, an early insertion will confer an obligation on,

Your obedient servant,
HUGH BIRT, M.R.C.S., &c.

Ashington, Storrington, Sussex,
July 16, 1839.

Solomon Stringer, ætat 16 years, the son of a small farmer in Westgrinstead, applied to me, June 2, 1839, in order to ascertain if I could inspire him with the prospect of regaining the vision of his right eye, which had been lost for the five preceding years.

However, the curiosity of the case being in its history, I will endeavour to subjoin it as follows:—My patient, with other boys of his own age, proceeded in the destruction of a wasp's brood, by "flogging out," as it is here named, and by so doing his eye was struck with one of the branches of the black thorn, used for the above purpose; and, as will hereafter appear, one of the spinæ entered the cornea and inflicted a penetrating wound, leaving its apex adhering to the capsule of the lens. However, this was not observed at the time by the surgeon then called in, Mr. Morgan, of Henfield, a highly respectable and intelligent practitioner: he treated the case as conjunctivitis only, I should imagine, and soon allayed its progress, telling the boy he would regain the use of the organ in a short time. Unfortunately, however, his predictions were not verified, and the patient, from that period, 1834, gradually became worse as to vision, until he completely lost it, about five months from the reception of the accident. I saw the case was a soft cataract, and determined to depress it. I invited Mr. Hurst, of Pulboro, and Mr. W. Barker, of Tarring, who kindly obeyed my call, and lent me their able assistance. After the application of the belladonna, and the dilatation of the pupil, we could observe a small black substance adhering to the inferior portion of the capsule, which proved to be the woody substance afore-mentioned. I now altered my intention, and immediately resolved to perform the operation of extraction, by which means I should afford an opportunity to the foreign body escaping. I operated by the lower section, but could not, unfortunately, discover the substance in question. However, six weeks have elapsed since the operation, and the case is going on favourably, without any prolapsus iridis, or any any other unpleasant symptoms. The organ is gradually resuming its tone, and doubtless the case will prove a fortunate one.

OF

DRUGS ON SALE IN THE ENGLISH MARKET,

With their Prices and several Duties.

INFLUENCE OF THE SYMPATHETIC NERVES ON POISONING.

To the Editor of the Medical Gazette.

SIR,

HAVING made some experiments on a subject which has excited considerable interest within the last few years—the physiological action of poisons—I am anxious to direct your attention to a point, as far as I am aware, hitherto unnoticed.

After making a wound on the inside of the thigh of a rabbit, I applied to it six drops of a solution of hydrocyanic acid. The animal was dead in four minutes. After some unsuccessful attempts, I succeeded in dividing both sympathetic nerves in the lumbar region of another rabbit, much about the same size and age. To a similar wound on the thigh, I then applied the same quantity of hydrocyanic acid. No effect appeared to be produced for nearly ten minutes, when, some slight convulsions coming on, I repeated the application, but it was not till sixteen minutes from the time I applied the first quantity that the animal was dead.

A short time since I made a communication to Dr. Christison on this subject, thinking that if, by future inquiries, it could be shewn that poisons exert their influence through the medium of the sympathetic nerves, it would explain many things connected with their physiological action at present very obscure. For example, their non-action when applied to cut surfaces of the brain, spinal cord, and its nerves; also when a poisoned limb is connected with the body by means of the spinal nerves alone, and the varying intensity of their action with the texture to which they are applied; for there can be little doubt that the blood-vessels and pulmonary cells require and receive a larger supply of ganglionic nerves than other textures.

The learned Professor has very politely answered my letter, stating that “he cannot find that any thing has hitherto been done of the least consequence towards ascertaining what part is performed by the nerves of the sympathetic system in the action of poisons,” and suggesting, “to repeat the experiment several times with the same poison in larger doses, and in different animals; and afterwards with other poisons, among which the most interesting would be strychnia, conia, nicotine, or the empyreumatic oil of tobacco, and any other very powerful poisons which produce a characteristic set of symptoms in acting on the nervous system.”

Now, sir, I have not time to pursue a

subject, however curious and interesting, which would require so many experiments to prove what Abercrombie calls “the universality of the fact.” I have therefore wished to direct attention to the subject by means of your valuable journal; and remain, sir,

Yours very respectfully,
THOMAS J. WELLS.

NOTICE.

The delivery of the MEDICAL GAZETTE in LIVERPOOL, will hereafter take place on Saturday afternoon, by Mr. Ed. Willmer, of the *Express* newspaper-office.

We regret that we cannot give insertion to Mr. Y——'s letter.

ERRATA.—Last No. p. 616, *note*, for “Mann,” read “Manuscript.”—P. 618, col. 2, line 43, for “which . . . circulation,” read “which lose their vitality: for a little time after respiration has ceased the circulation,” &c.—L. 53, for “mark,” read “spark.”

WILSON & SON, Printers, 57, Skinner-st., London.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.
By DR. VENABLES.

Lithic acid.—When we have the symptoms of stone in the bladder, or that its presence has been ascertained by sounding, we must endeavour to determine the species of calculus. Calculi in the bladder frequently become so smooth, from the action of the urine, that they produce little or no inconvenience. This is more particularly the case with the lithic acid, and instances are on record of large lithic calculi having been found in the bladder after death, which during life had not even been suspected. Here are several lithic calculi which were found, as I have been informed, in the bladder of a wheelwright, after his death, although, during his life, he betrayed no other evidence than occasionally a little irritation when voiding his urine.

The urine is, in these cases, almost always of the natural colour and appearance, but deeper. This is owing, perhaps, to the greater concentration of the urine, the specific gravity of which so exceeds that of health, that it amounts to 1.020 or 1.025. Generally speaking, too, it deposits crystallized sediments when it has become cold. When the pain and irritation are much increased, these sediments are also increased, and frequently at such times there is a great superabundance of mucus, and very often the amorphous sediments are also observed. When the calculus, however, consists of lithic acid, generally speaking the quantity of mucus is not very great, as

this species does not cause the secretion of so much mucus as some of the others. Should the urine be turbid when first passed, it generally becomes transparent after standing some time. The addition of an acid will, in many cases, cause the precipitation of lithic acid in the crystallized form, especially if the diathesis be actively in operation; though, in general, the acid is in a great measure precipitated before it leaves the bladder.

Oxalate of lime.—When a mulberry calculus exists in this bladder, it is often very difficult to determine its nature. It was formerly shown that the urine, as connected with this diathesis, does not exhibit any peculiar or distinctive characters; nor is its formation inconsistent apparently with good health. Therefore, notwithstanding the rough and tubercular surface of this calculus, if the bladder be not diseased, and the stone of moderate size, but little irritation is excited. But when large, it produces very great irritation and suffering. The urine, in such cases, generally contains much blood and mucus, but in other respects it is tolerably healthy. It has the usual acidulous reaction, and there are few or no deposits, except occasionally a little lithate of ammonia. Therefore, it is from the existence of stone, and the absence of those properties which characterize the existence of the other species, that we are to infer the oxalate of lime.

Cystic oxyde.—If a calculus of this description exist in the bladder, no doubt fragments of it will be passed, as occurred in the case I have related. Add to which, that the urine always exhibits characteristics, and such as can never be mistaken. Thus, for nearly four or five years, I continued to make frequent examinations of the urine, and it never exhibited any other properties than those which I have detailed; they might vary in degree, but were uniformly the same.

Phosphatic calculi.—Most of the calculi to which this designation is given, it has been already shewn, have a nucleus of lithic acid, oxalate of lime, or some other substance; and that calculi composed exclusively of this substance are extremely rare. However, as all the other diatheses terminate, as it were, in this, we often find large stones, consisting of the earthy phosphates, in the bladder. When this is the case, the agonies of the patient are beyond description. Independently of intolerable pain in the bladder and neighbouring parts, the general health seems to give way, inasmuch as it is said that an experienced person can determine the presence of such a calculus even from the mere "looks of the patient." Indeed, the agonies endured by the unfortunate victims of the phosphatic diathesis, as already described, aggravated tenfold, may perhaps give some faint, though very inadequate, idea of the miseries suffered by those having a calculus of this description in the bladder. Such sufferings are calculated to undermine and break down the strongest constitution.

In this form, too, the urine is peculiar and characteristic, so that it cannot readily be mistaken. For the most part it is passed in very large quantity, is somewhat opalescent, and mostly of a pale wheyish colour. Its specific gravity is generally very low, varying between 1.006 and 1.012. The greater the quantity of urine passed at a micturition, the lower the specific gravity; indeed sometimes as low as 1.002 or 1.003; when, perhaps, two or three pints, or even quarts, may be passed at a single micturition; and such cases have been mistaken for diabetes. It mostly deposits the phosphates in abundance, frequently mixed with some carbonate of lime. I have seen urine of this sort opaque when passed, deposit the phosphates, and then become comparatively transparent, but in a short time become again turbid. The first opalescence depends upon the suspension of the phosphates, upon the deposition of which the urine becomes transparent, but still it holds a quantity of super-carbonate of lime in solution. The excess of carbonic acid here will give this urine an acidulous reaction, but as the excess of acid escapes, or is neutralized by the evolution of ammonia, the carbonate of lime becomes insoluble, and being suspended in the urine, renders it again turbid*. With the phos-

phates there subsides a large quantity of mucus, the characters of which cannot be readily described, but which you may observe in this specimen, which very closely resembles phosphatic mucus. The urine, though it may be acidulous at first, yet very soon becomes alkaline; the theory of which has been already explained. In such circumstances the smell is very offensive, indeed almost intolerable; and so rapidly does such urine undergo these changes, that it is impossible to keep a house with such a patient sweet. In one very remarkable case which I met with in the country, where the patient, in the last stage, became helpless, and passed his urine involuntarily, the smell was sensible, not only all over the house, but even extended to the garden and lawn, at a long distance from the dwelling. There will, therefore, be no great difficulty in determining the nature of such a calculus in the bladder. To sum up, if we have symptoms of stone in the bladder, as such symptoms may arise from diseases and irritations of the urinary organs, we must endeavour to determine the real nature of the cause. Sounding the bladder, as it is termed, will often set the point at rest, as the stone may be distinctly felt. However, if the stone should be encysted, it may not be sensible to the sound, and then we shall be deprived of the evidence to be derived from this method. Then we must have recourse to the conditions of the urine; and if, with the general symptoms, we find a calculous condition of the urine, we shall be fully justified in regarding the case as one of stone. Lastly, the general symptoms indicating, and the sound confirming, the existence of a stone in the bladder, we must have recourse to the examination of the urine to determine, at least so far as can be determined, the nature of the stony concretion, the rules for which have been dwelt upon already at sufficient length.

Treatment of stone in the bladder.—If we could be present and attempt the expulsion of a renal calculus from the bladder immediately on its arrival there, we probably should, in most instances, or at least in a great proportion of them, succeed. Therefore, if proper means have been adopted, in favourable cases, the calculus is mostly expelled. In some cases, however, this does not take place immediately, owing to irritation, spasm, &c.; but when these have subsided, the calculus often comes away spontaneously, and perhaps when least expected.

* That this is the true explanation of the above phenomena, may be proved as follows:—If the urine be filtered, and a little acid added, effervescence takes place. If such urine be heated, it becomes turbid, from the separation of a whitish powder, which, collected and examined, proves to be carbonate of lime. Lastly, if the transparent filtered urine be distilled, at a very

moderate temperature, from a retort into a jar filled with and inverted over mercury, a gas escapes, and the urine becomes turbid. The gas, if examined, proves to be the carbonic acid gas, and the precipitate will be found to be carbonate of lime.

The principles of treatment for the expulsion or favouring the exit of a calculus from the bladder are much the same as those already detailed for effecting the same object from the kidney; for it is well known that whatever bulk will pass along the ureter will pass along the urethra. Hence one of our first objects will be to allay all irritation and spasm. The means consist in freeing the system, as far as can be done, from all causes and sources of irritation. Thus, the antiphlogistic regimen, depletion—general and local, according to circumstances—and the prevention of fecal accumulation, present the most obvious means. To these succeed the use of narcotics and antispasmodics, as hyoscyamus and opium, which will allay the irritation of the urinary organs, and especially the spasmodic action of the sphincter vesicæ, which often is the only effectual opposition to the calculus entering the urethra. When these objects have been effected, the expulsion is to be favoured by diuretic purgatives, and such as increase the flow of urine. "By this plan," says Prout, "I have seen calculi removed from the bladder in a few hours, which had been apparently retained there for several months, and in one instance, beyond a doubt, as long as five months*."

But the stone, from various accidental causes, may have acquired such a size as that it cannot pass the urethra. If, therefore, after a reasonable trial of the above measures, it does not come away, means for dilating the urethra by metallic bougies, sounds, catheters, &c. should be adopted. Sir A. Cooper has extracted calculi by means of a forceps contrived by Mr. Weiss, and, indeed, has succeeded in this way when every other means had failed†. But it may happen that the stone has acquired such a magnitude as will render its expulsion or extraction, by any of the foregoing methods, quite hopeless; then the treatment evidently will depend upon circumstances, and the principles must be modified according to the prevailing diathesis; it will be more intelligible, therefore, to consider this subject in connection with the peculiar diathesis.

Lithic acid.—A calculus having been ascertained to exist in the bladder, and its

composition having been ascertained by the means specified to be the lithic acid, we must proceed to adopt such measures as will afford the greatest relief. Now the distress and sufferings of the patient are usually proportioned to the severity of the existing diathesis. If the urine be in an unhealthy state, the more unnatural and the more loaded it is with sediments, whether crystallized or amorphous, the greater the distress. Therefore we must first endeavour to restore the urine to a healthy condition, or at least bring it as nearly as possible to a natural state. This, in the lithic acid species, is to be attempted by the means already mentioned upon this head, and the constitutional irritation is to be subdued by venesection, local blood-letting, and the use of anodynes. Alteratives, too, in this diathesis, are of essential service; such are, the Plummer's pill, for example, five grains of which may be taken over night, and a purgative consisting of tartrate of potass, or the Rochelle salts, with infusion of senna, the following morning. If the urine be very acid, some carbonate of potass may be added, or the alkaline carbonate given with some bitter infusion at intervals during the day. In some instances we may give a strong infusion of *uva ursi* with the alkali, or ten or fifteen minims of the solution of potass, with tincture of hyoscyamus, during the day, pursuing the plan above at night. We may persevere in the above till the urine begins to get natural, when we must discontinue the use of the alkalies, or at least in so active a form; for if the urine become alkaline it will produce more irritation of the urinary system, more especially the bladder, than even the lithic diathesis itself, and, perhaps, may bring on the phosphatic diathesis.

We must now carefully attend to the state of the urine, and at the same time continue mercury in alterative doses, such as five or ten grains of blue pill, every third or fourth night, with a purgative in the morning, consisting of a drachm or two of Rochelle salts, with the solution of bicarbonate of magnesia, mentioned in a former lecture, and taken in a state of effervescence. Indeed, the solution of magnesia will often answer every purpose; but, when the bowels are more torpid, the activity of the medicine should be proportioned. Where the phlogistic diathesis is strongly predominant, this may be broken or kept in check by the occasional exhibition of antimony in nauseating doses, as from fifteen to twenty minims of antimonial wine, two or three times a-day, so as to keep up some degree of nausea. By this means, not only will the urine in all probability be brought to a natural state, but may be kept so; and all the dis-

* On Diabetes, &c. p. 260.

† "If a small stone cannot be made to pass in the way I have mentioned, you will probably succeed in extracting it from the bladder by means of the urethra forceps. Indeed, I may say that you will never fail in doing so, unless the stone is beyond a certain magnitude, or there is something in the condition of the bladder to prevent it retaining a moderate quantity of urine; or unless there is a large tumor of the prostate projecting into the bladder, behind which the calculi may lodge, out of the reach of the instrument."—Sir B. Brodie's Lectures on Cal. Dis. *MED. GAZ.*, May 21st, 1831.

troubling symptoms will either altogether disappear, or be greatly abated; and still further, the calculus cannot, under these circumstances, increase in size.

Having attained our object so far, we must enjoin strict attention to diet and regimen, and above all, to avoid all those circumstances already mentioned as either inducing or aggravating this diathesis; and then probably the patient, in favourable circumstances, will experience little or no inconvenience more than if he had no stone at all. Indeed, this will be almost certain, if the calculus be not very large, and that it be smooth, or not very rough. But if it be large and rough, and that the patient use violent or much exercise, no means can wholly alleviate his sufferings, although even in such cases great relief may be afforded by strict attention to the means specified as above.

Lithate of ammonia.—When a calculus of this sort exists, alkalies are inadmissible, for there is in such circumstances a great tendency to the phosphatic diathesis. This species is found to prevail more in children; therefore the cautious adoption of the means for the phosphatic diathesis must be had recourse to. "I doubt very much, however," says Prout, "if any treatment will prevent, under these circumstances, the phosphatic diathesis from being sooner or later established*."

Oxalate of lime.—In the case of oxalate of lime, the urine deviates, at least so far as we know, so little from the healthy condition, that we do not well know what plan of treatment would prove most effectual. In cases of oxalate of lime, from the rough and tuberculated surface of the stone, a good deal of inconvenience is frequently experienced. We must, therefore, as far as possible, endeavour to obviate these, and to correct any unnatural conditions of the urine, should they exist. The use of anodynes, as in the lithic acid, and the exhibition of chlorine, hydrochloric acid, &c., as already directed, when considering the oxalate of lime diathesis.

Cystic oxide.—If, from the properties of the urine, we presume the existence of a cystic oxide calculus in the bladder, we must pursue the same means as have been directed in this diathesis, but more especially those recommended in the phosphatic. The phosphoric acid may be given; and we should also recollect that, in consequence of the tendency to the phosphatic diathesis, that the use of alkaline remedies, at least for any great length of time, will be very hazardous. Therefore, if the use of an alkali be at all indicated, it should be used only until the object intended has been attained, and it should

then be laid aside. Perhaps, too, the milder alkaline remedies, as the citrate of magnesia, or the solution of the bicarbonate, as already mentioned, would be preferable to the alkalies themselves in any form. But perhaps any thing that we can do can only be looked upon as merely palliative.

Phosphatic calculi.—When stones consisting of the phosphates exist in the bladder, we cannot be too expeditious in altering the condition of the urine, and restoring it to a healthy state. But still it must be acknowledged that, under the present circumstances, this is very difficult, if not altogether impossible, to accomplish. Dr. Prout states that he was never able to accomplish this purpose in a single instance, even after the most fair and persevering trial of almost every means hitherto recommended, or that he could devise as likely to effect his object; and therefore, he states, he could only procure temporary relief by the various exhibition of opiates; and he therefore looks upon lithotomy as the only alternative in this distressing disease*.

However, there may be objections to this, or the patient may refuse to submit to the operation; we must then have recourse to the means recommended in the phosphatic diathesis, and persevere strictly in their use, in the hope of mitigating the sufferings of the patient. As, however, there does not seem to exist any very great probability of our being able to correct the state of the urine, we cannot hope to prevent the gradual, though perhaps somewhat retarded, growth and increase of the stone.

With respect to the other means, keeping the bowels regular by such means as are suitable to the diathesis, and the free use of anodynes and astringents, are the most essential. Thus opium, or perhaps morphia, in this diathesis is the most effectual. According to Dr. Prout, hyoscyamus is better suited to the lithic acid diathesis, and opium to the phosphatic; but he also states, "that he has seen striking temporary relief produced even in cases of phosphatic calculus, by large doses of hyoscyamus combined with the uva ursi†." At the same time opium may be used as a suppository: opiate enemata injected into the rectum, or even urethral injections of opium, may be used; but it should be recollected in this case, that the urinary passages are already in a high state of irritation, and that it is the local irritation which renders this diathesis so obstinate and uncontrollable. Therefore, every means of soothing, such

* On Diabetes, &c. p. 263.

* Ibid. 264.

† Ibid. pp. 264, 265.

as the warm bath, fomentations, and the sitting over the steam of warm water, as for piles, and such similar means, should be adopted. Dr. Prout says, "In severe paroxysms I have seen great temporary relief produced by a lotion composed of the liquor plumbi acetatis dilutus and tincture of opium, applied to the perineum as hot as possible, by means of sponges, linen cloths, &c.*"

Are there any solvents for stone in the bladder?

—This is a very important consideration, but also one which I believe can lead to nothing either settled or satisfactory. Indeed, when we consider the great difficulty of dissolving calculi even out of the bladder, unless we bring to our aid attrition and mechanical reduction to very minute particles, with strong lixivium and increased temperature, we certainly have no very encouraging prospects. It is true that of late some foreign writers have instituted experiments, in which they found that calculi left in certain menstrua or solvents lost weight, and that this occurred even in running streams possessing no very great powers as chemical solvents. But upon all these it may be observed, that the circumstances of the two cases have but few analogies. In the first place, a calculus immersed even in a very weak solvent is in circumstances much more favourable for its solution than when placed in the urine, because, in the first place, there are no modifying circumstances either to control, limit, or subvert, the chemical action of the solvent; neither does it hold in solution the constituents ready upon the first favouring circumstances to be precipitated and deposited upon the calculus, and thus increase its size. Further, the solvent, or rather the agency of the solvent, is limited, or wholly confined, merely to keeping the urine in a condition unfavourable to any further deposition of the calculous principle, and, consequently, can exert no solvent power upon the existing calculus. Therefore it appears that although calculi out of the bladder may be worn away, and reduced in size, by the mechanical attrition of fluids, or slowly by the solvent agencies of chemical menstrua, that, in consequence of the many counteracting agencies, such effects are not to be expected in the bladder, at least by the internal exhibition of remedies. Indeed, in some species of calculi—lithic acid, for instance—the alkali is not capable of exerting any solvent power over the calculus, for it is combined mostly with carbonic acid, which the lithic acid, as you already know, will not displace. In the phosphates, as has been already stated,

in consequence of the irritation excited by the calculus, we cannot restore the urine even to a healthy state; how, therefore, can we expect to induce such a chemical condition as would enable it to dissolve such a stone when existing in the bladder? Therefore, it appears that we cannot, by the use of internal medicines, hope to make any impression upon a calculus already existing, and that the utmost we can hope for is to be able to prevent future accretion, and the increase in size of the calculus.

From the effects of chemical reagents upon the different species of urinary calculi, it occurred to some, that the introduction of these into the bladder would be attended with similar results, and hence solvents of the different species have been injected in a diluted state. This plan, however, will totally fail in lithic acid calculi. The alkaline carbonates, as already shewn, have no effect upon the lithic calculus; and the caustic alkalies, and even the carbonated, are very deleterious to the mucous membranes of the bladder. But to be effectual as solvents, the caustic alkali must be tolerably concentrated, and even thus, upon the masses of compact lithic acid I find that their agency is very trifling, even though long subjected to it, and which would be attended with the worst consequences in the human bladder. The other solvent, nitric acid, has but little effect in so diluted a state as is necessary to use in the living subject, and therefore little is to be expected from the mechanical or extraneous use of solvents in this form. Dr. Prout states that he has witnessed some trials of this sort, but, he says, "The results, I am sorry to say, were by no means such as to impress me with any very favourable notions of the general practicability of this plan; and, indeed, when the very weak state of the solvent that can be thus employed is taken into account, the consequent length of time for contending the experiment, and, above all, the refractory nature of certain calculi, I confess I am very much disposed to doubt if any solvent at present known can, in the great majority of instances, be ever so administered as to produce the desired effect; and this, I believe, is the general opinion on the subject*."

But in the case of the phosphates and the cystic oxide, circumstances are certainly somewhat different. "The mineral acids undoubtedly exercise a much greater chemical action on calculi composed of the phosphates than alkalies do on those which are composed of lithic acid. It is not, indeed, possible to exhibit them by

* Ibid.

* Ibid. p. 284.

the mouth in such quantity as to render the urine sufficiently acid for the purposes of a solvent; but we have no right to conclude from thence that they may not produce this effect if injected into the bladder by the urethra*.

Acting on this principle, Sir B. Brodie informs us that he instituted a series of experiments for the purpose of investigating this subject. He began by injecting a solution of nitric acid in water, at first in the proportion of a minim to the fluid ounce, and afterwards gradually increased, till at last two minims and a half were added to the ounce, and the persons not only suffered no inconvenience, but, on the contrary, when there was chronic inflammation of the mucous membrane, they experienced considerable relief. Sir B. Brodie next ascertained what effect such a solution exerted upon a calculus composed of the mixed phosphates, and the result was sufficiently decisive to induce him to try it in an actual case. A case having presented in which the existence of a calculus of the mixed phosphates was unquestionable, the acidulous solution was made to pass into the bladder by one leg of a double canula, and so constructed that it could pass out by the other, thus subjecting the calculus to a continued stream of the diluted acid. The fluid was injected several times, and afterwards tested by ammonia; the phosphates were thrown down. The result, however, was, that two calculi, which appeared to be portions of the original one broken down by the use of the injection, were at last voided with the urine. The conclusions of Sir B. Brodie, therefore, are:—

1. That where the mucous membrane is affected with chronic inflammation, the urine depositing a viscid alkaline mucus, a very beneficial change may be produced by the injection of very diluted nitric acid.

2. That a calculus composed externally of the phosphates may be acted on by this injection, so as to become gradually reduced in size while it is still in the bladder of a living person.

3. That there is reason to believe that calculi, composed throughout of the mixed phosphates, such as are met with in some cases of diseased prostate gland and bladder, are capable of being entirely dissolved under this mode of treatment.

These are the conclusions of Sir Benjamin. Now it is to be recollected, that that when calculi of the mixed phosphates are found in the bladder, for the most part there is general disease of the urinary organs, and particularly of the bladder;

and, as remarked by the above authority, lithotomy, and even lithotripsy, are hazardous operations in such cases. Therefore, any means of dissolving a stone in such circumstances is a truly valuable addition to our stock of information; and the only consideration is, by what means this may be most effectually accomplished, and with the least irritation.

VELPEAU'S CLINICAL LECTURES ON OPHTHALMIA.

BY J. HENRY BENNET, B.L. & B.S.

Sorbon.

On the Treatment of the various forms of Blepharitis.

I HAVE hitherto laid aside all consideration of specific causes and constitutional peculiarities, in speaking of this class of diseases. I shall, therefore, follow the same plan now we have to determine the treatment which should be adopted.

If we take a rapid survey of the various therapeutical means we can oppose to each of these affections when they are purely inflammatory, we shall see that they may all be divided into two classes—those which are direct, and those which are indirect.

Having made this division, I must state, that, in my opinion, all indirect remedies, such as blood-letting, baths, revulsives, &c. ought merely to be considered as adjuvants, useful, it is true—necessary even in some cases; but never to be depended upon alone, if you wish to obtain a radical cure. My opinions on this subject have not been formed *à priori*; they have been adopted only after mature consideration, and are founded on a great number of experiments, many of which some of you have witnessed. No doubt the symptoms of the malady are often more or less mitigated by an indirect plan of treatment, which may consequently be of great assistance towards effecting a final cure; but, in the great majority of cases it does not suffice alone. The affection is local and external, and as such, a local treatment only can arrest its progress, and effectually restore the tissues to their normal state.

We will now examine the treatment of each form of blepharitis in particular. I intend, at the termination of these lectures, to resume the treatment of ophthalmia, taken in a general point of view.

* Lectures on Cal. Dis., by Sir B. Brodie, MED. GAZ., June 18th, 1831.

Mucous Blepharitis.

Topical astringents are the best remedies we can employ against this form of inflammation; and among these, liquid collyria are by far the most efficacious. Numerous astringent collyria have successively enjoyed the favour of the profession; from these we may select three—those containing nitrate of silver, sulphate of zinc, and sulphate of copper; their efficacy being, in my opinion, much more clearly established than that of any other. I have often tried these collyria, and have always derived great advantage from their use. The one which contains the nitrate of silver, appears, however, to produce a more rapid amelioration than the other two; I now seldom make use of any other. It is, indeed, a most valuable remedy, as most of you who have followed my practice for any length of time must acknowledge. The formula which I follow, varies as the inflammation is more or less acute. I generally begin with half a grain or a grain of the nitrate of silver to an ounce of distilled water, increasing progressively to six, eight, or even ten grains to the ounce of water.

This treatment is, you see, extremely simple; nevertheless, for it to succeed, certain precautions must be used, and it is owing to their having been neglected that some practitioners have not derived from the remedy the benefit they had been led to anticipate. This remark may not only find its application in this instance, but also in many others in the course of these lectures.

The first point to be ascertained is, that that the prescription has been accurately prepared. This is of extreme importance where the quantities are so small, and ought especially to be attended to in hospital practice. Two or three drops of the collyrium should then be instilled into the eye, twice or thrice a-day, care being taken, at the same time, that the liquid comes in contact with every portion of the inflamed membrane. This may be attained by directing the patient to lean his head back, and then gently separating the eyelids with the fore-finger and the index of one hand, whilst with the other you allow a few drops of the liquid to fall into the eye from the pial itself. The patient should then be directed to turn the eye in different directions for a few seconds. This must be repeated several times in the course of the day, as already stated, for three or four days following, and the strength of the solution increased, should it appear necessary. The patient may then be allowed to rest for a day or two, when the collyrium is again resumed, as before. It often occurs that the amelioration is very slight whilst the remedy is used, but

that as soon as it is laid aside the inflammation rapidly abates. This circumstance leads many persons to conclude, that, so far from having been benefited by the collyrium, their cure has been retarded. This, however, is a most erroneous opinion, and one which only a person unacquainted with pathology could form.

Thus treated, this disease seldom lasts more than ten days—that is, when purely inflammatory, without any complication, as we now suppose it to be. In some cases the inflammation will disappear in less than twenty-four hours. I must not omit to say, that if the patient is strong, robust, of a sanguineous temperament—if he complains of cephalalgia, and the face is flushed, it will be well to have recourse to bleeding. Such a measure, however, I must again remind you, is not indicated by the malady itself, but by the general state of the individual.

Glandular Blepharitis.

General treatment is not more efficacious in this form of blepharitis than in the one we have just examined. Ointments, however, should be preferred to collyria, as the latter do not remain sufficiently long in contact with the seat of inflammation. The astringent ointments employed against this affection are almost innumerable. Those most generally used are the ointments of Janin*, Lyon†, Regent‡, Desault§, and those containing the nitrate ¶ of silver and the bichloride of mercury ¶. These ointments, which are efficacious preparations, should not be used indiscriminately in every case. If the glandular inflammation assumes the diphterial form, the best application is the white precipitate ointment, the proportions of which are, Axun. ʒi., Hydrar. Bichlor. ʒi. Should the circle or ribbon I described become red and shining, you must have recourse to the ointments of Janin, Lyon, Regent, or Desault. If there are slight ulcerations along the internal free edge of the palpebræ, and the secretion

* The following are the formulæ of these preparations:—

† ℞ Hydrar. Binoxyd. gr. xv.; Ung. Rosati, 4 drachms. Tere et misce.

‡ ℞ Butyri Hydrolato Rosarum Loti, 18 drachms.; Camphore, 6 gr.; Oxidi Hydrar. 1 drachm.; Acet. Plumbi Cristal. 1 drachm. Tere simul Oxidum Hydragryi et Acetatem Plumbi, adde Camphoram ante pulverisatam, dein butyrum.

§ ℞ Hydrar. Binoxyd. Tuthie prepar., Acet. Plumbi, Alum. usti, aa. 1 drachm.; Hydrar. Bichlor. gr. xii.; Ung. Rosati, 1 ounce. Misce.

¶ ℞ Adipis, 1 drachm.; Nitra. Argen. 1 gr. Misce.

¶ ℞ Hydrar. Bichlor. 1 drachm.; Adipis, 1 ounce. Misce.

from the Meibomian glands is very abundant, the nitrate of silver ointment must be preferred.

You have had ample opportunity in our wards to convince yourselves, that a treatment directed on these principles is decidedly efficacious. You must, however, always bear in mind, that glandular blepharitis is an extremely obstinate malady, one which will long set at defiance every means we employ. Aware of this circumstance, you must be cautious not to promise your patient more than you afterwards may find yourself able to perform.

Granular Blepharitis.

This form of inflammation is extremely difficult to eradicate, more so than any we have yet spoken of, as you may learn by examining several patients now in our wards. You will find that they have been for some time affected with this complaint, and that every means which has been hitherto employed has failed. I have myself occasionally been successful, but never until after a lengthened treatment. If you keep in mind the extreme tenacity of this complaint, you will not be surprised to hear that the remedies which have been recommended or employed are exceedingly numerous. These remedies are principally astringent topical applications; their number, indeed, is so great, that I shall not even attempt to name them, but merely lay before you the results of the frequent trials I have made of the more important preparations.

When I first began to treat these diseases, I thought the collyrium containing the sulphate of zinc likely to prove beneficial. I soon found, however, that no reliance could be placed upon it, and have, consequently entirely laid it aside. I next had recourse to a rather strong solution of the nitrate of silver, eight or ten grains to an ounce of distilled water. The greater number of you have seen how slight is the benefit to be derived from this remedy. Finding that these collyria appeared to have little or no influence, although so efficacious in some forms of ophthalmia, I successively tried all the principal preparations recommended by authors. Thus, in a great number of cases, I employed collyria containing subacetate* of lead, deutochloride† of mercury, calomel‡. I also employed laudanum in every form, the collyrium of Dupuytren§, the oint-

ments of Janin, Desault, Regent, &c. oxide of bismuth pulverised, a powder formed with equal parts of calomel and sugar: none of these remedies, however, appeared to modify the disease. I then had recourse to caustics. In 1831 I had under my care a female, who had been labouring under very severe granular blepharitis for some months. The conjunctiva of the superior eyelid—the principal seat of the disease—was thickened and covered with fungous granulations. I cauterized lightly, five or six times, the inflamed surface with the solid nitrate of silver, at six or eight days' interval, and obtained a complete cure. Since that time the nitrate of silver, although sometimes successful in my hands, has often failed to produce a similar result. Should you make use of this remedy, you must be careful how you apply it. The nitrate of silver should be drawn slightly across the inflamed conjunctiva, merely so as to whiten the surface. Were the cauterization to give rise to loss of substance, a cicatrix would be formed, which would in all probability produce entropion, with the usual train of disagreeable symptoms. When the solid nitrate of silver is used, this accident may occur, although the greatest circumspection has been employed; I have, therefore, sometimes substituted for it the sulphates of copper or of iron, the action of these preparations not being quite so energetic. The use of these remedies has been attended with advantage to the patient in some instances, but generally the disease has not been perceptibly modified.

I have not only given a trial to every kind of topical application likely to prove beneficial, but I have also had recourse to the various direct methods of treatment recommended by ophthalmologists. In a great number of cases I have applied blisters to the nape of the neck, the temples, the mastoid region, the arms, and the legs; I have even applied them over the orbit itself. In no instance, however, did these measures seem to make much impression on the disease. I have also tried blood-letting, colchicum, purgatives of all kinds—mercurial, saline, resinous—and still the results have been as unsatisfactory as before. I have employed iodine internally and externally, in every shape, and in a few instances with apparent success. The patients, however, were of a lymphatic constitution, had been long affected with this form of blepharitis, and had been treated in every possible manner. I dare not, therefore, assert that the iodine effected the cure; it may have done so, or it may not. The remedy which I have perhaps found the most efficacious, is a powder containing sulphur and calomel;

* R. Subacet. Plum. gr. v. ad xv.; Aquæ destill. oz. iv. Misce. Ft. collyr.

† R. Hydrar. Bichlor. gr. ʒ; Aquæ destill. oz. i. Misce.

‡ R. Calomel. dr. i.; Aq. destill. oz. vi. Misce. Ft. collyr.

§ R. Sacchari Albi, drachm ii.; Hydrarg. Binox. gr. x.; Tuthlæ, gr. xx. Tere et misce.

and yet, although in many cases it has proved exceedingly beneficial, its efficacy, I must confess, has in other instances often appeared doubtful.

This survey of the various remedies employed in the treatment of granular blepharitis has not led us to any very satisfactory conclusion; indeed, a really efficacious treatment of this disease is yet to be found. In the present state of our knowledge, no plan that we can adopt appears, in many instances, to exert much influence over its progress. The following rules may, nevertheless, be laid down:—

The patient should at first be bled two or three times, according to the strength of his constitution and the state of his general health; purgatives may also be given with advantage, and repeated once or twice. Then use the collyrium, containing the nitrate of silver, for six or eight days, applying at the same time the nitrate of silver ointment, if the free margin of the eyelid is inflamed. Should no amelioration take place during this period, it is useless to expect any benefit from the nitrate of silver; you must, therefore, give the other remedies we have examined a trial. If the various collyria and ointments fail to make any impression on the disease, you must, as a last resource, resort to cauterization with the solid nitrate of silver, the sulphate of copper, or the sulphate of iron.

Purulent Blepharitis of new-born Children.

Although by far the most serious of the different forms of inflammation we are examining, purulent blepharitis is the least refractory to the action of therapeutic agents. Leeches, emollient poultices, blisters, purgatives, &c. have been much extolled against this malady. They are undoubtedly valuable remedies, but as accessories only. Here, again, topical applications, aided by attention to diet, and the rules of hygiene, are alone to be depended upon for a radical cure, at least in the great majority of cases. Among these, the collyrium with the nitrate of silver or the salt in substance, when it is possible to cauterize directly the inflamed surface, have seemed to me more especially worthy of confidence. Sometimes the palpebræ are so much swollen that it is impossible to separate them sufficiently to employ the solution in the usual manner. In this case you may apply the remedy by means of a small syringe, the extremity of which is introduced between the palpebræ, near the outer angle of the eye. In every case, however, where it is practicable, the internal surface of the eyelids should be exposed, and the nitrate of silver lightly drawn across. Cauterization, practised

in the above manner, has proved, in my practice, the most successful plan of treatment.

In the chronic stage, methodical compression, in addition to the means I have already mentioned, has often proved extremely serviceable. I need scarcely add, that extreme cleanliness is indispensable; and that in all cases, when it is practicable, the patients should be removed to a pure healthy atmosphere, if the one they are living in does not present the desired conditions.

Ciliary Blepharitis.

I have but a few words to say respecting the treatment of ciliary blepharitis. It is the same, in nearly every respect, as that of the granular form of inflammation. The ointments most serviceable in the one, will also be found most serviceable in the other. Thus I have often subdued this affection with the nitrate of silver ointment, as also with those of Janin, Desault, and Regent. I must again remind you, that it is more especially during the first stage of this disease that the treatment you make use of, whatever it may be, is likely to succeed.

CLINICAL REPORTS

OF

DIFFICULT CASES IN MIDWIFERY.

By ROBERT LEE, M.D., F.R.S.

Physician to the British Lying-in Hospital, and
Lecturer on Midwifery at St. George's
Hospital.

[Continued from p. 562.]

SECOND REPORT.

Cases of Accidental Uterine Hemorrhage.

MAURICEAU has related thirty-five cases of uterine hæmorrhage in the latter months of pregnancy, in which the placenta did not present, but had adhered to the upper part of the uterus, and been detached by some accidental cause. Twenty-one of these cases occurred before the year 1682, and in almost all of them he delivered artificially, by turning the child. The treatment, in these cases was, therefore, the same as that which he had employed in the sixteen cases of placental presentation, referred to in my last report, and differed in no respect from the treatment recommended by Ambrose Paré and Guillemeau, in all the varieties of flooding in the latter months. But in the year 1682, Mauriceau's case, No. 307,

occurred, and in the treatment of this he deviated from the former practice; and instead of delivering immediately, by turning the child, he ruptured the membranes and left the labour to nature with the happiest result.

Mauriceau gives no account of the causes which induced him to make this important change in the treatment of cases of uterine hæmorrhage in which the placenta did not present, and to adopt that method which was afterwards so strongly recommended by Puzos, in 1743, and considered by himself and almost all later writers as his discovery. The great fatality which attended the operation of turning, in cases of accidental uterine hæmorrhage, was the reason assigned by Puzos for rupturing the membranes, and pursuing, what he terms, a middle course between forced delivery and leaving the process wholly to nature.

From the history of a case of accidental uterine hæmorrhage which occurred to Mauriceau in 1685, and another in July 1686, where he had recourse to the operation of turning, it is probable he was not convinced of its safety in all cases before the month of August 1686. His 450th case then occurred, and the pains being feeble, and the hæmorrhage great, he ruptured the membranes, by which means, he says, the infant could advance into the passage without pushing the membranes before it, and further detaching the placenta as it had previously done, and inducing the hæmorrhage. The liquor amnii having escaped, after the rupture of the membranes, the labour pains, which before had been feeble and useless, speedily became strong and efficient, and the patient was happily delivered of a living child in half an hour, and the mother recovered favourably.

His 429th case occurred in 1687, and in this, also, he ruptured the membranes, which, he says, should be done in all similar cases. Cases 480 and 496 occurred in 1697, and in both of these the membranes were ruptured, and the labour left to nature. The reason why he had recourse to this practice is again clearly stated in the history of the last of these cases. Case No. 542 took place in 1688. The patient was in the ninth month of pregnancy, and the feet presented, and he ruptured the membrane and extracted the child by the feet. In case 585, which occurred in

1690, he also ruptured the membranes as soon as they became tense, and again states the reason why he did this. In cases No. 624 and 633, which happened in 1691, hæmorrhage took place in the seventh and eighth months of pregnancy, and in these he also ruptured the membranes with the happiest effect. These facts prove that we are indebted to Mauriceau for a knowledge of the practice, now generally adopted, of rupturing the membranes in cases of accidental uterine hæmorrhage; or, that he was first who had recourse to it. His aphorism, No. 52, likewise proves that he was fully aware of the importance of rupturing the membranes when hæmorrhage occurred in the first stage of labour.

Portal, Rœderer, Levret, and other foreign authors, who succeeded Puzos, do not appear to have placed that reliance upon rupturing the membranes in cases of accidental uterine hæmorrhage, which the practitioners of this country have generally done since the time of Smellie. That Smellie was fully aware of its importance, and frequently employed artificial dilatation of the os uteri after he had ruptured the membranes in flooding where the placenta did not present, his works afford the most satisfactory evidence.

Dr. Rigby has related sixty-four cases of accidental uterine hæmorrhage, and though many of these "were very alarming cases, as the patients lost large quantities of blood, and were extremely faint, not one proved fatal, not one but terminated safely, by waiting for the efforts of nature to expel the contents of the womb*." At least eight of Mauriceau's thirty-five cases ended fatally.

Out of sixteen cases of accidental uterine hæmorrhage, where the membranes were ruptured by Dr. Rambotham, seven proved fatal†.

Thirteen cases occurred to Dr. Collins, in the Dublin Lying-in Hospital, two of which proved fatal; and ten to Dr. Joseph Clark, four of which ended unfavourably.

"In my own practice," observes Dr. Merriman, "upwards of thirty cases have occurred of accidental uterine hæmorrhage during parturition, in which I have adopted the method of rupturing

* Essay on Uterine Hæmorrhage, 5th edition, p. 262.

† Observations on Midwifery, vol. ii. p. 169.

the membranes, as a means of lessening or suppressing the flooding, and as yet have had no reason to be dissatisfied with the plan; for in every instance the discharge has entirely ceased, or has been so much diminished as to secure the safety of the patient; and yet there were some among these patients whose cases, from the profuse hæmorrhage, were abundantly alarming*." Dr. Meriman has informed me that he has since witnessed three cases in which the flooding was not arrested by rupturing the membrane. The twenty-seventh case now related was one of these.

Dr. Hamilton states, that during the last thirty years he has met with only two cases where he has adopted this practice, and on both these occasions he resorted to it with great reluctance. Except in cases where the os uteri is rigid, and where the operation of turning is opposed by the patient or attendants, he says the practice must be the same as in hæmorrhage, from the attachment of the placenta over the os uteri, that is, wherever danger threatens, the operation of turning must be had recourse to†.

The following report contains the histories of all the cases of accidental uterine hæmorrhage which have fallen under my observation, and of which notes were made at the time they occurred. A faithful account of all the unfortunate cases, as well as of those which terminated favourably, with the plan of treatment adopted, may assist in enabling us to determine the degree of reliance which can be placed upon rupturing the membranes—the period when it ought to be resorted to with the greatest prospect of success—and the method of accomplishing delivery where it entirely fails to arrest the hæmorrhage.

Of the twenty-four cases of accidental uterine hæmorrhage here related, there were six in which the discharge of blood was not checked by rupturing the membranes. In four of these, delivery was accomplished by craniotomy, one by turning the child, and one by the forceps. In sixteen of the twenty-four the membranes were ruptured with the most decided advantage; and in the remaining two cases of the twenty-four the membranes were not ruptured, nor was artificial delivery had recourse

to. There was internal uterine hæmorrhage in the four fatal cases. In two of these, I believe, death could not have been prevented by any means we possess, but it would have been better practice in these, and in some of the other severe cases, to have ruptured the membranes sooner, before the powers of the constitution were destroyed by the great loss of blood.

CASE XXIV.—October 29, 1827.

Mrs. Turner, No. 22, Drury Lane, in the 8½ month of pregnancy, mother of eight children, had nearly died from flooding in a former labour. Last night had a severe rigor of three hours' duration, followed by pains at intervals in the region of the uterus. At 8 o'clock this morning a great discharge of blood took place; and at half-past 11, when I first saw her, a very large quantity of blood had been lost. The countenance was pale; extremities cold; pulse 120, and extremely feeble. Blood still flowed from the vagina. The os uteri soft, and very little dilated, and the pains of which she complained produced no sensible effect upon it. I immediately ruptured the membranes, and this was followed by regular strong pains, the disappearance of the hæmorrhage, and the descent of the head of the child. The orifice of the uterus was also gently dilated during the pains, and for an hour there was a prospect of the labour being speedily terminated by the natural efforts. The pains, however, again became more and more feeble, and in two hours they ceased completely, and the hæmorrhage was renewed; and it was evident she would speedily sink if not delivered artificially. As I had good reason to believe that the child was dead, and feared, from the great exhaustion, she might die during the operation of turning, I had recourse to craniotomy, which was easily performed. The placenta immediately followed the extraction of the child, and large masses of coagulated blood. The hand was passed into the cavity of the uterus, and at the same time strong pressure made over the hypogastrium; but the uterus would not contract, and a stream of blood flowed over the hand till it was withdrawn altogether. Mr. John Prout then dashed cold water over the naked abdomen, and afterwards applied a binder and compress around the abdomen, and introduced linen rags, soaked

* Synopsis of Difficult Parturition, p. 119.

† Practical Observations, vol. ii. p. 264.

in vinegar and water, into the vagina. By these means the hæmorrhage was at last arrested, but she afterwards died from inflammation of the uterus.

CASE XXV.—On the 5th November, 1828, at 2½ A.M. Mr. Grant, of Thayer Street, called me to see Mrs. Jones, æt. 31, who was in the ninth month of pregnancy, and had been exposed to great fatigue during the whole of the preceding day.

At 5 P.M. of the 4th November the membranes gave way, and the liquor amnii was discharged without uterine contractions. Mr. Grant saw her soon after, and found the head presenting. There was no uterine hæmorrhage or unfavourable symptom. At 8 o'clock in the evening, her husband returned to inform him that she had fainted, and on recovering complained that she could not see the objects around her. There was then a slight oozing of blood from the vagina, and feeble pains. The symptoms gradually put on a more alarming appearance, till half-after two o'clock in the morning. The extremities were then cold; the respiration was laborious, and the pulse could not be felt; abdomen distended. The os uteri was fully dilated, and the head was sufficiently low in the pelvis for the forceps to be applied. There were feeble pains. I applied the forceps easily; but as she was almost insensible, and it was impossible to preserve her steadily in a position which admitted of the extraction of the head without injuring the soft parts with the instrument, and as the external hæmorrhage became much more profuse, and the symptoms more formidable, the blades of the forceps were withdrawn, and the delivery was accomplished in a few minutes by the perforator and crotchet. A large mass of clotted blood followed the child; and soon after the placenta, and an immense gush of fluid blood, succeeded. The hand was passed into the uterus, and a large quantity of coagula extracted; and the hand was kept some time in the cavity, to make it contract, but without success; and the flow of blood continued in spite of pressure, cold, and stimulants, till she sank, at 5 o'clock in the morning.

CASE XXVI.—On the 18th November, 1829, a midwife called me to a woman residing at 338, Oxford Street, who was in the ninth month of preg-

nancy, and had been suddenly attacked with uterine hæmorrhage, at 3 o'clock in the afternoon. She had been in perfect health, and had partaken of a hearty dinner, when a gush of blood suddenly took place from the uterus. Slight pains soon followed. I saw her an hour after this; when she was faint, and was suffering much from sickness and vomiting. The os uteri was dilated to the size of half-a-crown; the orifice thick and rigid. I immediately ruptured the membranes, and a large quantity of liquor amnii escaped. The hæmorrhage ceased, and the pains became strong and regular. An hour after, the pains had almost entirely gone off, and the flooding returned, with great faintness, hurried breathing, and feeble pulse. It was evident death would soon take place if delivery were not speedily effected. The thick rigid condition of the orifice rendered turning impracticable, and she was therefore delivered by craniotomy. The abdomen was compressed and the placenta extracted; but though very little more blood was lost, the extremities became colder, the breathing more laborious, and the vomiting more urgent; and she died in two or three hours after delivery.

CASE XXVII.—At 4 A.M. on the 22d June, 1839, I was requested, by a medical friend of great experience and reputation, to see a patient in the ninth month of pregnancy, who had awoke two hours before, with pain of the abdomen and sickness at stomach. Vomiting, coldness of the extremities, and great faintness, followed. As she was in perfect health at bed-time, the symptoms were believed to arise from indigestion, and some medicine was prescribed for its relief. At 4 A.M. the symptoms were not relieved, and pains in the lower part of the back began to be experienced, with a slight discharge of blood from the uterus. The orifice of the uterus was slightly open, and the lips thick. The head of the child presented. At 5, the hæmorrhage increasing, I ruptured the membranes, and gently dilated the orifice with the fingers during the pains. The flow of blood, however, still increased, and the symptoms of sinking became so alarming, that it was evident artificial delivery was the only thing that could save her life. The movements of the child had

not been felt since the first attack, and the orifice not being in a condition to allow of the easy introduction of the hand to turn, we resolved to have recourse to the perforator and crotchet. The delivery was easily accomplished; but though no blood was lost after the extraction of the child, and the placenta soon followed without assistance, she continued gradually to become worse, and died at a quarter to 8 o'clock.

We examined the body the following morning, and found the uterus soft and uncontracted, with a large dark-coloured clot in its cavity. The softening of the walls of the uterus, which could not be the effect of putrefaction, was so great that the points of the fingers could readily perforate them. The decidua was found adhering to a great part of the lining membrane of the uterus. The lining membrane itself was seen perfectly natural, at the upper and back part of the uterus, where the placenta had adhered, and every where else. There was not the slightest trace of any portion of this membrane being wanting.

CASE XXVIII.—On the 16th April, 1829, I was called by a midwife to a patient residing at 12, Great White Lion Street, who was at the end of the eighth month of pregnancy, and who had been attacked, fourteen days before, with a severe flooding. It had returned three or four times, to an alarming extent, and this day she was so much affected by it that it was obvious she would sink if not speedily delivered. No part of the placenta could be felt through the os uteri, which was soft and dilatable, though but little dilated. The presentation was natural. I ruptured the membranes, dilated the os uteri gently, and made pressure with the binder. Slight uterine contractions followed, and continued regular for a short time; but they gradually went off altogether, and the hæmorrhage was renewed to a dangerous extent. I passed up the hand into the uterus, and turned the child without difficulty. It was born alive and well. The placenta was removed soon after, and the hæmorrhage did not return; yet she sunk into a state of the most alarming exhaustion, and seemed for a considerable time on the point of expiring. She, however, gradually rallied, and in three weeks she was going about and suckling her

child, as if nothing unusual had occurred.

CASE XXIX.—At 8 P.M. October 24, 1835, I was requested, by the overseers of the parish of St. Andrew's, Holborn, to visit a patient in the parochial infirmary, who was in the ninth month of pregnancy, and had been attacked with profuse uterine hæmorrhage two days before, and which still continued. The head of the child presented; the os uteri fully dilated; membranes ruptured; pulse rapid and feeble. Extremities and face cold; great faintness. The pains were regular and frequent; but they had no effect in pressing the head forward. Mr. Dunn agreed with me in thinking that, as there was no great hæmorrhage going on, and the pains were regular, it would be proper to wait for the natural efforts, and support her strength by stimulants. After an hour, the coldness of the face and extremities had increased, the pulse was more feeble, and the pains, which were feeble and irregular, were producing no effect in advancing the head, and it was clear she would not be delivered without artificial assistance. The child had not been felt to move for two days. The head being sufficiently low for the forceps, and the parts dilated, I readily applied the instrument, and extracted the head. The cord was round the neck and did not pulsate. The placenta soon came away, and no hæmorrhage followed.

It would have been better practice in this case to have delivered sooner, by turning or craniotomy.

CASE XXX.—On the 12th July, 1835, Mrs. C——, when eight months pregnant, had a discharge of blood from the uterus, without any apparent cause. By remaining constantly in the recumbent position, with cold applied to the hypogastrium, the discharge diminished, but never entirely ceased. At 6 A.M., 22d instant, the flooding returned, with feeble pains at intervals. At 8, the os uteri was felt closed, and high up. At 3 o'clock the hæmorrhage continued, with great faintness, a rapid pulse, and pains in the abdomen like cramps.

I ruptured the membranes with difficulty, and discharged the liquor amnii, and gently dilated the orifice with two fingers, and made pressure over the fundus. The pains continued feeble and irregular, till 7 o'clock at night, when there was great faintness and a

feeling of weight and distension of the abdomen. The binder was firmly applied round the abdomen, and wine and other stimulants given; and the pains becoming stronger, the child was expelled dead, with the cord around its neck, at 9 P.M. A great quantity of coagulated blood escaped immediately after the child, and the placenta soon followed. More than half of the uterine surface of the placenta was covered by a dark-coloured clot of blood, which firmly adhered to it. This part of it was in a morbid state, being less than one-half thinner than the healthy portion, and the death of the child and hæmorrhage were both probably to be referred to this cause.

There could be no doubt about the propriety of rupturing the membranes in this case when it was done; but I am doubtful if it would not have been better to have delivered six or eight hours after, by turning or craniotomy, when the orifice was so dilatable as to allow of delivery with safety. Where there are symptoms of internal hæmorrhage, it is not safe to delay so long to empty the uterus.

CASE XXXI.—A lady, eight months pregnant, was attacked with uterine hæmorrhage, on the morning of the 14th November, 1838. When I saw her, at 5 P.M., the medical attendant informed me that the placenta did not present, and that the membranes were ruptured and the liquor amnii discharged. I found the orifice half dilated, the membranes unruptured, and the hæmorrhage still continuing, with great faintness. The membranes were immediately opened, and the hæmorrhage ceasing, and the pains becoming strong and regular, the child was expelled (dead) in half an hour. The placenta soon came away, and no flooding afterwards took place.

The placenta was in a diseased condition, some parts being three times the natural thickness, hard, and of a yellow colour. On cutting into these thickened parts, masses of coagulated blood were found in the interstices of the vessels. It was a perfect specimen of apoplexy of the placenta; and the death of the fœtus, and the accidental separation of the placenta, were both to be referred to this cause.

The good effect of rupturing the membranes was most striking in this case.

[To be continued.]

CLINICAL OBSERVATIONS

ON

THE USE OF THE AIR-DOUCHE IN THE
DIAGNOSIS AND TREATMENT

OF

DISEASES OF THE EAR.

BY T. WHARTON JONES, ESQ.

[For the Medical Gazette.]

No. I.

CIRCUMSTANCES having of late forcibly drawn the attention of the profession to catheterism of the Eustachian tube, and injections of atmospherical air into the tympanum, it behoves every one to contribute what mite of information he may possess, at all calculated to clear away the difficulties or doubts which hang about the subject; for, like most new modes of treatment, considerable misconception prevails regarding it, both as to the principle and performance of the operation, as well as its advantages, being on the one hand overrated, and on the other underrated.

Carefully observed and faithfully reported cases, it is obvious, are the only means of guiding to a correct judgment. Many cases are to be found in the works of Deleau and Kramer, but they do not record the daily progress of the treatment: for this reason I have thought the following cases, extracted nearly word for word as they occur in my case-book, might be read not without interest. And here I would express a hope that these contributions will be received as they are offered—viz. as imperfect observations on a subject not, indeed, of easy investigation, but by no means incapable of it—a subject which, it is hoped, surgeons will see the propriety of attending to more than hitherto, so as to be able to discriminate what can from what cannot be done, and what it is safe from what it is unsafe to do. In all this we must keep in mind the precept—"Nil fingendum, nil excogitandum, sed inveniendum quod natura ferat—quod natura faciat."

It is to be premised, that we endeavour to form our diagnosis of the state of the Eustachian tube and cavity of the tympanum on the principle already adopted in diseases of the chest—viz. to hear, when it is impossible to see or touch the disease, the only difference

being, that the air producing the sounds in the tympanum is put into motion artificially by the air-douche.

In regard to the air-douche as a means of treatment, all that can be effected by it is the gradual dispersion of any accumulation of mucus which may exist in the middle ear, or the rendering pervious the Eustachian tube, the walls of which have been glued together by thickened mucus.

The eye and ear, though apparently so very different from each other, coincide in many respects both in their structure and in their diseases. As the diseases of the former are much better known than those of the latter, the cautious use of this analogy will be of material service in our examination of the morbid conditions of the ear. Thus, for the sake of example, it may be mentioned that the conjunctiva, that part of the eye which is the seat of some of its most important diseases, is a mucous membrane situated at the peripheral surface of the eyeball. In the ear, some of the most common cases of the derangement of its function depend, in like manner, on the morbid condition of a mucous membrane—that lining the cavity of the tympanum—which, being situated at the peripheral surface of the labyrinth, the essential part of the apparatus of hearing, bears exactly the same anatomical relation to it as the conjunctiva does to the eyeball. Again, the nasal duct, a mucous canal, is the seat of some not unfrequent and very troublesome affections of the eye. The Eustachian tube, which resembles the nasal duct in every anatomical particular, does so also in a remarkable degree in its pathological states. Many more examples might be given of the similarity between the structure and diseases of the eye and ear, but these are sufficient to direct attention to the fact. It is to be borne in mind, however, that in consequence of the difference of conditions required for the exercise of the functions of the two organs, the same elementary form of disease shall have a very different effect on vision and hearing. For example, inflammation and obstruction of the nasal duct has not such a direct effect on the exercise of the function of the eye as the same state of the Eustachian tube has on that of the ear.

In the case of the eye, we can readily remove any accumulation of thickened mucus by means of a sponge and warm

water; but the more inaccessible cavity of the tympanum requires to be cleared out by more complicated means. In applying the air-douche for this purpose, or for the purpose of diagnosis, we ought to go on much the same principle as is followed when it is wanted to blow dust, &c. out of the pipe of a key—viz. give free room for the regurgitation of the air, both where the catheter is inserted into the mouth of the Eustachian tube, and where the nozzle of the tube of the air-press is inserted into the dilated end of the catheter.

But as in catarrhal ophthalmia, for instance, it is not enough to wipe away the discharge from the eye, but also necessary to make some local application to the conjunctiva, if not to employ some general remedy; so in many cases we must medicate the membrane lining the cavity of the tympanum at least (if we do not think it necessary to adopt any more general treatment), after the accumulated mucus has been removed by the air-douche; or in the event of no accumulation existing, there may still be a morbid state of the membrane lining the cavity of the tympanum, admitting of being as beneficially acted upon by some local stimulating application as the conjunctiva in chronic conjunctivitis.

It is as simple a matter to put a drop into the eye as to wipe away a discharge; but in the case of the ear, it is as complicated a proceeding to apply a remedy directly to the membrane lining the cavity of the tympanum as to disperse accumulated mucus. Watery injections are inconvenient in their application, and cause pain. The vapour of acetic ether, admitting of being easily sent in, and exciting no pain beyond a prickling sensation, has been found the best adapted.

The cases which derive advantage from the injection of ethereal vapour, Dr. Kramer considers cases of nervous deafness; but I believe some change in the membrane lining the tympanum, will, in many instances, be found a more likely cause of the symptoms than any affection of the auditory nerves, as well as the more likely condition to be benefited by the contact of the vapours of acetic ether.

We have, as yet, no correct knowledge of the diseases of the labyrinth. A correct diagnosis, as far as may be, having been formed, of course it is advisable to employ, before or in addition

to purely local treatment, leeching, blistering, or whatever other more general remedies may be indicated, the same principles that guide in the employment of general treatment in diseases of the eye, &c. guiding us here.

To place in a striking point of view how far the air-douche serves as a means of diagnosis, and how far as a means of treatment, I take the following calculation from Dr. Kramer's "Tabular view of the frequency and curability of diseases of the ear," remarking that it corresponds with my own, though less extensive, experience here. Out of 300 cases of diseases of the ear of all kinds, 200 in round numbers require the air-douche to assist the diagnosis, but about 30 only are curable by it. Of the remaining 170, about 30 are put down as cured, and about 50 as relieved, by the injection of vapours of acetic ether; this treatment having been continued for months. Of the remainder, 80 were considered as incurable from the first, and not treated (farther than the exploratory treatment, I suppose); the rest remained rebellious to treatment.

As, in the following cases, admeasurement of the hearing-distance by a watch is constantly referred to, it may be well to remark, that the capability of catching conversation is not always in proportion to the power of hearing a definite and equable sound, like that of a watch. The power to follow conversation, is, in fact, sometimes greater than we might suppose indicated by the distance at which a watch is heard; but, on the other hand, it is also sometimes considerably less, and this I have particularly remarked in cases treated, and so far improved, by the injection of vapours of acetic ether. Notwithstanding this, an approximate conclusion regarding the state of the hearing, sufficient to regulate our diagnosis and treatment, can be made by means of the ticking of a watch, particularly as the sound can be admitted to the ear under examination, always under similar circumstances.

CASE I. — Accumulation of Wax in external Auditory Passages. — Obstruction of Eustachian Tubes. — Cavity of the Tympanum free.

A. B., a woman-servant, aged 40.

Wednesday, August 8, 1838. — *Left ear*: Hearing distance by a watch, two inches, with noise in the ear sometimes like a waterfall.

A year last January, the affection came on for the first time, in consequence of cold. The deafness continued for about six weeks, and then went off suddenly. About the end of the following summer the deafness came on again, and then went off as before. Was attacked again in the following winter, but that time the deafness and noise in ear continued three months. The present attack has continued six weeks.

Right ear. — Hears the same watch at a distance of nine feet ten inches. Had noise in the right ear last year, but not now. The right ear was as bad as the left when first attacked.

Throat a little red, but not swollen. Sense of smell not so acute as formerly, and nostrils rather dry.

Considerable accumulation of dark-brown wax in both auditory passages.

Wax ordered to be syringed out, preparatory to further examination.

Thursday, 9th. — Has had both ears syringed out. The passage on the right side is now quite clean, and free from any accumulation of wax; but the lower wall, about the middle, has been fretted by the point of the syringe. The membrana tympani on this (right) side, is opaque and slightly yellow; the handle of the malleus, however, can be distinctly seen.

Still some wax in the left passage, so that only the lower part of the membrana tympani can be seen; and this part appears to be in the same state as the membrane is on the right side.

Noise in the left ear entirely gone, but still feels stuffed.

Hearing distance of the right ear, fifteen feet, seven inches; of the left ear, fifteen feet, four inches.

Ordered the left ear to be syringed again, and a solution of the Acetate of Lead (gr. iij. Aq. Dest. ℥j.) to be poured into the auditory passages two or three times a-day.

Friday, 10th. — Hearing distance of right ear, thirteen feet, nine inches; of left ear, nine feet, six inches.

Still some wax in left auditory passage, which was ordered to be syringed out again.

A feeling of stuffing, in both ears, proceeding from the nose, as if she could not breathe.

Applied the air-douche to the left side, and found that the air did not penetrate to the tympanum.

To take a little medicine.

Saturday, 11th.—Still some wax adhering to the upper wall of the left auditory passage, but the whole of the membrana tympani can be seen. Has had some noise in the left ear like the singing of a tea-kettle.

Hearing distance of the right ear 10½ feet; of the left ear, 14 ft. 9 inches.

Applied the air-douche again to the left ear, but the air did not penetrate. Applied the air-douche also to the right ear. The air penetrated at first in a small whistling stream, and then with some gurgling, but yet not very freely. Stuffing on the right side a little relieved, but still exists on the left side.

The right ear heard the watch, after the application of the air-douche, at the distance of 17 feet 9 inches; the left ear at 11 feet 10 inches.

Monday, 13th.—Left auditory passage is now quite clear. Still some noise in left ear like the ticking of a watch, but not constant.

Applied the air-douche to the left ear. The air now penetrated a little, so that the sensation of stuffing is somewhat less. Applied the air-douche to the right ear also, when the air entered more freely than on Saturday, and with a rushing and gurgling sound.

Hearing distance of the right ear is now 18 feet 4 inches; that of the left ear is 19 feet 9 inches.

Tuesday, 14th.—The right ear just just hears the watch from one corner of the room to the other (about 25 feet). No stuffing.

Left ear.—Stuffing less; still some noise like the ticking of a watch occasionally. Just hears the watch from one corner of the room to the other.

Applied the air-douche to the left ear only to-day. The air now enters freely with a rushing and howling sound. After the douche, no noise in the ear, nor feeling of stuffing. The heaviness and confusion of the head which she had formerly are now gone. About five minutes after the application of the air-douche, heard the watch with the left ear pretty distinctly from one corner of the room to the other.

Wednesday, 15th.—Has had no noise in the left ear since yesterday. Stuffing very much less. No stuffing in the right ear. Throat and tongue pretty well.

Hears the watch distinctly with both ears from one corner of the room to the other.

To come again on Friday.

Friday, 17th.—Noise in the ears recurred this morning, together with the sensation of stuffing.

Right ear 14 feet 8 inches; left ear 16 feet.

Applied the air-douche to both sides. There was some gurgling heard in the right tympanum. Some stinging pain felt, more on the right side than on the left, when the air is sent in with any degree of force.

After the douche, heard the watch from one corner of the room to the other, but less distinctly with the right ear than with the left. Noise and stuffing gone.

Saturday, 18th.—No complaint, and hears well. Dismissed, cured.

REMARKS.—Though a simple, this is a very valuable and instructive case; and as such, I have chosen it to begin with.

The first thing to be noted is, the coincident accumulations of wax in the external auditory passages, with obstruction of the Eustachian tubes, complete on the left side, and incomplete on the right—circumstances indicating the previous existence of erythematous inflammation of the external auditory passages, and a catarrhal affection of the mucous membrane of the middle ear.

Though the right and the left auditory passages were equally stopped up with wax, the Eustachian tube of the right side was not completely obstructed; hence, perhaps, the cause of the difference in the power of hearing presented by the two ears before the removal of the wax.

But the circumstance which merits particular notice, and which, according to prevailing notions of the physiology of the ear, was not to have been expected, is the great increase of the hearing distance after the removal of the wax, notwithstanding the existence of obstruction of the Eustachian tubes discovered by the application of the air-douche—obstruction so complete on the left side as not to yield to the air-douche until the third sitting.

The obstruction of the Eustachian tubes appeared to be owing to a gluing together of their walls by thickened mucus. The sounds produced by the entrance of the air indicated a pretty natural state of the cavity of the tympanum; hence the rapid improvement in

hearing consequent on the removal of the wax, even while the Eustachian tubes remained obstructed, and the still further and equally rapid improvement, according as the latter were rendered pervious.

[To be continued.]

FATAL CASES

OF

OBSTRUCTION AND ENORMOUS DISTENSION OF THE BELLY,

Arising from a peculiar Conformation of the Colon.

BY ANDREW BUCHANAN, M.D.,

President of the Glasgow Medical Society, and one of the Senior Surgeons to the Glasgow Royal Infirmary.

[Concluded from p. 644.]

[For the *London Medical Gazette*.]

THE three cases which I have just narrated exhibit many striking points of resemblance. In all of them the most remarkable symptom was the extreme distension of the abdomen. So great was this distension, as to communicate, both to the unhappy sufferers themselves and to the bystanders, an apprehension of the actual bursting of the belly. On opening the cavity after death, the inflated bowels were propelled with such force through the wound, as rendered extreme caution necessary to avoid injuring them; and on puncturing the bowels themselves, the imprisoned gases rushed forth like the winds from the cave of Æolus, or, to speak a little more plainly, with a violence that would have extinguished a candle held at some distance from the aperture. To those who have not seen this complaint, I cannot convey a more accurate idea of it than by comparing it to the disease which occurs in cattle after eating too much wet clover or other succulent herbaceous food. I have seen several cows affected with this complaint, and in none of them was the swelling greater than in the cases described above.

The next most remarkable circumstance attending these cases was the total obstruction of the bowels; to overcome which the most powerful purgative medicines introduced into the stomach, and all clysters and suppositories,

were quite ineffectual. At the same time, the facility with which clysters could be injected into the rectum, as well as the examination of that intestine with the finger, showed the cause of the obstruction to be at some distance from the external orifice.

Another circumstance worthy of remark is, that in all these cases, previous to the occurrence of complete obstruction, the bowels had been long affected with constipation. This was rendered obvious, independently of the report of the patients, by the accumulation of feces in the bowels, which was so very large, that it must have been a long time in collecting. The same point was still further evinced by the extreme dilatation of the colon, which shewed clearly the existence of a dilating cause, which had been in operation most probably for years before the death of the patient. The fully inflated colon, in its normal state, I have found to be about two and a half inches in diameter: now in the cases above mentioned, it was from five to six inches in diameter; that is, it contained at least four times as much feces as when quite full in its ordinary state. It was the large intestine alone that was thus dilated; for the small intestines, although fully inflated, were not wider than natural.

Death took place in about twelve or fourteen days from the occurrence of the total obstruction of the bowels. The disease must therefore be regarded as an acute one; and this enables us to distinguish it from certain chronic affections, attended with swelling of the belly and obstruction of the bowels. To what cause is death to be ascribed in such cases? The mere obstruction of the bowels cannot be considered as an adequate cause, since men have been known to live for more than a quarter of a year without any alvine evacuation. Neither was the cause inflammation of the bowels; for although inflammation had obviously been going on in one of the cases mentioned above, it must have been a mere accessory, since there was no inflammation in the other two cases. Can the elevation and immobility of the diaphragm, and the encroachment of the abdominal viscera upon the cavity of the heart and lungs, be regarded as the cause of death? It may probably be an accessory cause; but I am disposed to think that the principal cause of

the patient's death is the excessive distension of the belly, which produces the most excruciating and unremitting pain, and thus gradually exhausts the powers of life. In the analogous disease of cattle, already mentioned, death seems to proceed from the same cause; but it takes place in them much more rapidly—generally in the course of a few hours—owing to the distension being much more sudden, and acting upon tissues not previously habituated to that kind of irritation.

The symptoms enumerated above—the enormous tympanitic swelling of the belly, the complete obstruction of the bowels, the emptiness and large size of the rectum, and the acute course which the disease observes—appear to me to be sufficiently characteristic to enable us to distinguish this disease from all other kinds of tympanitic swelling and constipation.

With respect to the appearances on dissection, in all the cases the colon was the organ principally, and, as was universally thought, primarily affected. It was much longer than usual, and occupied an unwonted situation, lying in front of the small bowels; it was also much enlarged, having an area four times larger than when fully distended in its ordinary condition. These appearances are partly to be referred to primordial conformation, and partly to the long-continued action of a distending cause. That the great length and unusual disposition of the sigmoid flexure must be referred to primordial conformation cannot, I think, be doubted. On the other hand, the great width of the intestine must have been gradually produced, and could not proceed from original formation, as was obvious from the attenuation of its coats and other appearances. Before I was aware that the length of the intestine varied from original conformation, I laboured to persuade myself that the elongation of the colon, as well as its dilatation, might be the effect of long-continued tension. How easily we impose upon ourselves by such reasoning will be seen from a case quoted below, in which the colon, from original formation, was shorter than usual; and the narrator, to explain the difficulty, argues that an increase of width must be necessarily attended with a diminution of length.

In the two cases last narrated, a twist of the colon was supposed to be the cause

of the obstruction of the bowels; and this opinion accords with that entertained of all the other cases of this disease which I have found on record. Nevertheless, I much doubt the accuracy of this opinion. When we remove the intestines, to examine them out of the body, we find them very apt to become twisted, knotted, and otherwise variously entangled. Nothing so well illustrates the wisdom of the provision by which such accidents are prevented from taking place within the body. By a twist of the intestine may either be meant, that a single ply of the intestine is twisted round its own axis, or that an angle of the intestine is twisted—that is, that two conterminous plies are twisted round each other. This last kind of twist will be adverted to in reference to a case quoted below. It is certainly possible, but we cannot easily conceive a force acting within the body capable of producing it, and maintaining it when produced. The other kind of twist is that supposed to have existed in all the other cases. I cannot, however, see how it is possible, without an opening in the mesocolon large enough to admit of the intestine revolving on its axis, to produce such a twist as would cause obstruction of the bowels. I can conceive it possible that a violent and irregular action of the muscular fibres could produce a twist, half round, of a particular portion of the intestine; by which I mean, such an oblique folding of that part of the intestine, that a given point of its circumference would be carried from the side on which it naturally lay to the side diametrically opposite; but I cannot conceive the production of a complete twist of the intestine, by which I mean a point of the circumference being carried first to the opposite side, and then completely round to the situation from which it originally set out. I can conceive no force, acting within the body, capable of producing such an effect; and, waiving the question of the existence of an adequate force, I believe the effect to be physically impossible without rupture of the mesocolon. Still further, any twist depending upon irregular action of the muscular fibres could not, as appears to me, be maintained for so long a period as twelve or fourteen days, and still less for whole months. Now I have shown that, in the preceding cases, the bowels bore marks of having been for a long

time in a state of obstruction, although it was only when that obstruction became complete that the disease here under consideration was developed.

In the history of the case first narrated, I have described in what way the proximal convolution of the sigmoid flexure passed in front of and compressed the extremity of the colon, a little above where it terminates in the rectum. Now when we consider the great length and unusual position of the colon in the other two cases, and in similar cases upon record, it appears to me not improbable that the same, or a similar cause of obstruction, may have existed in them also. There is one circumstance with respect to the course of the colon in case first, which may either be explained as proceeding from original conformation, or from subsequent displacement; I mean the sweep to the right which the intestine took after leaving the left ileum, and before ascending to the epigastrium. That this disposition was not the effect of primordial conformation, it is impossible to say; but we might oppose to that opinion the analogy of two cases described above—that of Dr. Hunter, and that observed by myself at the Cholera Hospital—in which the intestine, immediately after leaving the ileum, passed obliquely to the upper region of the belly. If such was also the original conformation in case first, we must suppose that when the feces began to accumulate in the oblique portion of the colon, they carried it downward by their weight towards the pelvis, as appears to me would naturally take place.

In describing the two cases referred to at the beginning of this essay, I mentioned as a circumstance worthy of remark, that in both of them the colon entered the pelvis on the right side, instead of descending in the usual way over the promontory of the sacrum, and entering it in the centre. The end of the colon was thus removed as far as possible out of the reach of the danger of being compressed, by the proximal portion of the sigmoid flexure passing in front of it. It seemed, therefore, as if nature, retaining in her vagaries the same provident spirit which distinguishes her more uniform operations, had foreseen the danger to life which the unusual formation of the colon would produce, and had taken steps to avert it.

I have been for many years past anxious to have an opportunity of dissecting a cow dead of over-distension of the belly. I entertain little doubt that, on examination, it will be found that the distension of the paunch and adjacent parts of the alimentary tube produces, by its pressure, a mechanical obstacle to the transmission of the excrementitious mass; or, more probably, prevents the act of regurgitation, which, in ruminating animals, is essential to digestion. This appears to me at least to be the most probable explanation of the confinement within the body of the animal—of the wind and excrement with which it is distended almost to bursting. Should this conjecture be verified, there will be a very close analogy between this disease of cattle and the disease of the human subject described above. In both it is the severe tympanic distension of the belly that occasions death; and the chief difference between them appears to be, that while in cattle the tympany is produced by the sudden ingestion of flatulent substances into the stomach, in the human subject it is produced by the gradual accumulation of them in the colon.

From the account now given of this disease it must be obvious that, in treating it, all purgative medicines are useless, as well as all clysters administered in the ordinary way, so soon as the rectum has been emptied of feces. The first and great object of our treatment should be to remove, if possible, the mechanical obstacle to the evacuation of the bowels. To facilitate this object the patient should be placed upon his hands and knees, or standing, with his body inclined forward, which has the effect of freeing the end of the colon from the weight of the first turn of the sigma lying over it. An instrument should now be introduced into the intestine, for the purpose of dilating the compressed portion. The instrument which appears to me best adapted for this purpose is the œsophagus tube, armed with a large sponge at the end. The sponge is easily fastened by means of a string attached to it, and passing through the tube; while, by means of the other half of the string running outside the tube, the sponge can be withdrawn when we wish to use the tube as an injecting instrument. In the first instance, however, we are to use it as a probe and dilator. After carrying it up

as high as we may deem necessary, it is to be withdrawn, when, by examining whether or not the sponge be smeared with feces, we can ascertain whether or not it has passed the compressed portion of the intestine. If it have passed, we should reintroduce it, and by passing and repassing it up and down through the compressed part, we should endeavour if possible to form a free passage, by making an indentation in the soft feculent sac lying, in the position of the body here supposed, below it. Very probably we may succeed in this way in procuring a discharge of feces, which, without any contraction of the muscular fibres, would be protruded along the passage by the elastic force of the condensed air in the surrounding intestines. If we do not succeed, the tube must be again carried up as far as possible, and the sponge withdrawn, when we must inject tepid water or air, as may be found best to answer the purpose.

Suppose that we do not succeed in procuring any evacuation by these means, or that we succeed only partially, so that the tension remaining undiminished, it is still obvious that death must ensue, is the patient to be abandoned to his fate, or are there still other means of relief in our power? I answer without hesitation, that in the circumstances just supposed we should puncture the bowels. With what view should this operation be put into practice? Not certainly for the evacuation of feces, which could not be prevented from escaping in part into the peritoneal cavity, and would so cause death. It should be performed, therefore, solely with the view of discharging air from the bowels, which will have the double effect of relieving the sufferings of the patient, and facilitating subsequent attempts to evacuate the feces through the natural passages. In what situation should the puncture be made? This question reduces itself to the more simple one—in what part of the colon should the puncture be made? for there is no other part of the intestine, in such cases, accessible to puncture. The whole of the sigmoid flexure, and greater part of the left colon, containing only feces, are excluded from consideration, and the transverse colon is excluded by the uncertainty of its position. The right colon is the part of the intestine most uniform in its seat, and it is likewise distended almost entirely

with air. I would therefore recommend puncturing the right colon, about the middle of its course, with a small trocar. On withdrawing the stilette, the confined air should be allowed fully to discharge itself, after which the attempts to evacuate the bowels may be renewed, probably with better success.

Still further to illustrate this disease, I subjoin the history of the only three examples of it which I have been able to find in the records of medicine.

The first occurs in the *Sepulchretum Anatomicum* of Bonetus—the father of pathological anatomy, and, we may therefore add, of rational medicine. It is extracted from the observations of Tidiæus, who flourished in the end of the sixteenth century; but not having access to the original work, I translate from the *Sepulchretum*, lib. iii. sect. xiii. p. 197:—

A pregnant female, during the whole period of gestation, and not less during the last month than before, was engaged in needlework without ceasing, from an early hour in the morning till late at night, constantly sitting, as it were, contracted and incurvated upon herself, with her head down, as is usual with those so occupied. Hence she became so costive, that she would have no movement for whole ten, fifteen, or even twenty days. This she esteeming of small consequence, neglected, persevering as long as she was able at her sedentary employment, until, on account of the incredible swelling and pain of her belly (both of which proceeded from the retention of the contents of the bowels), she was no longer able to sit at work. The unhappy woman at length takes to bed, the pain and swelling of the belly, and feeling of anxiety thence arising, increase daily, and to such an extent, that it was obvious to all who saw her that she was in a most dangerous condition. Suppositories and clysters, administered to move the bowels and alleviate pain, availed but little; for whatever was the quantity or quality of the clyster administered, it only remained some time in the rectum (as afterwards appeared), soon coming away, and bringing nothing along with it. Labour at length came on, and the midwife being called, the fœtus, although immature, was nevertheless born alive. But notwithstanding the expulsion of the fœtus the belly did not in the least diminish in size, but was

just the same, that I may not say greater; and the swelling, and resistance, and pain remained, so as to be terrible in appearance to the bystanders, who thought that the belly would burst on account of the excessive tension. It is needless to say more: the patient died, herself requesting that her belly should be opened after death and inspected, which was accordingly done.

The peritoneum being divided, and the omentum lifted up, the colon was the first object that presented itself, removed from its natural situation, and altogether gangrenous. Its colour was red, with a tinge of green (*ex caeruleo rubricano*), which colour also was visible through the abdominal muscles and skin, attenuated by over-distension. The intestine was distended with mere excrement, and of such a size as to resemble, in that respect, a jug, that would admit a boy's head. All the other higher intestines were, beyond measure, turgid with flatulence: hence the colon, at that part where it descends from the left kidney, had departed from its natural situation, as far as the region of the umbilicus, under which, situated between the tracts of the recti muscles, it was seen descending in the middle of the belly, in a straight line from the stomach. This arose partly from the pressure of the wind contained in the bowels behind it, and partly from the quantity of excrement in itself, which, extending the intestine laterally, rendered it shorter, or caused a contraction in point of length. Hence, without doubt, a twist of the lower part of the colon having taken place, where it is continuous with the rectum, the passage of the egress of faeces and wind, and for the ingress of clysters, was completely shut up. On opening the colon, such a glut of fetid excrement flowed forth as if you had slain some beast of burden. And, hence it is evident what may be brought upon pregnant women by a too sedentary mode of life and neglect of functions of the bowels, more especially in the last month of gestation.

It is worthy of remark, that the twist of the colon is here spoken of rather, apparently, as a deduction of reason than as a matter of observation. "*Hinc absque dubio ipsius coli.....contorsione facta.*" To me it appears highly probable that the severity of this disease arose from the unusual position of the lower part of the colon. It lay in front

of the small bowels, right in the middle of the belly, in which situation it must have been compressed, between the inflated small bowels lying behind it, and the gravid uterus lying throughout its whole course in front of it. This is, therefore, obviously the same disease as before. The symptoms are graphically described, and coincide exactly with those observed in the preceding cases: and further, the disease originates in an abnormal formation of the lower end of the colon. It is, however, a variety of the disease, the colon being shorter than natural instead of being longer. Such a formation could not, so far as I can see, be dangerous but to pregnant females. The fact of the bowels being seen through the parietes of the belly is confirmed by a case given below.

The next case was observed by Dr. Abercrombie, of Edinburgh, in the year 1815, and is recorded by him in the 16th vol. of the *Edinburgh Medical and Surgical Journal*, p. 15.

A man, aged 60 (23d April, 1815), was affected with vomiting; pain in the abdomen, which was swelled and tympanitic; obstinate costiveness; pulse 108, and soft; countenance pale and exhausted; pain not increased by pressure. Had been ill a week, during which powerful remedies have been employed, without benefit. Had formerly two attacks of the same kind, one of which continued a week. This man lived in great distress till the 28th, without any remarkable change in his symptoms. The swelling of the abdomen increased gradually, until it resembled that of a woman at the most advanced period of pregnancy; yet, to the last, he could bear pressure upon every part of it. His pulse varied from 108 to 116. His death was sudden: he had been out of bed and dressed the day before, and, on the morning of the day on which he died, he did not appear worse than usual.

On opening the abdomen, a viscus came into view, which appeared to be the stomach, enlarged to three or four times its natural size. On a more accurate examination, this turned out to be the sigmoid flexure of the colon, in such a state of distension that it rose up into the region of the stomach, and filled half the abdomen. The stomach was contracted and healthy. The small intestine was healthy at the upper part; lower down it became distended, and of

a dark colour; at the lower part it was very much distended, with some spots of gangrene. The colon was greatly distended—in some places it was not less than five or six inches in diameter—and terminated in the distended sigmoid flexure already mentioned. The rectum was healthy, and collapsed. The sigmoid flexure was of a dark livid colour, and contained air and thin feces. What appeared to be the cause of this affection remains to be mentioned. The enlarged sigmoid flexure was found to have taken a remarkable turn upon itself, so that what was naturally the right side of it lay to the left, in contact with the descending colon, and the left or ascending part of it lay on the right. The consequence of this was, that the rectum, as it descended from the former, passed down behind the lower or first turn of the sigmoid flexure, where it first takes the turn from the descending colon: also, the rectum itself, at this part, received a twist, as if half round. Exactly at the point where this twist was, the distension and dark colour of the intestine terminated abruptly, and it became white and collapsed. At this part, however, there was no mechanical obstruction, for the parts were pervious, and, except the twist, perfectly healthy: and farther, it happened, in this singular case, that I had an opportunity of ascertaining the state of them during life. On the 25th, three days before his death, having exhausted all the ordinary means, I was induced to examine the rectum with a large ivory-headed probang, and I found, at a certain depth (which was afterwards found to correspond with the point where the rectum was twisted), a slight obstruction to the passage of the probang; however it passed up with little difficulty, and was withdrawn without any. A piece of the intestine of an animal, tied at the end, was carried up beyond this point, and then strongly distended by injecting water into it. In this distended state it was retained for some time, and then slowly withdrawn; but no discharge followed, though, as I have already mentioned, the distended part contained only air and fluid feces.

The case is valuable, on account of the singularity of the course of the sigmoid flexure of the colon, and the minuteness with which it is described. It is to this case that allusion is made

above, in speaking of the possibility of a twist occurring in an angular portion of intestine, such as is the sigmoid flexure. Here the two conterminous portions of the colon, forming the angle, were turned half round each other; but it is obvious that there is no physical impediment to their making a complete revolution, or even more than one: but what force acting within the body could produce such an effect? The cause of the obstruction seems not to have been the twist, but the compression of the lower end of the colon, between the proximal end of the sigmoid flexure, greatly distended, lying in front of it, and the inflated small bowels lying behind it. This is, therefore, the very same kind of obstruction that occurred in the case first narrated, only arising from a different disposition of parts. The marks of inflammation observed, render it probable that the patient's death was accelerated by that cause, and did not proceed from mere overdistension of the belly, which was no larger than that of a woman at the full period of gestation. The author, indeed, has ranked this case among those unconnected with mechanical obstruction of the bowels. He seems, also, to have looked upon the length of the sigmoid flexure of the colon as the effect of distension, and not of original conformation.

The only other case which I have to bring forward occurred in our own city, and was treated by the late Dr. Richard Miller, in the Royal Infirmary, in March 1819. No account of it, so far as I know, has yet been published. The following abstract is taken from the 14th volume of the Manuscript Essays of this Society:—

Michael O'Connor, æt. 47, labourer. Nothing had been passed through his bowels for seven days before his admission in the hospital, and he had been previously subject to constipation. His belly was much swollen and tympanitic. The strongest purgatives and injections were administered without any effect. Dashing cold water upon the feet, and every thing else that could be thought of, was tried, but the bowels could not be moved. Meanwhile, the swelling of the belly gradually increased, and, before the patient died, the integuments and muscles of the abdomen were so much upon the stretch that "the convolutions of several of the

intestines" could be seen through them. Death took place three days after admission to the hospital, and ten from the time of the last alvine discharge.

The stomach was healthy, and quite empty. The small intestines were greatly distended by flatus of an extremely foetid odour. The colon was also most enormously inflated, particularly the ascending and transverse portions. The left colon, again, and the sigmoid flexure, were literally stuffed to the utmost with feculent matter, and about six inches in diameter. At the termination of the colon in the rectum, over the promontory of the sacrum, the gut formed a turn on itself, from left to right, as if half twisted round. From the pressure exerted from above, by the "extreme" collection both of excrement and air, this twist was found to form a complete obstruction. The mucous tissue of the intestines, especially of the colon, was of a reddish colour throughout. This appearance did not extend beyond the twist, in the situation of which it was of a much deeper hue than elsewhere. The rectum was empty, and of its natural colour. The peritoneal covering of the bowels was every where natural, as well as the other abdominal viscera. It is to be regretted that nothing more is said of the length and course of the sigmoid flexure of the colon than that "this part of the gut lay more inclined towards the linea alba than in its natural situation;" and at another place, that "the sigmoid flexure was inclined, and actually a little displaced upward."

Glasgow, 110, St. Vincent Street,
June 28, 1839.

PRACTICAL OBSERVATIONS

ON THE

TREATMENT OF STRICTURE OF THE URETHRA.

By MR. URE.

[For the London Medical Gazette.]

By stricture is meant such a morbid contraction of the urethra in one or more points as impedes or obstructs the flow of urine.

The canal of the urethra has, in the natural state, a diameter of about four lines nearly all its length; but its orifice

is usually narrower, being only two-and-a-half or three lines in diameter.

Strictures have been divided into two kinds: the one spasmodic or inflammatory, susceptible of spontaneous resolution; the other chronic, depending on organic change. The latter present every variety of texture, from simple swelling of the mucous membrane to callous thickening consisting of dense gristly-like substance. The most common form is that which resembles the effect of a thread tied round the canal; though by irritation or improper treatment, it will ere long pass into the indurated state just described.

The more prominent local symptoms of the chronic variety are—a slight discharge of matter from the urethra, and a frequent desire to evacuate the urine, which issues in drops, or in a forked, twisted, wiry, or thread-like stream.

As a great proportion of the fatal diseases of the bladder may be traced to this source, I have been induced to draw up the following observations, with the view of pointing attention to certain modes of treatment in which, perhaps, some novelty may be found.

I. Of dilatation.—This plan is adapted to the majority of cases, and deserves the preference whenever it is practicable. Its application, however, requires both skill and consideration, much more, indeed, than is commonly supposed.

When a bougie or sound is introduced along the urethra, it determines, independently of any mechanical operation, a distinct physiological effect, characterized in the first instance by a modification of the sensibility, a quickening of the capillary circulation, attended with augmented secretion; but afterwards by subsidence of irritation, and restoration of the healthy condition of the part. The process of methodical dilatation ought to be conducted as gradually and cautiously as possible, commencing with slender gum-elastic or catgut bougies, which will pass through the stricture without producing pain or hæmorrhage. M. Beniqué has devised the following ingenious method of penetrating narrow, and otherwise impervious, strictures*. He employs a curved metallic tube (*b*), whose anterior extremity is a little widened, in order to give in that point adequate thickness

* De la Rétention d'Urine, p. 14.

to the metal. A mandrel (*c*), accurately adjusted, converts the end of the tube into a smooth and rounded sound, presenting no inequalities capable of injuring the passage it has to traverse.

Whenever the stricture offers to the sound such resistance as moderate pressure will not overcome, it is to be there fixed, the contained mandrel withdrawn, and replaced by a bundle of parallel bougies, the number of which will be greater, and the diameter smaller, in proportion to the development of the stricture. As soon as the end of this bundle meets the obstacle, we keep the tube with one hand in the same position, while with the other we endeavour to push gently one of the bougies forwards through the stricture. Should the first fail, we try the rest in succession, till we accomplish the desired object. This done, we draw out the rest of the bundle, and then the metallic tube. The bougies ought to project four or five inches from the external orifice of the tube, to allow freedom of manipulation.

In this way a bougie has been presented to every point of the opposing surface, without subjecting the patient to annoyance from necessity of repetition. When the stricture resembles a cone, whose base is directed towards the meatus, and whose truncated apex gives exit to the urine, M. Beniqué replaces the mandrel, not with a bundle, but with one, or at most two bougies. The chief advantage of this plan is its counteracting the resiliency of the bougie.

The annexed figures represent the application of the instrument.

At first, especially with irritable subjects, the introduction of a bougie should be only momentary, though it may afterwards be prolonged to a few minutes. Having derived the full benefit from the use of the more slender instruments, others should be passed commensurate in size with the progress of dilatation. Bougies that are cylindrical to within about an inch from the extremity destined to enter the bladder answer well; but when the stricture is situate in, or beyond the bend of the urethra, the gum-elastic sounds, *à courbure naturelle*, are preferable, as they are not susceptible of injuring the urethra. The temporary dilatation, performed at suitable intervals, is more beneficial than the permanent, recommended by several eminent surgeons.

For when a bougie is too frequently introduced, or too long kept in, the urethra, constantly irritated by the presence of a foreign body, re-acts, and renders nugatory the effects of treatment.

FIG. 1.

FIG. 2.

FIG. 1.—*m, m, m*, Section of a stricture whose orifice, *a*, is not situated in the centre of the canal.

b, A metallic canula, closed by a moveable obturator, *c*.

FIG. 2.—The obturator has been taken out, and replaced with a bundle of small catgut bougies, *d, d, d, d*. Each has been individually advanced in succession; one of them, *b*, having penetrated the stricture, has passed beyond it.

In many instances the persevering use of these instruments will effect a perfect cure in a few weeks; in other cases months will elapse ere the patient derives the wished-for relief. One of the best means of accomplishing the dilatation is by the softened ivory bougies, which I was led to try at the suggestion of Dr. Güterbock, of Berlin. These, consisting of condensed gelatine, are somewhat elastic, and extremely tough, so that there is no risk

of their breaking. They present the essential attributes of a bougie in the highest possible degree. Nothing can exceed their pliancy and lubricity; and the ease with which they glide along the urethra is very remarkable. A field-officer, for whom I have employed them with success in relieving the incipient symptoms of stricture, was quite unconscious of the transit, and expressed astonishment upon my telling him the instrument had reached the bladder. In this instance a highly polished gum-elastic bougie, No. 4, would not pass without creating uneasiness, while an ivory one, two sizes larger, traversed as above described.

There is no more effectual means of subduing the morbid sensibility of the urethra, which is so frequently the sequel of gonorrhœa and the forerunner of stricture, than the use of the soft ivory bougie, introduced daily, or every second day, and withdrawn after the lapse of a few minutes. The instrument should have a volume which will permit it to penetrate with facility, and be introduced with great slowness and gentleness. The effect thus produced is more constantly successful than any other treatment, and if somewhat tardy, is at the same time more lasting. The prevailing practice of thrusting in the rude ill-finished bongs commonly kept in the shops, is extremely pernicious.

Febrile paroxysms resembling ague occasionally follow the passage of instruments into the urethra; these may be prevented by leaving one of the soft-ivory catheters in the bladder. This may be worn for days without the patient being scarcely conscious of its presence. It is, moreover, less prone to become encrusted with urinary deposits than those made of gum-elastic or metal*.

M. Civiale advises, in order to avoid, during our manipulations, the mucous lacunæ, which, he says, for the most part occupy the dorsal surface of the canal, to press the end of the instrument, especially if it be small, to one or other side, or towards the inferior than the superior surface†. This counsel is di-

rectly the reverse of what is commonly prescribed.

I need scarcely observe, that the presence of active inflammation contra-indicates all instrumental interference. Stricture depending on this cause must be combated by abstraction of blood, opiates, and the warm bath. Tampering with bougies aggravates the symptoms and tortures the patient.

II. *On the application of nitrate of silver.*—Every surgeon conversant with the treatment of stricture must have occasionally met with cases where mechanical dilatation, however long continued, or skilfully performed, has failed to effect a cure. Many of these may be radically overcome by the judicious application of nitrate of silver. The method of lateral cauterization, as originally proposed by Ducamp, in the year 1822, and the subsequent modifications introduced into this system by M. Lallemand, are objectionable, because they involve the risk of the escharotic acting upon sound parts*. The cauterization supposed to have been performed upon the internal surface of the stricture, observes M. Civiale†, has been only expended upon a spot anterior to it. If the instrument be pushed with force, or made to execute repeated movements of rotation, its extremity injures and perforates the sides of the urethra. Hence the numerous false passages that have been discovered; hence the attacks of hæmorrhage, often sufficiently copious to awaken the utmost anxiety and alarm‡. Besides, the *cuvette*, in many instances, does not slide forwards, and thus the contained nitrate, instead of being concentrated upon the stricture, dissolves, and combines with the mucus, in which the conductor is bathed. The effect is then null, or nearly so; for while the greater portion of the solution is lodged in the tube, the remainder comes in contact with merely the anterior part of the urethra. The

* Leroy, in *Bulletin de l'Académie Royale de Médecine*, tom. iii. p. 256.

† *Op. cit.* p. 234.

‡ At page 26 of M. Lallemand's work, entitled "*Observations sur les Maladies des Organes Genito-urinaires*," we find a case recorded, in which "acute pain, accompanied with frequent calls to void urine, hæmorrhage, and constriction of the sphincters of the anus," followed the introduction of his port-cauterie; and in the Sixth Observation, that "urgent desire to evacuate the contents of the bladder, with complete retention, prolonged and violent rigors, and acute pain about the bladder and kidneys" ensued, in consequence of cauterizing a healthy part of the urethra.

* These instruments are prepared by removing the earthy constituents of ivory. Before being used they ought to be immersed for several hours in water, and well smeared over with cerate. They are not expensive.

† *Traité sur les Maladies des Organes Genito-urinaires*, p. 200.

practitioner in this way, contrary to his intention, operates from before backwards. Hence the disease is often materially aggravated and rendered incurable; the frequent repetition of the practice giving rise to an irregularly thickened state of the parietes of the canal, sometimes pervading the greater part of its extent. This is attended with a troublesome discharge of matter; and paroxysms of agonizing pain referred to the neck of the bladder, the prostate gland, the spermatic cord, or the testicles, whereby the patient is rendered miserable for the remainder of his days.

To obviate these serious objections various improvements have been suggested in the construction of instruments, among which we would enumerate those of M. Pasquier and of M. Leroy d'Etiolles, as being well adapted for effecting the application with safety and precision.

As it is essential, in the first instance, to obtain a correct knowledge of the nature, extent, and situation of the stricture, I shall describe the method, *par empreinte*, as now generally practised in Paris*. A yellow wax bougie, having an equivalent volume to the width of the stricture (as nearly as can be estimated), is to be passed along the urethra into the bladder. It should be grasped by the stricture, but not forcibly. In general these soft bougies can be introduced with considerable facility. In the event of failure, a slight preliminary dilatation may be procured by means of the slender gum-elastic bougies formerly mentioned. Having reached its proper destination, the soft bougie is left *in situ* for the space of ten or fifteen minutes, after which it is withdrawn by a quick movement. The part which had been grasped by the stricture will be found to present a corresponding mark, amounting sometimes to a notch, sometimes to a mere dimple, scarcely visible to the naked eye, but which may be detected by gliding the finger along its surface. According to the form and situation of this impression, we are enabled to determine the dimensions and direction of the stricture, and also its distance from the orifice of the urethra. Nor are we liable to receive a fallacious indentation from the

natural curve of the urethra under the pubis, from lacunæ or false passages, or to mistake a spasmodic for an organic stricture, as has occasionally happened with other emplastie instruments.

M. Leroy employs for the exploration graduated bougies of gum-elastic, terminating in a round knob, on the principle of Sir C. Bell. These may enable us to recognize well the valvular folds of the mucous membrane; but when the lateral projection is but a fraction of the transverse area of the tube, and the stricture terminates posteriorly in an elongated cone, the indications will be less precise and more difficult of attainment.

After this preliminary investigation, we may, provided the stricture has an area of a line or a line and a half, introduce the port-caustic with its platinum *curette*, corresponding in length to that of the stricture. It is necessary in every case that there should be a partial dilatation beforehand. When we are satisfied that the tube has arrived at the obstacle, the *curette* is to be slowly protruded and then fixed by means of the screw, with the nitrate of silver directed to the affected part; where the stricture is annular, it is, on the contrary, to be left free, and made to revolve upon its axis. After this operation has lasted a minute, the *curette* is to be drawn back into its sheath, which, with the urethra, is to be depressed before removal. By this manœuvre the mucus, should it contain any portion of dissolved nitrate, will flow into the tube; thus all risk of its irritating the healthy surface is prevented. The application so conducted is productive of little or no uneasiness, not more than follows the introduction of an ordinary bougie.

The annexed figure (3) represents the two ends of the instrument in question: *c, d*, are the extremities of the elastic tube; *b*, the head of platinum or gold, fastened by a pin; *e*, the metallic tube attached to the other end of the elastic one; *f*, the screw passing through both tubes; *a*, the platinum spoon or *curette* upon its thin elastic stem, which plays freely within the tube *c, d*, and whose other end *g* is continued into *h*, a quadrilateral rod upon which the screw *f* can be made to press.

The instrument recommended by Mons. Leroy for the retrograde application, consists of a curved tube, *a, a*, fig. 4, made of silver, or of gum elastic,

* This method is by no means new, a description of it being given in Lemonnier's *Traité sur la Maladie Vénérienne*, printed in 1689.

FIG. 3.

FIG. 4.

surmounted like his exploratory bougies, with a small knob *b*, close to which is an elongated aperture, *c*, about half an inch in length, for the purpose of allowing the contents of the *cuvette* to come in contact with the stricture. The *cuvette*, *d*, which is nearly half an inch long, is attached by one extremity to a silver rod, *e, f*, about ten inches long, whereof three and a half inches, *e*, is spiral, in order to impart flexibility and the power of rotation in a curve. The above part, instead of being spiral, is sometimes chain-work. A silver canula is preferable to one of gum-elastic, as the *cuvette* is apt to tilt out of the eye of the latter, and do mischief. The instrument is to be introduced beyond the most remote stricture, and then partially withdrawn, until the knob, *b*, is felt to hitch against the distant margin. The *cuvette* containing the fused nitrate of silver, inserted with its convex metallic surface to the notch, is then to be turned round till the nitrate faces the stricture; it is to be thus retained for a minute, and straightway restored to its former position, and removed with

its canula. The operator must be provided with two separate canulas, one having a superior, the other an inferior aperture, to suit the direction of the stricture. In every case we ought to be quite certain that we have passed the extreme obstacle, before the nitrate of silver is permitted to act.

Immediately after the application has been made, the patient voids urine better than before; but on the day following there sometimes ensues a degree of retention, from closure of the canal by a plug of coagulated mucus. This is easily removed by injecting a little tepid water from a gum-elastic syringe, furnished with a long, narrow, softened ivory tube. The introduction of a bougie for this purpose is both painful and hazardous. About the second or third day, some sloughy shreds are voided along with the urine. We have now to repeat the passing of the soft bougie, to ascertain whether the stricture be completely overcome; persevering in

the use of the nitrate of silver till no trace is left upon the wax. We may even determine this by the relative facility with which an ivory bougie passes along; and if so, we spare the patient the annoyance which the wax may cause while traversing the under part of the mucous membrane. It is seldom that a single application suffices; in the majority of cases, it must be renewed at intervals of four or five days for some weeks, until a No. 6 bougie will pass. But we must be guided by the result, discontinuing the practice whenever we perceive that the patient ceases to derive benefit; otherwise its protracted use cannot fail to do harm*.

As a general rule, the application ought to be confined to cases in which the stricture is of limited extent. Where there is general callous thickening, it is inappropriate. It is not intended that the nitrate of silver should destroy the stricture, as may happen; it merely induces some change in the vital actions of the part, which is followed by relaxation of the narrowed portion. No satisfactory explanation has yet been offered of its *modus operandi*.

We usually remark, soon after its employment, a mucous or purulent discharge, which commonly subsides, of its own accord, in a few days. In some rare instances, the gleet which had previously accompanied the stricture becomes greatly increased in quantity, and continues so for a considerable time. More generally, however, chronic discharges of long standing disappear entirely upon its removal.

To complete the cure, ivory bougies, or gum-elastic sounds, having the natural curvature, ought for some time to be daily introduced for a few minutes, progressively augmenting in size till we come to a diameter of $2\frac{1}{2}$ or 3 lines. By and by they may be passed twice a week, and ultimately every eight or ten days. The subsequent dilatation is always necessary to protect against a relapse.

There is another form of stricture, in which the urine may percolate through

the obstacle, while even capillary bougies cannot be introduced, or, if so, but partially, seeming to penetrate a spongy mass, and give rise to hæmorrhage. Here we must have recourse to the *direct* application of nitrate of silver, on the principle recommended by Ambrose Paré, and afterwards adopted by Mr. Hunter and his follower, Sir Everard Home, but practised in a much improved manner*.

The instrument I have found best suited for this purpose was first shewn to me by M. Leroy d'Etiolles, along with several other ingenious contrivances for the treatment of urethral diseases. It does not differ materially from that of M. Labat. It consists of a flexible canula (*a*, fig. 5), graduated into

FIG. 5.

inches and fractions of an inch, surmounted by a platinum ferrule, and of two silver rods, partly spiral, whereof one (*b*) terminates in an oblong knob,

* For ulceration of the mucous membrane of the urethra, characterized by pain experienced in particular points of the canal during the passage of an instrument or the evacuation of urine, the momentary application of nitrate of silver is a most valuable remedy. I succeeded in curing, by two applications, an intractable case of this kind, where the patient had been long needlessly tormented with the introduction of bougies, by a surgeon of repute.

* This method is also adapted to cases of very thin valvular stricture, almost membraniform, which the sound or bougie passes with a slight jerk, and beyond which the resistance ceases entirely to be felt.

while to the other (*c*) is attached a little platinum cup (*d*), for holding the fused nitrate of silver. The cup cannot pass beyond the rim of the ferrule. The chief improvement in this instrument is the adaptation of the spiral.

It is introduced containing the rod (*b*), whereby the orifice is closed so as to present a hemispherical surface. As soon as it has arrived at the stricture, the rod is withdrawn, to make way for the capsule with the nitrate of silver. While this is being done, the end of the canula must be kept steadily against the stricture. The nitrate of silver now in contact with the part, is to remain from 30 to 60 seconds, and is then to be removed; and after depressing the urethra for a reason formerly assigned, the canula may be taken out. To ensure success, it is of importance that the latter be large enough to fill the canal.

When thus cautiously applied, we have no reason to dread the disastrous consequences which have attended its indiscriminate and injudicious employment according to the old method. With that dangerous weapon, the armed bougie, false passages, hæmorrhage, intense irritation, severe paroxysms of fever, and retention of urine, have been repeatedly produced; but here the action of the remedy is wholly confined to the affected part, and is thus exempt from peril or uncertainty. After having submitted it to the test of ample experience, I can confidently affirm that I have never known it occasion ought beyond a little heat in the part, and a slight discharge from the urethra, sometimes tinged with blood. Here, as in every other instance, the first effects produced are a change in the sensibility, and an augmentation of the capillary circulation, followed by a softening down of the texture to which the agent has been directed; and so long as it is limited to modify the vital properties, the results are favourable. The application may be repeated every five days.

The following case is adduced, in corroboration of the practice:—On the 29th of March last, I was requested by Mr. Hering, a gentleman practising in Foley Place, to see Mr. D—, labouring under obstinate stricture. This patient is 46 years of age. He has had gonorrhœa twice or thrice; the last time was in the year 1830. Twelve months prior to that date, he was obliged, on returning from a hot cli-

mate, to submit to treatment for some obstruction of the urinary passages. For two or three years back he has been subject to irritation of the urethra, accompanied with a gleet discharge. When I saw him, he complained of frequent calls to make water, which he voided in a forked, twisted, and small stream. On endeavouring to introduce a moderate-sized bougie, it was arrested by a spongy substance, and gave rise to pain and hæmorrhage. I may observe, that repeated attempts had been made to effect a cure by means of bougies previously, but in vain. On more minute examination, I found the stricture was situated about five inches and a half from the external meatus; there was, in addition, a slight narrowing, about three inches and a half from the same point. Having determined on the antero-posterior application of the nitrate of silver, I commenced at once with the principal stricture, in the manner above described, renewing the practice at suitable intervals for a few weeks. During this period, the patient was so little incommoded as to be able to return home to the country each time, and pursue his ordinary avocations. On the 20th of May, I passed with ease a No. 4 gum-elastic bougie; and, in the course of other eight days, a No. 8 gum-elastic sound, *à courbe naturelle*, having previously discontinued the use of the nitrate of silver. Since then I have occasionally introduced, and always with the utmost facility, the soft ivory bougies, both strictures having quite disappeared.

The most efficient means of relieving the severer forms of retention of urine, connected with stricture, I propose to consider in another paper.

13, Charlotte Street,
Bedford Square, July 17, 1839.

REMARKS

ON

“THE PHARMACOPŒIA OF THE
ROYAL COLLEGE OF PHYSICIANS,
EDINBURGH, 1839.”

By RICHARD PHILLIPS, Esq. F.R.S. &c.

[For the London Medical Gazette.]

I HAVE participated in what I believe to have been the anxiety of the medical and chemical world for the appearance of this work. It has been in prepara-

tion for no inconsiderable time, and common report has attributed its progress and completion to the labours of Dr. Christison. That this opinion has been correctly formed is confirmed by the following passage in the last number of the *Edinburgh Medical and Surgical Journal*. "Whilst we give the Edinburgh College of Physicians full credit for the excellence of the work which bears their name, it would be unfair in us, possessing the local information which we do, not to express our conviction that a great part of its value is due to the labours and exertions of its accomplished President, Dr. Christison. It is, indeed, fitting that the President of a College of Physicians should be a man of scientific eminence; and especially that, when the body over which he presides publishes a new Pharmacopæia, he should be both competent and ready to take a principal share in its formation. We are certain that we do not in any respect depreciate the merits of other members of the Edinburgh Pharmacopæia Committee, when we say, that we believe the greater part of its excellence is owing to Dr. Christison's scientific knowledge, laborious manipulations, and indefatigable research into the books of British and foreign pharmacologists."

Were it not perfectly superfluous, I would willingly add my testimony to the great scientific acquirements of Dr. Christison: his name is almost sufficient to set criticism at defiance; but, as chemical facts do not differ from others in being "stubborn things," I shall freely and fully state what I believe to be facts respecting this pharmacopæia. I shall do so plainly, but, I trust, without giving offence either to the Royal College of Physicians as a body, or to their learned and scientific President as an individual.

The first article that requires notice is the second in the *Materia Medica*; it is

ACETUM BRITANNICUM. *British vinegar.*—Of this it is stated that its density is from 1006 to 1012. "In four fluid ounces complete precipitation takes place with 30 minims of solution of nitrate of baryta." This means, I presume, that the sulphuric acid which vinegar contains is perfectly thrown down by the assigned quantity of the barytic solution. Vinegar-makers are permitted to add to vinegar 1-1000th

of its weight of sulphuric acid; and it can hardly be supposed that they do not avail themselves of this privilege to its full extent. Let us, therefore, see what quantity of sulphuric acid four fluid ounces may contain. The density of vinegar being taken at 1006, four fluid ounces weigh 1760 grains, and the sulphuric acid which it contains amounts to 1.76 grain; as 49 of this acid decompose 130 of nitrate of barytes, 1.76 will require 4.66 for that purpose.

The College test solution of nitrate of barytes is prepared by dissolving 40 grains of the salt in 800 grains of water; and assuming, what may be admitted without sensible error, that the bulk of the solution does not materially differ from that of the water, the question to be determined is, how much nitrate of barytes is contained in 30 minims of the test solution.

A fluidounce, or 437.5 grains of water = 480 minims, 800, therefore, = 877, holding 40 grains of the barytic salt in solution; consequently, 30 minims contain 1.36 grain only, instead of 4.66 grains, as required; so that more than 100 minims of the solution are necessary to produce an effect, which, according to the College, is complete with 30.

Being unwilling to trust entirely to calculation, especially when experiment is so easy as in the present case, I procured some vinegar from a source which I knew to be respectable: its density was 1019, which exceeds the greater specific gravity stated by the College. With four fluidounces of this I mixed 30 minims of the test barytic solution; the precipitate formed was separated by filtration, and 60 minims more were added to the clear vinegar: this occasioned a much more abundant precipitation than the 30 minims, and after again filtering, nitrate of barytes being added, it occasioned the formation of more sulphate.

Four fluidounces of this vinegar gave a quantity of sulphate of barytes which indicated an excess of 0.3 of a grain of sulphuric acid: this may be attributed to the error of experimenting, and the sulphates contained in the water used in preparing the vinegar.

I found, also, that the saturating power of this vinegar is accurately stated in the London Pharmacopæia: one fluid ounce saturated a drachm of crystals of carbonate of soda.

ACETUM DESTILLATUM. *Distilled vinegar.* "Density 1005." "One hundred minims neutralize 8 grains of crystallized carbonate of soda." One hundred minims of a liquid whose density is 1005 weigh 91·6 grains, and this quantity of distilled vinegar saturates 8 grains of carbonate of soda; 100 therefore = 8·7 grains. Now, 144 of crystals of carbonate of soda = 51 real acetic acid; and consequently $8·7 = 3·07$, which is the per centage of acetic acid contained in the distilled vinegar: this quantity amounts to only about 3·5ths of that which the undistilled vinegar contains; and no inconsiderable portion of the loss of 2·5ths is occasioned by the College needlessly directing only 6·8ths of the vinegar to be distilled.

ACETUM GALLICUM. *French vinegar.* The introduction of this seems uncalled for. It appears, however, from the College statement, that the quantity of sulphuric acid added to vinegar in France is precisely the same as that in England; for of the foreign article it is also stated, that "in four fluidounces complete precipitation takes place with 30 minims of solution of nitrate of baryta." Having obtained some French vinegar, I found its density was 1016; I added the proper quantity of the test solution to a portion of it, and I certainly found that sulphate of barytes was precipitated. After filtering the vinegar, I added dilute sulphuric acid to it, which occasioned the formation of much more sulphate than had been occasioned by the sulphuric acid in the vinegar.

To determine, within certain limits, how little sulphuric acid this vinegar actually contained, I added the test in the proportion of 15, instead of 30 minims, and I found, when the vinegar had been filtered, not only that nitrate of barytes occasioned no precipitation in it, but that dilute sulphuric acid did. It is, therefore, evident that the vinegar did not contain half enough sulphuric acid to occasion "complete precipitation" of the nitrate of barytes. Of the French vinegar which I employed, 100 minims saturated nearly 14 grains of crystallized carbonate of soda, while an equal quantity of English vinegar, exclusive of the sulphuric acid which it contains, saturated little more than 12 grains; consequently the French is stronger than the English vinegar by nearly one-sixth.

ACIDUM ACETICUM. *Acetic Acid.* "Density not above 1068·5." "One hundred minims neutralize at least 216 grains of carbonate of soda;" meaning, I presume, as before, in the state of crystals: let us, then, inquire how much real acid per cent. it contains. One hundred minims weigh nearly 98 grains, and these saturate 216 grains of carbonate of soda; 100 therefore = 220 grains of the carbonate, and as $144 = 51$ of acetic acid, $220 = 78$, which, according to the College, must be the quantity of real acid per cent. in acid of 1068·5.

From Dr. Thomson's statements it appears, that acetic acid, of density 1068·2, contains only 53 per cent. of real acid: in order, therefore, to determine whether the enormous difference of nearly 25 per cent. originates with the College or Dr. Thomson, I prepared a quantity of acetic acid of density 1068·5 by diluting some glacial acid, with which I had been favoured by Mr. Morson. 100 minims were not saturated by 140 grs. of carbonate of soda, but super-saturated by 150. Had this quantity of carbonate been neutralized, the acid would have contained rather more than 53 per cent. of real, which agrees (very nearly) with Dr. Thomson's statement, and of course differs from that of the College to the amount of about 25 per cent., as already mentioned.

It is further observed, in the Pharmacopœia, that when acetic acid of 1068·5 has 20 per cent. of water added to it, the density is increased. By referring to Dr. Thomson's table, the probable inaccuracy of this statement will be apparent. He mentions that acid of density 1068·2 consists of 1 atom acid, 51 and 5 atoms water, $45 = 96$; and when 2 atoms of water, = 18, are added, the density of the acid is so far from being increased, that it is diminished from 1068·2 to 1063·49. On this occasion, experiment is neither tedious nor difficult, and I therefore made it, and I found that a mixture of 5 parts by weight of acid of 1068·2 with 1 part of water gave a dilute acid of 1062·8; the density being diminished, and nearly in the ratio stated by Dr. Thomson.

I have yet to notice a remarkable discrepancy in the College statements respecting the density of their acetic acid. In the *Materia Medica*, p. 2, we are informed that its density is "not above 1068·2," whereas at p. 44, under the head of Acids, we find that "the density

should be not above 1065." The difference in figures seems trifling, but that is by no means the case with the strength of the acids of these densities. When I have had time to prepare the acid according to the College process, I shall be able to learn which of these statements is correct, if either be correct. In the meantime I have examined the relative strengths of acid of these densities. I find that 100 minims, = 97 grs. of 1065·3, saturate 232 grs. of carbonate of soda in crystals; it is therefore composed nearly of 1 equivalent of acid, 51 + 1 equivalent of water, 9 = 60. Now I have mentioned that 100 minims of 1068·5 are incapable of saturating 150 grs. of carbonate of soda, consequently these acids, which the College seem to consider of equal strength, differ as greatly in this respect as 232 from 150, but it must be admitted that what the College have stated, though erroneously, of acid of 1068·5 is as nearly true of that of 1065·3 as 216 to 232.

I must confess that I have been greatly surprised at the errors and contradictions which I have now exhibited. To recapitulate, they are as follows:—Not one-third enough nitrate of barytes is ordered to precipitate British vinegar, while more than twice the requisite quantity is ordered for French vinegar; the density of acetic acid is first stated to be 1068·5, and its saturating power 216, when in fact it is below 150; the density of acetic acid is afterwards stated to be 1065, the saturating power of which is about 232: it is asserted, that when acid of density 1068·5 is mixed with 20 per cent. of water, that its density is increased, whereas it is diminished to 1062·8.

ACIDUM BENZOICUM. *Benzoic Acid.* The only properties by which this acid is characterized are that it is "colourless; sublimed entirely by heat." Now these qualities belong to the following preparations:—

Ammonia carbonas.—Colourless; "heat sublimes it entirely."

Arsenicum album.—Colourless; "entirely sublimed by heat."

Sublimatus corrosivus.—Colourless; "sublimes entirely by heat."

Hydrargyrum.—Colourless; "entirely sublimes by heat."

Calomelas.—Colourless; "heat sublimes it without any residue."

ACIDUM MURIATICUM. *Hydrochloric Acid of commerce.* "Density at least

1180." I have never met with it so strong, and suspect that any thus dense must contain a large quantity of sulphuric acid. "It always contains a little sulphuric acid, oxide of iron, chlorine, and bromine." I should like to see the evidence of its containing the last-mentioned element. Why is so usual an impurity as sulphurous acid omitted?

ACIDUM PYROLIGNEUM. "*Diluted acetic acid obtained by the destructive distillation of wood.*" If this acid be, as admitted, acetic acid, for what purpose is the name of pyroligneous acid now introduced? It is merely making a distinction without a difference.

ACIDUM SULPHURICUM. *Sulphuric Acid of commerce.* "Density 1840, or near it." I have never found it less than 1844. "When diluted with its own volume of water, only a scanty muddiness arises, and no orange fumes escape." The muddiness that arises is, I presume, sulphate of lead, which is thrown down.

ACIDUM TARTARICUM. *Tartaric Acid.* The formula for preparing this acid was, I presume, intended to be similar to that of the London Pharmacopœia; but, by an oversight of no small moment, the process has been deteriorated. The London College directs 7 pints and 17 fluidounces of diluted sulphuric acid to decompose a given quantity of tartrate of lime, and the Edinburgh College orders precisely the same quantity. They have, however, forgotten that their diluted sulphuric acid is different from that of the London Pharmacopœia, although the directions for preparing it immediately precede those for the tartaric acid, and in the very same page.

The London diluted sulphuric acid is prepared by mixing $1\frac{1}{2}$ fluidounces of the strong acid with $14\frac{1}{2}$ fluidounces of water; while the Edinburgh Pharmacopœia directs 1 fluidounce of acid to 13 fluidounces of water: their comparative strengths by weight are about as 100 to 78, and by volume the difference is still greater; the Edinburgh College should have directed more than 10 pints of dilute sulphuric acid, instead of less than eight.

Under the head of *Acidum Citricum*, a corresponding error is committed, and with an appearance of precision that renders the mistake more remarkable. In preparing this acid the London College directs four pints of lemon-juice, four and a half ounces of chalk, and twenty-

seven fluidounces and a half of diluted sulphuric acid: the Edinburgh Pharmacopœia orders the same quantities, except that the diluted sulphuric acid is reduced by half an ounce. "Diluted sulphuric acid, twenty-seven fluidounces, or in proportion to the chalk required." So that the sulphuric acid is reduced by half an ounce, when it ought to have been increased by nearly eight ounces.

AMMONIÆ CARBONAS. *Sesquicarbonate of ammonia.* "Heat sublimes it entirely: a solution in water, when treated with nitric acid in excess, does not precipitate with solution of nitrate of baryta or silver." Now, these are not the peculiar properties of sesquicarbonate of ammonia; they belong equally to the carbonate and bicarbonate.

AMMONIÆ SPIRITUS. *Solution of ammonia in rectified spirit.* "It does not effervesce with muriatic acid." This is a mistake, for effervescence does occur, as in liquor ammoniæ, if the acid be strong.

[To be continued.]

CLIMATE AND DISEASES OF EGYPT.

THE increased facilities of travelling, and the well-directed energy of the present ruler of Egypt, will probably multiply the number of visitors of a land so rich in interest. Some of our readers will, of course, be in the list, either travelling for their own gratification, or as the medical attendants of invalids who hope for relief under the bright sky of the Delta. Hence they will thank us for such information as we have been able to cull for them from two books which have fallen into our hands. The one is a little work by Dr. Morpurgo, an Italian physician, entitled, "*Considerazioni mediche sull'Egitto*," printed at Smyrna, in 1831; the other is the recent work by Dr. Cumming, called "Notes of a Wanderer." His book has naturally the advantage of treating of English wants, and supplying answers to English questions; while Dr. Morpurgo's brief essay is the composition of one who had practised in Egypt as an hospital physician, as well as in private families.

Doubting how he ought to treat his

patients, he divided his inflammatory cases in the Alexandria hospital into two classes; the one he treated with bleeding, repose, low diet, mucilaginous drinks, and clysters; the other with bleeding and contrastimulants. For inflammation of the thoracic viscera he employed, by preference, antimonials or digitalis; for that of the intestines or liver, mercurials, or cherry-laurel water, or depressing narcotics; for inflammations of the vessels, sulphate of iron or digitalis; for phrenitis, cherry-laurel water or extract of hyoscyamus. The doses were those recommended by the followers of the contrastimulant theory. Antimonials, under whatever form they were given, very frequently produced vomiting; and Dr. Morpurgo was obliged to abandon their use, as he saw that they augmented the irritation of the diseased organs. He never obtained any advantage from the extract of hyoscyamus, and was twice obliged to combat the first symptoms of poisoning. In one case, a child, aged three, being attacked with diarrhœa, he gave the extract in the dose of a quarter of a grain; in the other, the patient was a man of forty, suffering from chronic bronchitis, and the symptoms came on after taking half a grain.

Of the patients treated merely with detraction of blood, low diet, and mucilaginous drinks, he lost five or seven per cent., according as it was winter or summer.

Of those who were treated with contrastimulants, seven or nine per cent. died when antimonials, drastics, and narcotics, were among the remedies; when these were not used, the mortality was the same as when medicines were not given. Dr. Morpurgo has found emetics and purgatives generally injurious in Egypt, and rarely useful. He is so convinced of the inutility of internal remedies, in the treatment of inflammation, that when suffering from a dangerous inflammation of the mucous membranes, at Alexandria, in the beginning of 1831, he did not allow his physicians to give him any medicine. It was resolved, in consultation, to bleed him; one of the physicians proposed, in addition, to administer some kermes mineral, but this Dr. Morpurgo refused. After the bleeding, a copious perspiration broke out, which was critical. If he had taken the kermes, he says, a

Te Deum would have been dedicated to it on the appearance of the perspiration.

Climate.—Dr. Morpurgo informs us that the air is generally pure, but that the temperature is very variable in those parts of Egypt which are washed by the sea, or inundated by the Nile and its canals; but that it is almost constant in those which are in or near the Desert. The thermometer and the hygrometer frequently vary several times a-day at Alexandria. In Rossetto, in Damietta, and generally speaking in the Delta, and on the banks of the Nile, the air is full of moisture. In Cairo, and in the interior, neither the thermometer nor the hygrometer is subject to sudden changes. In Alexandria, in the hottest part of the summer, the thermometer seldom rises higher than $86\frac{1}{2}^{\circ}$ of Fahrenheit; in Cairo and other places, it rises to $99\frac{1}{2}^{\circ}$, $101\frac{3}{4}^{\circ}$, 104° , and even $106\frac{1}{4}^{\circ}$ (30° , 31° , 32° , and 33° of Réaumur).

Dr. Morpurgo does not think the wind called the *Khamsin* quite so insupportable as travellers assert. It makes the sky cloudy, indeed, and the air hot; but he says, very coolly, that he has never found it raise the thermometer in the shade, at Cairo, above 33° of Réaumur—i. e. $106\frac{1}{4}^{\circ}$ of Fahrenheit.

Dr. Cumming, in his journal under the date of March 6th, 1837, says that the *Khamsin* has been blowing for four days, bringing clouds of dust, and raising the thermometer from 64° to 87° ; at midnight it was 78° .

The following temperatures are, we believe, all the rest that are mentioned in Dr. Cumming's book:—

At Alexandria, on the 31st of October, 1836, at 10 p.m., the thermometer was at 76° . On the 25th of November, at Cairo, it fell in the morning to 48° .

In going up the Nile, he suffered more from cold than heat. Under the date of February 11th and 12th, he says that the thermometer has not been lower than 50° ; on the 17th it was 52° . The blinds of his boat were rickety, and the vessel in general rather unsound, so that he could not keep himself warm in bed under six covers.

Diseases.—The diseases of Egypt are mostly inflammatory. Indeed, Dr. Morpurgo goes so far as to say, that among thousands of patients whom he has seen and treated in Cairo and Alexandria, whether civil or military, there

was not a single case that could not be classed among sthenic ones. Some of them required vigorous antiphlogistic treatment; in others, low diet, repose, and the avoidance of every impression that might have been too exciting, were sufficient; but he never met with a single case that required stimulating treatment.

Ophthalmia.—This is very common and very violent in Egypt. One of the great causes of its frequency among the lower orders, he believes to be the bad air of their dwelling-places, as well as in the streets. The experiments of Fleurens, showing the effect of bad air on animals, are very instructive. He took fowls and shut them up in low, moist, and ill-ventilated places. After some time he killed them, and found their lungs full of tubercles, and the cornea covered with ulcers. In treating this disease, Dr. Morpurgo never derived any advantage from blisters or mercurials, nor from bathing the eye with cherry-laurel water or narcotics. General and local bleeding, and bathing the eyes with tepid water, were always beneficial. Bathing the eye with a solution of zinc was useful towards the end of the disease, when the conjunctiva was rather congested than inflamed; and sometimes succeeded in checking the ophthalmia at its commencement, chiefly when it had been caused by the sudden action of light. Blood may be abstracted at a very early age; he has often applied ten or twelve leeches to the temples of children one or two years old, and thus arrested the course of a dangerous ophthalmia. He says he was induced to try mercurials, because the physicians of Belgium and Holland told him they had used them with benefit, giving them till salivation was produced. In order to see whether ophthalmia was contagious, Dr. Morpurgo took purulent matter discharged from the eyes of several patients, and put it into the sound eyes of others, without ever producing ophthalmia.

We must add, as our commentary, that these experiments were most scandalous.

Enteritis and Hepatitis.—Under the former of these heads Dr. Morpurgo includes dysentery, as it is essentially an inflammation of the intestinal tube.

If the physician is called in time to a case of enteritis, he is to prescribe re-

pose, one or two bleedings, a considerable number of leeches to the abdomen and anus, mucilaginous drinks, fomentations to the abdomen, and emollient clysters, provided the rectum is not in too irritable a state. When the disease is well treated, it is generally cured in about nine or ten days.

Sometimes, however, in epidemic enteritis, accompanied by dysentery, the physician cannot hope to arrest the progress of the disease, but only to moderate its course. Having begun by some abstraction of blood, he must prescribe a general bath (provided the patient is strong enough to bear it), low diet, repose, fomentations, and unirritating drinks, and will leave the rest to nature; for if he persevered in taking away blood, he would kill the patient. It often happens that dysentery, though mild at first, becomes serious by the ill-timed administration of purgatives, or from the use of beans cooked in oil, which the Arabs take by way of medicine. Yet from time to time cases are narrated of dysentery which have been cured under the use of drastics; indeed, a philosopher has said, *il y a des maladies que les médecins ne peuvent pas tuer*.

Chronic gastritis, hepatitis, and congestion in the system of the vena portæ, are to be treated after the method commonly described by authors.

The other diseases discussed by Dr. Morpurgo are—meningitis and encephalitis [phrenitis], intermittent fever, herpes (which he uses in a very comprehensive sense), boils, small-pox, venereal maladies, palpitation of the heart, phthisis, scrofula, gout, and the plague. Palpitation is the scourge of the Pasha's army. It appears to be a form of nostalgia, the recruits being often raised by pure force, and most unwilling to serve. Phthisis, scrofula, and gout, are exceedingly rare in Egypt.

So far our Italian brother; let us now turn to Dr. Cumming's account. Dr. Cumming, who had resided in India, and was suffering under disease of the chest, consulted Andral, who gave the following opinion of his case, and of the treatment which ought to be pursued:—

“Monsieur —, chez lequel je me suis rendu en consultation il y a peu de jours, présente les signes d'un emphy-

sème pulmonaire. Il ne m'est pas démontré qu'il ait des tubercules; *plusieurs circonstances* toutefois doivent faire craindre le développement ultérieur de ceux-ci. Je conseille les moyens suivans:—

“1. Frictions assez long-temps continuées au-dessous des clavicules avec la pommade stibiée.

“2. Usage habituel du *Datura Stramonium*, dont Monsieur fumera les feuilles comme celles du tabac.

“3. Vers la fin du mois de Mai, Monsieur se rendra à Bonnes (dans les Pyrénées), dont il boira les eaux pendant six semaines. Il se rendra ensuite à Cauterets, dont il boira aussi les eaux; il prendra spécialement celles de la source de la Raillière, et il les coupera d'abord avec du lait.

“4. Vers la fin de l'été, Monsieur se dirigera dans l'Italie, et y passera tout l'hiver.

“5. Monsieur suivra constamment un régime doux, et il évitera avec le plus grand soin l'influence du froid, de l'humidité, de toutes les variations brusques de température.

“ANDRAL*.

“2 Avril 1836.”

Dr. Cumming, however, did not follow this advice very strictly; he did not drink the Pyrenean waters, but, after spending some months in France, Italy, and Switzerland, went to Alexandria, where he arrived at the end of October. He passed the winter in Egypt, and became quite fascinated with its climate. He says—“He who feels the cold fogs of cloudy England fall like lead upon his soul, sour his

* Mr. —, whom I saw in consultation a few days ago, presents the signs of emphysema of the lungs. I do not think it proved that there are tubercles; but *several circumstances* make me fear their ultimate development. I advise the following remedies:—

1. Long-continued friction below the clavicles with the tartar emetic ointment.

2. The habitual use of stramonium, of which Mr. — is to smoke the leaves like tobacco.

3. Towards the end of May he should go to Bonnes, in the Pyrenees, and drink the waters for six weeks. He should then proceed to Cauterets, where he is also to drink the waters, particularly those of the Raillière spring, which he is at first to mix with milk.

4. Towards the end of the summer he should go to Italy, and spend the whole winter there.

5. He must constantly keep to a mild regimen, and avoid with the greatest care the influence of cold, moisture, and all sudden variations of temperature.

ANDRAL.

April 2, 1836.

spirit, and impair his health, should haste him to the Nile, to inhale for a season its balmy and exhilarating air."—Vol. ii. p. 61.

And in an earlier part of the same volume he speaks as follows:—

"In England we are apt to associate pestilence and death with the very name of Egypt; but this vulgar prejudice must vanish before the omnipotence of truth. The invalid who comes here for the winter, should not be later of arriving at Alexandria than the middle or end of October; he should lose no time in pushing for Cairo, nor remain there beyond the end of November. The higher he proceeds, the drier and milder the climate becomes. He should bring with him from Europe a plentiful supply of warm clothing, a good stock of appropriate books, a pair of pistols and gun, and a canteen for two persons."—(Vol. ii. p. 10.)

Perhaps the author's recommendations are rather too zealously given. For, in the first place, many invalids have not pluck and stamina enough for the voyage of the Nile. Dr. Cumming was obliged to seize his head boatman and thrash him soundly, and recommends this kind of stimulation as the true method of getting on. Now your genuine invalid, pale, shattered, and hesitating, who cannot be persuaded into a party of pleasure, and must go to bed at half-past nine, though he left a Sheridan in the drawing-room, would shrink from seizing "a malignant and a turbaned" Arab by the throat, and would be more fit to be thrashed than to thrash. Still there may be invalids like Dr. Cumming, stout in heart and arm, though weak in lung, who might get over this difficulty; but for pulmonary patients we should imagine that the excursion up the Nile is too cold in winter; they had better stay in their lodgings at Cairo. Then comes the question, to which we find no answer in Cumming, nor in Morpurgo, can an Englishman of refined habits live comfortably through the winter at Cairo? At Naples he will find pictures and statues, books, music, theatres, and every variety of social amusement, English and Italian. At Cairo we doubt if there is even a very good hotel. Dr. Cumming tells us, that at Alexandria, knives, forks, and plates, are dear, and difficult to be had.—(Vol. i. p. 202.)

Wheel carriages are, we believe, almost, if not quite, unknown. The author made an excursion from Cairo to the pyramids, chiefly on donkey-back, the time of transit being five hours and twenty-five minutes, and passed the night in a tomb. If he could do this as an invalid, assuredly in his healthy days he must have been made of iron and caoutchouc.

We make no question, however, that if the present enlightened ruler of Egypt, whose mind grasps the smallest details, as well as the largest generalization—like the trunk of an elephant which can root up a tree, or pick up a pin—were to learn how many British invalids would profusely reward any thing done in their behalf, Cairo might soon boast a splendid hotel; and the comforts of English life would spring up at the magic touch of Mehemet Ali.

The diseases of Egypt, though probably not quite so formidable as they were formerly thought, must not be left out of the account, when we balance the Delta against Naples or Sicily. Dr. Cumming had a most dangerous illness, apparently arising from a very slight cause.

He was seized with dysentery on the 23d December, 1836, in consequence, as he believes, of eating a small portion of water-melon; the attack commencing two hours afterwards. He had no medicines of any kind, but the body was spunged, and the abdomen fomented, with hot water. Recovery took place with difficulty, but his convalescence was rapid.

He contrasts this attack with a precisely similar one which he had at Cawnpore, in the autumn of 1829. On that occasion he was largely bled, "had fifty leeches applied to the abdomen, and during the first four days of the disease, in addition to extensive mercurial frictions, I swallowed 216 grains of calomel! True I recovered, or rather, I did not die; whether in consequence of, or *in spite* of, the above heroic treatment, I will not venture to say.

"My face was swelled to an enormous size, every tooth was loose in my jaws, and for six or eight weeks I could eat no solid food. My constitution received a shock, from which it never fairly recovered; and I was finally obliged to come to Europe on furlough. On the present occasion, fortunately for me, the

'vis medicatrix naturæ' was my sole physician, and I am now almost as well as before the attack commenced."—(Vol. i. p. 291.)

Of course every practitioner of physic will do well to take a tolerable stock of medicines with him to Egypt; opium, quinine, and calomel, being among the more necessary articles. The following extract gives some useful hints to medical travellers:—

"On rising to depart, his chief secretary, a venerable old man with white beard, begged of me to examine his eyes, and give him some medicine. I found a cataract in both, and one in a most tempting state for extracting. Of course, I could do nothing but make Mahmoud explain that his case was beyond the reach of physic. I have daily more and more occasion to regret my being so totally unprovided with medicines. Any thing coming from a Frank has a virtue in the eyes of these people; but I have not even a dose of salts in my possession.

"There is no profession so much esteemed, and consequently so well adapted for travelling in the east, as that of the medical man; but then he must go provided with the symbols of his art, else his knowledge is useless. I do not know a more profitable and agreeable manner in which a young surgeon (more especially if he intended to devote himself to the study of the eye) could dispose of his time, than by passing a winter on the Nile. With a good set of eye instrument, and an appropriate supply of medicines, he might not only do infinite service to himself, but also incalculable benefit to the poor natives. On reaching a village and dispatching his servant to the Sheik, to announce his calling and purpose, the halt, and lame, and blind, would immediately flock to him. He would have many opportunities of operating for cataract and other diseases; and he would also have better means of knowing and studying the people than any other traveller."—(Vol. i. pp. 338-340.)

We will conclude with one more hint to our younger readers. If they wish to travel with advantage, they should carry with them not only good medicine, good instruments, and good humour, but a knowledge of several languages to boot.

MEDICAL GAZETTE.

Saturday, August 3, 1839.

"Licet omnibus, licet etiam mihi, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."
CICERO.

THE NEW EDINBURGH PHARMACOPŒIA.

AFTER the lapse of twenty-two years the Royal College of Physicians of Edinburgh has very properly re-edited its Pharmacopœia; and, under the guidance of its accomplished President, Dr. Christison, has brought this useful compilation more nearly to a level with the progress made of late years in the art of healing, as well as the science of chemistry.

Many persons will be surprised, some few will be shocked, but more will be gratified, to find that the present Pharmacopœia is in English, being the first time that such an innovation has been ventured upon in these islands. It is the second instance, we believe, in Europe, of a Pharmacopœia having been published in the native language of the compilers, the first one having been the Parisian Codex of 1837, which, as our readers know, is written in French. The compilers of the Codex, as we observed last year, ground this change on the obvious reason, that French is better understood in France than Latin, and on the impossibility of their preventing the immediate appearance of some bad translation. In one point, indeed, they state the case too strongly against themselves; for, after observing that Latin is the language common to all civilized nations, they add, that it serves as the means of communication between the scientific men of all countries. Now this, though true of past ages, can hardly be predicated of the present one;

and if said of the 50,000 physicians and druggists of France, would be the reverse of the fact.

This change in France and Scotland, which will be the precursor of a similar one in other countries, is, of course, merely one of the symptoms of far greater alterations taking place on every side. The contest whether a Pharmacopœia shall be in Latin or English is part of the general struggle between the study of the ancient and that of the modern languages; and this again is allied to the still more comprehensive battle between elegance and utility. Shall we pursue our journey on horseback, through shady lanes, at the rate of twenty miles a day, or whisk along through the dreary channel of a railway at the same rate per hour?

Let us endeavour to weigh the claims of both parties like impartial critics, and act as umpires between the enthusiastic admirer of classical beauty and the mere dry utilitarian.

Before the revival of literature, and for some ages afterwards, Latin was the natural language of science, and in a great measure of the belles-lettres also. To publish a learned treatise in English two or three centuries ago, was almost as imprudent as in our days it would be to print it in Welsh. From the population of England being so much larger than that of Wales, the imprudence might seem to be less in degree, though the same in kind; but in truth, as now in Wales every person of cultivated education reads English, so then in England every person of liberal pursuits was supposed to read Latin; and the author who wrote in English exposed himself to become despised at home and unintelligible abroad. Still exceptions would occasionally occur; sometimes an author might write in his native tongue from caprice, from want of facility in Latin, or from compassion for the scientific wants of his less edu-

cated fellow-countrymen; and in a few instances, as was the case with some of Bacon's treatises, it might be expedient to publish a work both in English and Latin, in order to satisfy at once the wants of the unlearned at home, and those of the republic of letters throughout Europe. This custom of using a dead language to express the ideas of the living arose in part from Latin having been the language of the masters of the civilized world, and therefore the most obvious medium of communication in most of the countries subjected to their sway; and, in part, from the rude dialects of the tribes that broke down the Roman empire not possessing terms to express the niceties of medical description or physical definition, or the shades of refined sentiment.

But here, as in so many other cases, the use survived the necessity; and by the natural transmission of habits, long after the bold and the patriotic had stamped their own energy on the languages which they spoke, and engrafted the scientific diction of Greece and Rome on the homespun dialects of their ancestors, the majority of the learned still clung to the language endeared by so many associations, and hallowed by such a constellation of genius.

In several instances, when the authors were unable to express themselves with facility in the language of Terence and Cæsar, it was thought necessary to seek for some friendly aid, in order to clothe their ideas in the required dress; for it would have appeared to many as unseemly to rush into print in English, as to run into the streets in night-gown and slippers.

Thus, if we mistake not, both Newton and Sydenham wrote in their native tongue, and were indebted to others for the foreign garb in which their thoughts appear. A very curious instance of the doubtful struggle between ancient and modern languages, occurs in the pre-

face to the first volume of the Edinburgh Medical Essays and Observations, printed in 1733. The authors tell us that they had hesitated whether to publish the book in English or Latin, and that the latter would have been easier to them. At that time, and up to a much later period, educated Scotsmen did not speak the language of the Southron; to translate their Doric dialect into the more stately forms of the south, was more difficult than to write in the language of Rome; but the thirst for English medical books had begun, we suppose, to be sufficiently great throughout these islands to surpass the continental demand for Latin ones; and they made their choice accordingly. If we recollect aright, it is in one of the early volumes of the Transactions of the London College of Physicians, that Dr. Carter transmits a case in English, but regrets at the same time that the good old English custom of writing such narratives in Latin is going out of fashion. Without going the full length of Dr. Carter's regret, we must confess that this old custom of delivering medical histories in Latin had the incidental advantage, among others, of putting an extinguisher on those flaming narratives which are intended as mere baits to the laity. Few persons would print cases of organic disease cured by veratria, if the miracles must be trumpeted forth in Latin only.

In other professions the preference given to Latin is equally striking. In the law, written pleadings were in Latin until the reign of George the Second. In the church and institutions for education, examples crowd upon the memory. Thus the whole Romish service is in Latin, and a part of the prayers at our universities and public schools is still in the same language. So are the statutes of Oxford and Cambridge, more obsolete than the

dialect in which they are written. The disputations (or *keeping of acts*), once the chief method of ascertaining the proficiency of a student, are still stumpled through in Latin.

The old method of learning Greek through the medium of Latin, was not wholly extinct in our schools twenty years ago, and is certainly one of the reasons, and not one of the smallest, why Greek scholars are so very scarce. Whether this practice yet survives in any obscure corner, we know not.

The medical examinations at Edinburgh were in Latin until quite lately. With the gradual disuse of the Latin language as the familiar instrument of study and learned intercourse, the disadvantage of using it as the means of examination becomes apparent. A candidate quick in Latin, though unskilful in medicine, not only has an immense advantage over an unclassical compeer, but may even dumbfound a slow examiner by the ever-ready terseness of his latinity. The same sort of thing may happen to a certain extent even when the language of examination is English, but will, of course, be more likely when a dead language is resuscitated for the occasion. Perhaps the London College of Physicians has hit upon the true medium by mingling the two, and thus testing the depth of the candidate's acquirements, by his answers in his native tongue, and his knowledge of the older writers, by the facility with which he imitates their diction.

We may remark, that in many of the smaller countries of Europe (Holland and Denmark, for example), physicians still very commonly write in Latin; the reason being, probably, that the native practitioners form so small a public that an ambitious writer addresses himself to the choicer readers of every region in Europe.

But even if Latin were no longer used any where, its study would pos-

sess several strong recommendations. In the first place, Latin is required to read the works written before the period when modern languages began to be used for scientific purposes. In the second place, the study of Latin is the study of general grammar. As Latin is more difficult than any modern language, it serves as a good introduction to its easier successors; just as the Roman was taught in peace to carry heavier arms than he required in war. The man who can read Virgil with facility, is not likely to complain of the difficulty of Ariosto. It is thus that Latin may be said, with justice, to be an excellent introduction to living idioms, not so much from the resemblance of words, but because its more varied flexions and more complicated construction make it really a key, not only to the languages descended from it, but to those which have but a slight affinity. Yet impartiality obliges us to confess, that the key is often so long in making, that the lock is never opened.

In the third place, the study of the Roman classics is the study of literary elegance; and though it is inferior to that of the Greek ones, if the latter be pushed to its full extent, yet as this seldom happens, the Roman writers more frequently leave a deep impression on the mind than their Grecian masters. It is wholly impossible to read without profit the writings of those who sometimes spent a lifetime in the composition of a volume; something of accuracy and of elegance must be culled by the most superficial student, and deeper qualities will reward a more profound examination.

Another reason might be added in favour of the study of the Roman language, but its soundness is doubtful. Yet as it is constantly urged in one form or other, it may as well be stated. It is observed, that as Latin has hitherto been an essential part of every complete

system of instruction, it has been a sort of test of education; and if we find a man ignorant of this tongue, we almost always find that his education has been neglected in many other points. This may be true; but at best it is rather a hint to individuals as to matters which, in the present state of society, it is unsafe to neglect, than an argument addressed to great classes as to the knowledge which they should propose as most worthy of attainment. Thus we might advise a man to wear tails to his coat, as being most fashionable, but recommend jackets for a uniform, as being most handsome. Still we do not deny the force of this advice when given to individuals, though it would be of little weight if addressed to powerful bodies remodelling the education of a people. But as our readers may have seen from our previous remarks, we are not averse to the studies recommended by these timorous exhorters, though we would rather have them generously pursued through sympathy, than sullenly endured through fear.

Moreover, it may be doubted whether any medical body has such influence in society, that by totally discarding classical studies they could produce any other effect than that of lowering themselves.

Such are some of the arguments which might be adduced in favour of the study of the ancient languages, and particularly of Latin. The advantages of knowing modern dialects are even more obvious. Their study opens the boundless stores of knowledge set forth in French, German, Italian, and other languages. This study is the best possible introduction to the study of human nature, or rather is a great part of it; for he who knows a language is not far from knowing the people who speak it. No man speaks an idiom by a mere effort of memory; and to make new

phrases in harmony with the forms already existing, the speaker must have no superficial acquaintance with the predominant genius of the language, that is, with the spirit of the people stamped upon the words which it pours forth. The advantages to physicians in particular, of speaking living tongues are abundantly clear. They are a travelling race of men, and the painful inconveniences which arise from ignorance in this point are proved by daily example.

Many of our readers may recollect the mortifying adventure which happened a few years ago to the Rev. Mr. Gleig, when travelling in one of the Austrian provinces. Not knowing a word of the dialect of the country, he misunderstood what was addressed to him by some petty official personage, and answered with his pistol instead of his tongue. We believe he mistook a police-officer for a highway robber.

The student will, of course, not confine himself to one modern language. The Society of Apothecaries very properly recommend German as well as French; and those who have more time than their regulations suppose to be bestowed on education, may easily add other languages.

It is painful to make the discovery, after landing in some distant country, that a small stock of that remarkable dialect called *boarding-school French** is not a universal passport.

Dr. Cumming informs us, in his "Notes of a Wanderer," that on one occasion, when travelling in Germany, he dropped his umbrella; he wished the postillion to stop, but his cries only made the man drive the faster; had he known the simple word *Daß*, the umbrella might have been saved.

Another time he travelled in Greece on horseback without an interpreter, and all his Greek amounted to six words. We are indebted for another illustration of the subject to an anecdote very good-humouredly told by Dr. Sigmond, in his late work on Tea. One day at Moscow, he left his hotel with the name of the street written for him on a card by a Frenchman, as thus, *Rue de Démétrius*. After wandering about all day, he took a droschki, and attempted to return home, but in vain. He could not recognize the street, and the Cossack driver could not understand *Rue de Démétrius*. The driver accordingly took Dr. Sigmond to his own dwelling, gave him some capital tea, and fetched an Asiatic, whose various tongues were unfortunately all unknown to the doctor. A German came, but he did not know what street could be meant by *Rue de Démétrius*; at last a Frenchman arrived, who immediately translated the direction into *Metriffsky*, and Dr. Sigmond reached his hotel.

We shall continue our examination of the New Edinburgh Pharmacopœia on an early occasion. Meanwhile we will direct our readers to some observations by Mr. Phillips (p. 686), in our present number, pointing out certain chemical slips in the work.

ESTABLISHMENT OF A PROFESSORSHIP OF THE INSTITUTES OF MEDICINE,

In the University of Glasgow.

[From a Correspondent *.]

DR. BADHAM's chair in the University of Glasgow comprehends the Theory and Practice of Medicine. Dr. Badham confining himself to the Practice of Medicine, the COLLEGE, some six or seven years ago, appointed (with the consent of Dr. Badham) Dr. Harry Rainy, to give the lectures on the Theory or Institutes of Medicine. Dr. Rainy is a man of talent and great

* Something of the kind seems to have existed here in the reign of Edward III.; Chaucer says of his Priores:—

"Frenche she spake ful fayre and fetisly;
After the scole of Stratforde atte Bowe,
For Frenche of Paris was to her unknowe."

* The name is given.

knowledge of his profession; he, moreover, possesses a profound knowledge of physiology, in its present highly cultivated state. If, to all this, we tell our readers he adds zeal, it will not appear surprising that under his auspices the class of the Institutes of Medicine, in the University of Glasgow, should have attained such a high degree of popularity, that the number of pupils in session 1837-38 was 141—about double what it was when Dr. Rainy commenced lecturing. Nor was this casual or accidental. The commissioners of inquiry into the state of the Scotch Universities, mention, in their report concerning the University of Glasgow, the numbers of Dr. Rainy's class for a period of six years, and recommend the erection of it into a professorship. Of course, they recommend no particular person as professor; but it could not be doubted that Dr. Rainy was both the best qualified, and best entitled, to be so. Government has just established a chair of the Institutes of Medicine in the University of Glasgow, and appointed—we grieve to say—not Dr. Harry Rainy! We by no means deny the propriety of Government appointing persons of their own political principles to situations, in preference to others—the candidates being equally qualified, and the one not having any peculiar claim more than the other; but in the case before us, a gentleman, so far as we know, not better qualified to teach such a subject as the Institutes of Medicine than any other medical practitioner who has not attended particularly to the progress of physiology—a gentleman, we say, having no peculiar claims, except his political opinions, has been appointed to the chair, to the exclusion—nay, to the *ejection*—of him whose talents, labours, and zeal, formed the class.

ENDERMIC MEDICINE.

WE are indebted for the following analysis of Dr. Ahrensens's work on the administration of medicine by the skin, to a German journal (Schmidt's Jahrb. May 1839). Dr. Ahrensens had the advantage of carrying on his experiments in the Frederic's Hospital, at Copenhagen: his work is entitled *Dissertatio de Methodo Endermatica*.

FIRST SECTION.—He is of opinion that

a blister is generally the best method of removing the epidermis; but when speed is desirable, or a blister cannot be applied, as in the case of very sensitive, timid persons, or in children, he uses a mixture composed of two parts of very concentrated ammonia and one part of lard. This mixture is at first fluid, but after the glass vessel which contains it has stood for thirty hours in cold water, it becomes solid, and of a greyish-yellow colour: it raises a blister in ten or fifteen minutes. He found that the *pommade ammoniacale* of Trousseau and Bonnet, consisting of equal parts of concentrated spirit of ammonia and lard, with one-fifth of tallow, did not have the effect they describe.

When a local effect only is desired, the remedy must be applied to the diseased part itself; when a general effect is wished for, the application must be made to those spots which lie nearest to the organs which are to be affected. The author limits the application of more blisters than one to those cases where the disease is of great extent, and affects different organs. He believes the most suitable form of using the remedy to be in powder. It is generally unnecessary, and even injurious, to mix other substances with the remedy used, unless the drug by itself is too irritating; as is the case, for example, with the salts of quinine. Dr. Ahrensens found that the pain which these cause, when endermically applied, is much lessened if united with fat; when this was not done, he has seen ulcers produced which had not cicatrized in four, or even six weeks. In order to lessen the pain, he has also often applied a poultice with narcotic herbs. The medicines must be applied immediately to the exposed cutis. A high temperature and moisture accelerate the effect, as the author found by an experiment on two kittens. Perhaps (he adds) a poultice laid over the point of application serves the same purpose.

SECOND SECTION.—On the efficacy of individual remedies applied endermically.

A. *Narcotics*.—Morphia and its salts. The author prefers the sulphate of morphia, partly on account of its greater solubility, and partly because Pelletier asserts that it keeps purer than the acetate. He does not agree with A. L. Richter, that the acetate of morphia excites neither inflammation nor secretion on the cutis; for he has always seen a slight suppuration arise, so that it took three or four days to form a new epidermis. The reviewer coincides with him in opinion. Dr. Ahrensens had one opportunity only of applying the sulphate of morphia on the fourth day of a very violent spontaneous tetanus. The effect was very transitory, and the patient died on the same day. On dissec-

tion, there was found inflammation of the spinal marrow, and softening of its thoracic portion. According to all experiments hitherto made the endermic application of morphia is preferable to the internal use of opium in this disease; partly because the narcotic is in this way more easily incorporated with the system, and partly because morphia, introduced by the cutis, is not so irritating to the vascular system. The application is to be immediate, after the removal of inflammatory affections by bleeding, &c. When organic alterations have already taken place, the endermic application of morphia is as profitless as the internal use of opium. As to its application in delirium tremens, the author brings forward three experiments made in the Frederic's Hospital, which are not very decisive, indeed, but still shew that the endermic use of morphia is commendable, when the internal employment of opium or morphia is for any reason inadvisable.

Morphia was twice administered by the skin, in mania, as a palliative, and procured some repose for a time. The author used the acetate of morphia for spasms of the left side of the face, without any relief. Two cases of what appeared to be rheumatic neuralgia of the face, were cured by Dr. Ahrensen with the endermic application of the acetate and sulphate of morphia. He also entirely cured an *ischias nervosa postica* by three grains of the sulphate of morphia, after venesection, leeches, nitre, stramonium, and opium clysters, had been employed in vain. Of five cases of hemicrania, the endermic use of the acetate or sulphate of morphia was of no advantage in three; in another it produced only slight relief; but in the fifth, though the disease had lasted nearly half a year, four applications of the sulphate (increasing the dose from one to two grains), cured it so far that nothing remained but a sensation of heaviness, which afterwards went off spontaneously. The author often tried this remedy against toothache. It sometimes cured pain in the side, either originally unattended by inflammation, or when the inflammation had been removed.

In chronic and local rheumatism without fever, the author has seen excellent effects from morphia endermically applied; but acute rheumatism with fever is cured by leeches, small blisters, and vapour baths; and the application of morphia to the cutis is only a palliative. The reviewer cured a rheumatic hemiplegia of the face, after a perpetual blister behind the ear, and the rubbing in opodeldœ and laudanum had been tried in vain, with acetate of morphia. He first used it endermically with instantaneous advantage; but afterwards

internally, on account of the pain it produced when applied to the cutis.

A woman who laboured under intermittent fever, with a bronchitis which was becoming chronic, was cured of the latter by the author by the endermic use of acetate of morphia. To relieve coughing and produce sleep at night, the endermic use of morphia is to be preferred to the internal administration of opium, partly because the relief is quicker, partly because it is less heating. The author cured whooping cough in a girl, aged eight, by the daily endermic application of half a grain of the sulphate of morphia, eight times; and it did not produce narcotism. In another case where sopor came on after three applications, only a remission was effected.

The reviewer used the acetate of morphia in the whooping-cough of two adults, first endermically, and then internally, in the dose of half a grain in the evening; and by these means cut short in a few days a disease which is otherwise so obstinate. In children he has not yet employed it so as to be able to speak of it with confidence.

In vomiting and cardialgia, the author found the endermic application of acetate or sulphate of morphia most beneficial; when scirrhus was the cause, this method at any rate mitigated the symptoms for some time better than any other remedies. The endermic use of morphia in dysentery has been extolled by Gouzée, of Antwerp; but Dr. Ahrensen thinks the effect may be referred rather to the blister than to the morphia. The reviewer, however, says that this is incorrect, for he has often seen the acetate, given in the evening to the dose of a third or half of a grain, remove the pains and the tenesmus for nearly the whole night, and be the greatest comfort to the patient; but the pains and tenesmus return on the following day with the constant evacuations of blood and mucus. He adds, that morphia is the best palliative in dysentery.

The author cured a strangury consequent on a chronic dysentery, with the endermic use of morphia. He has also seen an intermittent hemicrania, which did not yield to sulphate of quinine, cured by one application of a grain of the sulphate of morphia, strewed upon a blistered spot which had existed for several days upon the back of the neck.

In a case of *febris nervosa versatilis*, Dr. Ahrensen once applied half a grain of the sulphate of morphia endermically with the greatest advantage. After the lapse of three hours the patient obtained five hours' sleep, from which he woke with perfect consciousness, and as if gifted with new life, so that he soon recovered.

He twice applied a whole grain in *typhus abdominalis*, on account of violent convulsion, but it hastened the death of the patients. He twice applied extract of belladonna with simple ointment, in chronic rheumatism, and spasms of the muscles of the face, but without effect. Three times he applied crocus [of antimony] against rheumatic headache; in one case this was followed by perspiration and a cure, no doubt, accidentally, as the two other times no effect was produced.

Strychnia.—The author has some excellent remarks on the application and effect of strychnia, or its salts, which are stronger than the pure alkaloid. He first warns us to be cautious; he has seen the peculiar spasms caused by strychnia come on when the remedy had been discontinued for a fortnight; when its application is continued they are brought on by every emotion of the mind, and every thing which excites the circulation. Three weeks after discontinuing the strychnia, the author examined the blood, and believes that he discovered traces of it.

In a case of paralysis of the right hand, from the poison of lead, the author saw a cure effected by the endermic use of the nitrate of strychnia; but in a second case, where there was paralysis of the whole left arm from the same cause, the same remedy was unattended with advantage. The author saw a paraplegia of rheumatic origin, which chiefly affected the right extremity, cured by the endermic application of the nitrate of strychnia, for about six weeks. In hemiplegia, after apoplexy, the result was always more or less imperfect. He also saw amblyopia, following typhus, disappear after four applications of the nitrate of strychnia, pushed to the dose of a grain; but, as he observes, perhaps this was owing to the mere blisters. In a case of amaurosis in a woman suffering from chronic metritis, after a fright, the same method seemed to be of some benefit. In a case of hysterical aphonia, it was of no avail. In two cases of paralysis of the muscles of the face, the author saw the happiest results from the application of the nitrate of strychnia to the cutis, but in two other cases none at all.

In three cases of enuresis, this method was used without success, as likewise in a case of St. Vitus's dance.

Febrifuge remedies: the sulphate and muriate of quinine.—The author treated three complicated intermittents with success by the endermic method. He says, "The endermic method is always to be preferred if the patients are labouring under diseases of the pharynx or oesophagus—if the fever is complicated with an inflammation of any organ, or a local neurosis—or,

lastly, if it is accompanied by pain in the spleen, and if the disease is of a pernicious type, we must join the internal to the external employment, in order that as much of the remedy as possible may be introduced into the system, and thus the threatened paroxysm may be more certainly averted."

For the place of application the author advises the epigastrium, or the region of the spinal cord; he applies eight grains, mixed with lard, all at once, in order to spare the patient the repetition of pain. He has not found combining the quinine with morphia either advantageous or the reverse. He cured a periodic headache by the endermic application of quinine to the back of the neck.

Expectorants.—The application of kermes mineral has always been followed, in the author's experience, by copious suppuration, and almost always by increased expectoration, but by no other symptom, though several are mentioned by other writers. The dose was in every case six grains.

Diuretics.—The author once cured a man of five-and-twenty, labouring under a catarrh, combined with ascites and hydrothorax, by the endermic application of squill mixed with lard. The local irritation was not very considerable. A copious secretion of urine came on, frequent night-sweats, and great expectoration. Digitalis endermically applied causes very violent pain; but the author several times employed it successfully in anasarca, in the dose of eight grains. This method of using it is to be recommended, when the state of the digestive organs altogether forbids its internal use, or forbids it after the lapse of some time. Iodine was tried in vain in the hospital, as it did not produce the slightest diuresis.

Purgatives.—Gamboge was applied in the hospital twice; in one case six grains were of no avail; in the other, the repeated application of ten grains had a good effect. A woman suffering under blind piles, whose bowels could be opened only by castor oil, and that with difficulty, after the endermic application of ten grains of the watery extract of aloes, had spontaneous evacuations on the two next days, which had long not been the case.

This method of incorporating remedies deserves all consideration, says Dr. Rösch, the reviewer; and while, on the one hand, Dr. Ahrensens avoids all exaggerated praise of endermic medicine, on the other, he is equally far from rejecting it.

SENSIBILITY OF THE ANTERIOR SPINAL COLUMNS.

At the sitting of the Académie des Sciences of the 20th of May, M. Magendie communicated the results of some experiments on the nervous system, of which the following is the abstract:—

The (roots of the) sensitive and the motor spinal nerves are equally sensible when they are both entire. If the sensitive nerves be cut, the motor immediately lose their sensibility. If the motor nerves be cut across at the middle of their roots, the end which remains attached to the spinal cord is perfectly insensible, but the other end (next the ganglion) preserves an extreme sensibility. In this case, the sensibility goes from the circumference to the centre.

If the sensitive nerves be cut at the middle of their roots, the end which remains attached to the cord is very sensible; the end which is attached to the ganglion has lost, on the contrary, all its sensibility.

At the *séance* of the 3d of June, M. Magendie communicated the following additional observations:—

I pointed out recently the singular fact that the anterior root of the spinal nerve receives its sensibility from the posterior root, and that this acquired sensibility comes from the circumference to the centre. I was curious to know whether the same kind of influence does not exist between the columns of the medulla. After having again confirmed the fact that the posterior columns have an exquisite sensibility, while that of the anterior is less marked, I cut on one side the posterior roots of a pair of lumbar nerves; I then examined the anterior column at the same level, and found its sensibility very slight, if not entirely destroyed. This influence was probably transmitted by the uninjured motor roots; but to verify this idea, I cut through the middle of the motor roots, leaving the sensitive roots entire: the same loss of sensibility in the column, at the place and above the place whence the roots arose, was now observed.

After repeating these experiments several times, I am enabled to conclude that the posterior column of the medulla spinalis, the sensitive roots, the ganglion, the spinal nerve, the motor roots, and, lastly, the anterior or motor column, form a kind of circular chain, of which each of the elements serves to transmit sensibility from the posterior cords to the anterior. Why is this transmission effected by so long a route, when it might have been effected by the simple intermedium of the sutural column? I know not; it is a new ques-

tion for experiments; but the fact of the influence of one part of the central nervous system on another, is not in itself less remarkable, and may, if it is confirmed, open a new route for researches in this still obscure subject. — *Comptes-Rendus*, May 20, and June 3, 1839.

LUMINOUS APPEARANCES IN THE EYES.

M. SAVIGNY, member of the Académie des Sciences, has for fourteen years suffered from such violent neuralgia in the eyes, that he has been constrained to remain in perfect darkness for the whole of that period. This darkness does not appear such for him, for the appearance of light, which, unfortunately, has a continual source in his eyes, incessantly fills the whole space. Lately, M. Savigny has made the following communication to the Academy on this subject:—

Every one who passes his finger on the ball of the eye, near the inner angle, produces in the dark a little circle of light, which appears at the external angle. These luminous appearances (phosphoric) are from eight to ten lines in diameter, never appear of themselves, and always are seen about the edges of the eye. Those seen by M. Savigny appeared under three forms, each of which assumed other forms. In the first, the appearance was circumscribed, circular, simple, or manifold; in the second, like a torn or shredded piece of cloth, or as a long band on the upper border of the eye; in the third, the appearance consisted in a single circle of many feet diameter, formed by a simple line parallel to the edge of the eye, and which at a certain distance appeared to surround the entire countenance. Seven years after the access of these appearances, in the year 1832, they increased much in intensity with regard to size, conformation, multiplicity, and brilliancy. The circular appearances had sometimes a diameter of from six to ten inches, were simple or festooned on their borders, sometimes of the colour of raw silk; or white, with silver or brilliant golden borders; sometimes yellow, orange, red, or black, with a broad border of gold or silver; sometimes they had the appearance of many concentric circles, with concentric undulations of the greatest fineness and most splendid brilliancy. The largest and most brilliant appearances were on the marginal parts, and frequently terminated above in a kind of cupola. The more crowded the figures were, the more they lost in splendour, colour, and distinctness of outline. At first they only appeared from time to time, but

now almost daily, and it only required simple contraction of the eyelids to produce them. Their size, form, colour, and brilliancy depended for the most part on the altered position of the organ. When this phenomena is produced by the pressure of the finger, the way in which the pressure is exercised has an influence on the kind of appearance. When the finger is pressed from the inner angle of the eye towards the outer, the luminous appearances are seen in exactly a contrary direction, and appear on all points of a large curve above the eye, which sometimes reaches as far as the other eye, but generally only reaches as far as the middle line. If, along with this pressure, a retrograde motion is made, the appearances are increased more or less, but they rise or sink in a quick and confused manner on the curve we have described. In general, when the pressure is firm, the appearance is larger, more regular, and more vivid; when the pressure is uneven, wary, and irregular. The luminous appearances generally begin and end with the pressure; but applying the pressure very frequently diminishes the power of producing these appearances. They always made their appearance when M. Savigny, wearied with the intolerable pain caused by congestion, pressed upon the bandage which covered both his eyes, in order, by pressure, to assist the eyelids in effecting the emptying of the vessels.—*Arch. Gén. Août 1838; and Dublin Journal of Med. Science for July 1839.*

LIVERPOOL NORTHERN HOSPITAL.

Dislocation of the lower end of the Fibula.

A. BEVINGTON, 6 years of age, fell from a height of thirteen feet, alighting on the outer side of the right foot. He was admitted into hospital about an hour after the occurrence of the accident. The foot when applied to the ground rested on its outer side, its plantar surface being turned inward. No fracture of the bones interested in the ankle-joint or tarsus could be discovered; the inner malleolus was intact, and the patient being of a spare habit, the fibula could be so far traced as to leave little doubt of its being also uninjured. The lower end of the fibula projected in a very remarkable manner, stretching the integuments over it; its connections with the tarsus and tibia had apparently been torn; the peroneal tendons seemed to have been displaced from their groove, and got rather to the inner

side of the fibula, and thus allowed the flexor communis and posterior tibial muscles to invert the sole of the foot as described. On putting the limb in a flexed position, extending from the foot, and at the same time pressing in the outer malleolus, the joint could be made nearly to assume its natural shape; but this speedily disappeared on the withdrawal of my efforts.

With the view of retaining the parts in position, Dupuytren's splints for fractured fibula was applied to the fibular aspect of the limb; the figure of 8 bandage, while retaining the foot in position, urged the obtuse end of the pad against the fibula, and thus assisted in preserving the contour of the joint. The patient is doing well so far; but I fear that, in spite of every effort to the contrary, a certain lameness will remain.

Dislocation of the head of the Radius backward.

About three months ago, a boy, aged 13, was shown me, who was stated to have fallen on the palm of his right hand from a height of several feet. On flexing the elbow-joint, and at same time applying my fingers to its posterior part, the head of the radius could be distinctly felt lying upon the outer and back part of the external condyle of the humerus, the bones composing the elbow-joint met at an obtuse angle, while flexion or extension of any moment was impossible. The hand was pronated, and usually retained in the patient's breeches pocket, to prevent the pain arising from the dislocated bone being pushed against the condyle of the humerus when the arm was allowed to hang down. The time of my seeing the boy was six weeks after the receipt of the injury. He had been to a Welsh bone-setter—a practice very common even among the better classes of Liverpool—and that worthy had, as he said, "set the bone." Of course, at a period so distant, any attempt at reduction was out of the question.

Taking into consideration the miserably impaired state of the joint's functions—the more than probability that the displaced bone had ceased to be directly connected with the synovial lining of the joint—and the good health of the patient, I conceive that excision of the head of the radius might be performed with every probability of success, as regards improvement in the motions and consequent usefulness of the elbow-joint.

NEW VACCINE VIRUS.

WE mentioned in our preceding No. (p. 516,) that Mr. Estlin, of Bristol, had obtained vaccine virus directly from the cow—and had transmitted some lymph propagated from it, to this country. We have since been favoured by our friend Dr. J. Carson, with lymph from this source, said to be but fourteen removes from the cow, and have used it in several instances. The disease which resulted had the peculiar characters described by Jenner, but more strongly marked than we have seen them from the matter at present in use. The inflammation did not make its appearance until somewhat later than usual (the fifth day,) but the vesicle was regular in its progress, rather larger perhaps than common, but flat and indented in the centre. The scab was thick, dark-coloured and firm—more strongly characteristic of the disease than any scab we have seen for a number of years.—*American Journal of Medical Science* for May 1839.

PRESCRIBING IN PRUSSIA.

HE disliked the whole system in Prussia, and would state a fact illustrative of its character. A friend of his being lately in Prussia, was desirous of having a prescription written by Sir H. Hallford made up; but he could find no apothecary who dared to do this, unless the prescription was countersigned by a Prussian physician; and he could get no Prussian physician to subscribe the prescription, until it should be previously signed by another Prussian physician. (Laughter).—*Lord Brougham's Speech on Education*, July 15, 1839.

LITERARY ANNOUNCEMENT.

PROFESSOR Rudolph. Wagner, of Erlangen, well known as the author of a very valuable "Lehrbuch der Vergleichenden Anatomie," and of several very valuable monographs, has published the first part of a Manual of Physiology, adapted as a text-book for lectures, as well as for self-instruction, and with a special reference to the education of medical men. It is to be published in four parts: the first, which has appeared, treats of Generation and Development; the second will comprehend Nutrition; the third will contain Sensation and Motion; and the fourth, General Physiology. A volume of plates, under the title "Icones Physiologicae," is also announced, but has not yet reached us,

to which very frequent reference is made in the text. That portion of the work which has already appeared, has been executed in the most masterly manner: the arrangement is admirable, and the style clear and interesting. If the other parts equal this, of which, from our knowledge of Professor Wagner's works, we can have no doubt, no book can be more admirably suited to the wants of English students.

We are authorized to announce that a translation of the work is in progress, the particulars of which will be speedily advertised as soon as it can be ascertained when the first part is likely to be published.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.

By DR. VENABLES.

You may remember, when speaking of the composition of the urine, we found *phosphoric acid* to be a predominant, and, indeed, a very important constituent. We found it also in excess, and that it was the acid selected by nature herself to hold by its excess the otherwise insoluble phosphates in solution. Hence an excess (at least to a certain extent) of phosphoric acid is not only natural and innocent, but absolutely essential to the healthy chemical constitution of the urine; and it will prevent the deposition of the phosphates. It occurred to me, therefore, that phosphoric acid might be injected into the bladder in much greater, and consequently in much more efficient, quantity than any of the other acids—as the hydrochloric or nitric, for instance. I have had three opportunities of experimentally determining this point. The first case was that of an old man severely attacked with *catarrhus vesicæ*; in which the urine was alkaline when passed, had a dreadful smell, and was loaded with a thick, tough or ropy, and adhesive mucus. This at last became so thick that the urine would not flow; and when a catheter was introduced, the eyes or perforations became so clogged and stopped up with this mucus, that not a single particle of urine could pass. In these circumstances, a solution of phosphoric acid, in the proportion of five drops of the acid, as commonly sold,

to the ounce of distilled water, and which was afterwards increased to ten, was driven, from an elastic bottle fitted with a gum catheter, into the bladder. The fluid was kept in the bladder for some little time, and then allowed to flow into the utensil. It was still found acid, but, upon filtering and adding ammonia to neutralize the acid, there was a considerable cloudiness, which partly precipitated, partly adhered, in an imperfectly crystallized or plastic form, to the sides of the jar. The urine at last began to flow more freely under the use of the phosphoric acid, both injected externally and exhibited internally; and when the quantity of mucus was reduced, the bladder having been emptied and injected with a solution of phosphoric acid, the washings, on being neutralized by soda, slowly deposited a precipitate, which, on examination, proved to be phosphate of lime. A second case was attended with somewhat similar results.

Upon one occasion only have I had an opportunity of seeing the efficacy of the phosphoric acid in the case of a phosphatic calculus. The case occurred in a person of about 56 years of age. He had been always subject to gravel, and occasionally passed some of the small fragments which I here shew you, and which principally consist of triple phosphate. Some years after, the urine frequently became loaded with mucus, of the character already described, and he was considered as labouring under *catarrh* of the bladder. Under these circumstances I saw him. The urine was very pale, frequently like spring water, specific gravity insensible to this instrument, neutral, but, in from one to two days, becoming alkaline and cloudy. When the urine was passed in less quantity and more concentrated, it was generally turbid, specific gravity 1.004 to 1.005, contained frequently a good deal of mucus, was alkaline, and of very foul odour. The symptoms characterizing

stone in the bladder were present, and on sounding, which was done at my request, a calculus was felt. The treatment usual in such cases, with the internal exhibition of phosphoric acid, was adopted; and the phosphoric acid, in the proportion of three minims to the ounce of water, injected by an elastic bottle, &c. into the bladder. The injection was kept in the bladder for a few seconds, and then allowed to run off. The strength of the solution was at last increased to ten minims to the ounce of distilled water. As it now irritated a little, a small quantity of tincture of opium was added, and the injection then gave no uneasiness. The injection was used three times every day, and on testing the injection after several times injecting into and escaping from the bladder, by means of caustic potass, the mixed phosphates were thrown down in small quantity. In about three weeks, the calculus which I shew you was voided. You see that the centre consists of a small lithic nucleus, with an external crust of the mixed phosphates. Shortly after this he passed some fragments of triple phosphate, and began to enjoy comparative ease. Directions were given to him, but for a considerable time I have lost sight of him.

It would therefore appear, that in cases of phosphatic calculi, the partial solution of such stones, by means of solvents injected into the bladder, may be attempted not only with safety but with some prospect of success*; and as the mechanical injection of the bladder produces no inconvenience, in the diseased states of this organ attending the phosphatic diathesis, the action of the acid upon the secretion from the mucous lining is calculated to prevent that irritation which this secretion exerts upon the urinary organs. This will tend to check the unnatural state of the urine in this diathesis; and these considerations alone, and independently of any chemical agency upon the stone, would be quite sufficient to justify recourse to the practice. But the injection seems to exert also some solvent agency, however trifling,

* I do not think that the salts precipitated from the diluted acid after repeated injection into the bladder, is wholly derived from solution of the calculous mass. It appears to me to be partly derivable from the action on the mucous secretion from the bladder, and partly from intermixture with the urine. The acid, too, would readily dissolve a layer of calculous matter just deposited upon the stone; and hence, in one or two instances in which we examined the injection immediately on its first ejection from the bladder, we found that it precipitated much more copiously on the addition of liquor potassæ, than a fresh solution used immediately after and passed several times through the bladder. Therefore, the solvent action upon the stone itself is probably but trifling, and hence the necessity of patience and perseverance, if we wish to effect any real good.

upon the stone, and thus, by perseverance, at least in the more favourable cases, we may ultimately effect the reduction and expulsion of the calculus; but, at all events, we shall afford considerable relief, and counteract the effects that would otherwise result from the unhealthy state of the urine. Lastly, the phosphoric, as being the acid in excess, selected by nature for holding the constituents of the earthy calculi in chemical solution, seems to be the best adapted for our purpose; because it produces less irritation and may be used of greater strength, and its solvent powers in the present instance are nearly equal to those of the nitric acid. These means, if assisted by the internal use of the phosphoric acid, and those previously mentioned, hold out the fairest prospect in one of the most serious and distressing complaints to which man has been subjected.

Phosphatic concretions in the prostate gland.—When the prostate has become diseased, it is apt to secrete phosphate and carbonate of lime. These concretions, however, as already mentioned, consist principally of phosphate of lime. This is generally cemented or accreted into masses by means of animal matter, and sometimes the quantity of animal matter is so abundant, that, if the earthy salt be dissolved out by an acid, the agglutinating animal matter will still retain the original shape of the mass. I have already shewn you some of these calculi, and they may always be distinguished by their composition and stratified structure. They are mostly small, but there are specimens in the College of Surgeons of a very large size.

With respect to the treatment, it must be mostly surgical, and therefore does not properly come within the sphere of our observations. The medical treatment consists in the occasional application of leeches, fomentations, and the other means of alleviating or subduing irritation; but for further particulars I must refer to the works upon surgery.

Nephritis.—Inflammation of the kidneys, unless arising from some mechanical irritation, is not so frequent as some other internal inflammations. It belongs to the class Pyrexia, and is a genus of the order Phlegmasia of Cullen. Consequently it commences with the usual symptoms of synocha fever—that is, rigors alternating for some time with heat, till at last an increase of temperature is permanently established. In some instances the febrile symptoms run very high, while in others they are but barely perceptible; but in almost all cases of nephritis the pulse is hard. After the febrile symptoms have been established, the patient complains of thirst, and the tongue is either coated with a yellowish-white mucus, or it is dry and

furred. There is, from an early period, considerable nausea, and for the most part frequent vomiting and retching. There is great anxiety and restlessness; the bowels are at the same time constipated, and not unfrequently a sense of twisting about the navel, and pains like those of colic in the abdomen. The urine at first is red, and, indeed, deeply coloured; afterwards, however, becoming colourless and limpid. When the disease is at its height, there is frequent desire of passing the urine; but very little is voided. If but one kidney be affected, there will be but scanty micturition; but if the inflammation have attacked both, then total suppression of urine will be the consequence. There is also severe pain in the loins, and this is of an acute and burning character, in the region of either one or both, according as the inflammation occupies one or both kidneys. With these there is a sense of numbness of the thigh, and a painful retraction of one or both testicles.

Diagnosis.—Nephritis may be confounded with one or two diseases; for instance, calculus, lumbago, &c. Inflammation will vary in intensity, according to the causes which excite it. Thus the inflammation arising from constitutional causes, is attended with pain of an obtuse character, and much less severe than that which attends inflammation from calculus. This difference probably depends upon the part inflamed. If the pain attacks the glandular portion, where the vessels are larger, the pain will be less; for the pain of inflammation seated in parenchymatous structures is always much less than from that occupying membranous, especially serous, tissues. This, of course, will enable us to account for the much greater intensity of calculous inflammation.

From lumbago (which in the general symptoms frequently so closely resembles nephritis as to be with difficulty distinguished) it may be known by the body being moved with but little increase of pain; whereas the pains of lumbago are much increased by motion. Also, the vomiting, nausea, and cough*, which attend nephritis, will be absent, or not necessarily present in lumbago. Idiopathic inflammation may be still further distinguished from the calculous form, by the pain and uneasiness not extending perfectly along the course of the ureters to the groin, nor is there that painful retraction of the testicles, nor numbness of the thighs, which so constantly attend calculus.

Causes.—With respect to the causes, they are those of the phlegmasiæ in general. Falls, concussions, and other injuries of the spine and back, will excite nephritis in the predisposed. Hence it has succeeded long-continued and violent horse exercise, more especially if the weather be very hot. Very stimulant diuretics, as turpentine, cantharides, and similar medicines, will bring it on.

Gout and rheumatism appear to act often as predisposing causes, such subjects being especially liable to attacks of nephritis by very slight causes, such are exposure to cold, damp, &c. "Hence these affections appear to constitute the link, as it were, by which inflammation of the kidney is connected with calculus in that organ, this latter affection being apparently produced by the metastasis of gout and rheumatism to the kidney, more frequently than by any other cause*." Be this as it may, the facts are unquestionable, whether the explanation be correct or not. It has also been remarked, that after inflammation, however excited, the kidney is often left in a sort of chronic excitement or irritation, in which it becomes exceedingly disposed to secrete lithic, or even the oxalic acids; and hence it happens, that after the age of forty, calculus is apt to form sooner or later after almost every attack of inflammation of the kidney, or even about the region of the kidney, whether the organ itself has been involved in it or not.

Treatment.—Inflammation of the kidney may terminate in resolution, suppuration, and abscess, induration, gangrene, &c. Resolution is the most favourable, and this should be the object of the practitioner. Therefore, in active inflammation, bleeding, both general and local, and to an extent proportioned to the strength of the patient and the intensity of the symptoms, should be practised. In less severe cases, cupping or leeches to the loins will be sufficient. There is nothing which seems to give such decided relief in inflammatory diseases of the kidney, as the warm bath and hot fomentations to the loins. These, therefore, should be amongst the very first remedies, and should follow immediately after the bleeding. Purgatives should also be given, but of course they must be of that sort which do not specifically irritate the kidneys. Many recommend calomel in active doses. "Internally at the same time, active doses of calomel may be exhibited, either alone or combined with opium or hyoscyamus, according to circumstances; and these may be followed, if the stomach will tolerate their use, by other purgatives, directed more or less to

* A cough is said frequently to attend nephritis, and to arise from the inflamed kidney irritating the diaphragm upon which it is said to press.

* Prout on Diabetes, pp. 212, 213.

the kidneys, according to the judgment of the practitioner*."

Mercury, perhaps, as a purgative, is not objectionable; but although this mineral proves beneficial in most parenchymatous inflammations, I think it does harm in all affections of the kidney, that is, if its specific effects on the system be induced. Therefore, it will be better to exhibit mercury solely as a purgative, and for this purpose it may be given with rhubarb or jalap, and its operation subsequently promoted by castor oil or a senna draught; emollient enemata, with or without opium, or hyoscyamus, should also be injected.

As the urine is, as already stated, suppressed, means for restoring the action of the kidneys should be had recourse to. The saline purgatives have this effect to a certain extent; and after the activity of the inflammatory action has been somewhat reduced by the measures above mentioned, they may be given both with the view of keeping up the solubility of the bowels, and to excite the functions of the kidneys.

But, perhaps, there is nothing so effectual for this purpose as large potations of mild or demulcent fluids; hence, linseed tea, gum water, barley water, or even simple water, if drank in sufficiently large quantity, will almost always cause the urine to be secreted, and at the same time relieve the irritation of the urinary organs themselves, which oftentimes is productive of the most urgent distress to the patient. For the same purpose we may give the nitric æther, colchicum, and juniper†, to rouse the kidneys to action, promoting the action by plentiful dilution with mild drinks; and perhaps nothing is better adapted to this purpose than the almond emulsion. The treatment of idiopathic inflammation must be somewhat different from that of inflammation arising from calculi in the kidneys, the management of which has been already detailed. If the symptoms have not completely yielded, but that a sort of chronic congestion remain behind, this should be removed by local bleeding, repeated occasionally, and the application of mustard sinapisms and plasters of ammonia to the loins. When the inflammation is of a gouty character, Dr. Prout states that colchicum is particularly beneficial, and in such instances warm mustard cataplasms must be applied to the feet. During the whole of the attack

the most rigid antiphlogistic regimen is to be adhered to.

Suppuration.—In some cases the inflammation terminates in suppuration, and an abscess forms in the kidney. The symptoms of this are somewhat similar to those which supervene suppuration in other parts of the body. When suppuration is about to take place, rigors generally are observed, and when established there are regular periodical exacerbations of fever terminating in succession with all the usual symptoms of hectic fever. But such an event is commonly indicated by the existence of pus, or a muco-purulent matter in the urine; and this, either by its own acidity, or by inducing an acrimony of the urine, produces great irritation both in the bladder and the urethra. The distinguishing characters of pus have been already stated; and if collected and placed in the field of the microscope, or examined in the manner already pointed out, pus may be determined by those properties.

In some cases, however, where the inflammation exists in the parenchymatous structure, and has not extended to the membranous portions of the kidney, the urine may remain clear for some time, and the patient then complains of an obtuse pain, with a sense of weight and fulness in the loins. This may be mistaken for lumbago, but is to be distinguished by the absence of those symptoms already pointed out as characterizing lumbago. After an interval, however, longer or shorter according to the circumstances, the abscess bursts suddenly into the pelvis of the kidney, and a large quantity of pus, often mixed with blood, is passed with the urine, and this is attended with a very great deal of irritation to the patient.

Inflammation of the kidney terminating in suppuration or abscess is generally caused by calculi, idiopathic inflammation more commonly terminating in resolution, hypertrophy, or tubercular induration. When the calculus is retained, sometimes the pus is not discharged with the urine, and the patient continues to suffer for a long period from a number of very distressing symptoms. In some such cases the abscess may point externally, and the pus may be evacuated from the loins. In some, the abscess has burst into the abdomen, and then it mostly proves speedily fatal. In the majority of cases, however, the ureter remains partially pervious, and pus continues to be observed occasionally in the urine, and at times small calculi and blood are voided. If the calculus remains, and that means be not adopted to arrest its growth, it is evident it must ultimately prove fatal, or will most certainly completely disorganize the kidney.

A peculiar kind of suppuration and

† I have found the following often very serviceable:—

R. Infusi Juniperi, drs. x.; Spir. Æth. Nitric. dr. ss.; Vin. Colchici, min. x.; Tinct. Hyoscyam. min. xx. M. It. haustus secundis vel tertiis horis sumendus.

abscess, partaking of a scrofulous character, has been noticed by many persons. This may or may not be complicated with calculi. The symptoms are often very obscure. In the latter and chronic stages of this complaint, Mr. Howship observes, the pain is almost invariably referred to the neck of the bladder. This, however, only takes place in the latter stages, as Dr. Prout mentions an instance which came under his own observation, in which the pain was entirely confined to the regions of the kidney and ureter, and the urine in this case was acid, and, excepting its containing pus, not very unnatural. In those cases, in which there is pain in the bladder, the urine will be generally found alkaline, and very fetid and unhealthy, and hence the pain in the bladder may be looked upon as arising from the acrimony of the urine. "The cases of this scrofulous affection of the kidney," says Prout, "that I have seen, have also been attended with indolent tumor and abscess of the inguinal glands, and by occasional pain and swelling in the testicles. They were accompanied by great extenuation of the body and derangement of the general health, and ultimately proved fatal*."

Abscess of the kidney must be treated on the same general principles as abscess and suppuration in other parts; that is, the patient's strength must be supported by such remedies as will enable the system to bear up against the debilitating effects of the discharge, and its consequences—the hectic paroxysms. Setons or issues, also, should be inserted in the loins, and they very often prove extremely beneficial. When calculus is the exciting cause, the means already pointed out, and adapted to the particular or existing diathesis, must be carefully and cautiously employed. To relieve pain, anodynes, and especially hyoscyamus, must be given in sufficient doses; and they may often be beneficially had recourse to in the shape of suppositories or clysters. Astringents, as the *uva ursi*, either as infusion or extract, must also be given. The *mistura amygdalæ*, with the compound tincture of camphor, I have often found to allay the pain and irritation of the bladder and urinary organs more effectually than any other remedies. There are many who use *copaiba* and the different balsamic medicines in such cases; but the propriety of all stimulating remedies seems extremely doubtful, if not absolutely injurious.

Indeed, in all chronic affections of the kidney, it is of the utmost moment to attend particularly to the state of the urine; for if this be neglected, a great deal of mischief may be done. Of course, we

must always ascertain whether there be any calculous diathesis present; and the means adopted must be regulated accordingly. But in abscess, as the urine by becoming alkaline is rendered highly irritating to the bladder, an acid should be exhibited. The best, perhaps, is the phosphoric; but in the peculiar circumstances under consideration, I have found chlorine best adapted; it has often seemed to me to excite a healing process in the abscess of the kidney. In all cases, too, of suppuration, the *tinctura ferri sesquichloridi* will be found a most valuable tonic. When there is a scrofulous diathesis present, the *ferri iodidum* may be given, in doses proportioned to the age and habits of the patient.

Induration cannot be determined by any characteristic symptoms; and if it could, it would have to be treated upon general principles. The iodide of iron, if there be no positive inflammatory action present, would be an appropriate remedy.

Gangrene may be known by the symptoms which usually attend upon this termination of inflammation. They are—sudden cessation of the pain, sinking, with irregularity of the pulse, which at last becomes intermitting; pale, anxious, and distressed countenance; sharpening of the features; cold, clammy, and viscid sweats; and ultimately hiccough. In such circumstances the case is hopeless, and the disease speedily proves fatal.

VELPEAU'S CLINICAL LECTURES ON OPIIHTHALMIA.

BY J. HENRY BENNET, B.L. & B.S.

Sorbon.

INFLAMMATORY DISEASES OF THE GLOBE OF THE EYE.

Conjunctivitis.—*Simple conjunctivitis*.—*Conjunctivitis with chemosis*.—*Partial conjunctivitis*.—*Papular conjunctivitis*.—*Granular conjunctivitis*.

WE are now about to commence the study of the department of pathology which deserves more especially the name of ophthalmology. The various inflammatory affections of the *palpebræ* might justly be treated apart from diseases of the eye, as these organs are merely the "*tutamina oculi*," destined to protect it from the action of external agents. Thinking it, however, better to follow the course usually pursued by authors, when treating of

* On Diabetes, &c. p. 216.

this subject, I have, in my former lectures, given an account of the different forms of blepharitis. I shall now proceed to examine the inflammatory affections of the conjunctiva, the cornea, and the iris. I also intend making a few observations on what has been called *scleritis*. These diseases I shall consider as purely inflammatory, as existing without any complication, and entirely independent of specific causes, reserving until a latter period the examination of the influence which these causes may exercise on ophthalmia in general. By thus gradually proceeding from what is simple to what is compound, our ideas will necessarily be more clear and more precise than were we to follow any other method.

The characters which serve to distinguish the inflammatory disease we are about to examine, are drawn, in a great measure, from the vascular appearance of the affected tissues. The importance of this symptom has been so generally admitted, that in these later times many anatomical researches have been undertaken, with the view of throwing additional light on the distribution of the vessels of the eye. As I think it indispensable that you should be acquainted with the results of these researches, I shall enter into a few details on the subject.

Nearly all the arteries of the eye derive their origin from the ophthalmic branch given off from the internal carotid. The divisions of this artery, you are well aware, do not all follow the same direction, or terminate in the same tissues. Viewed in this light, they may be divided into four sets. Some supply the eyelids, others the conjunctiva; some, again, are distributed to the sclerotic, whilst others pass into the interior of the eye. These groups anastomose freely with one another.

The arterial network of the eyelids is principally formed by three branches—the nasal, the lacrymal, and the frontal arteries. These arteries, however, are only distributed to the mucous surface of the palpebræ, and to their free margin; the cutaneous surface is supplied by the temporal, the infra-orbital, the transversal, and angularis faciei. Thus the arterial circulation is carried on by two different sets of vessels, which anatomical fact may account for our meeting separately with the different forms of blepharitis.

The conjunctiva also presents two distinct sets of arteries. Some of these are given off by the branches we have seen supplying the mucous surface of the palpebræ, the remainder are ramifications of the superior and inferior muscular branches. These arteries are exceedingly numerous; they may be seen presenting the appearance of tortuous, arborescent filaments, frequently anastomosing with one another,

moveable at the centre of the ocular conjunctiva, immovable near the cornea and near the fixed margin of the tarsal cartilages. Near the cornea, they communicate with the arteries of the sclerotic, and with those of the interior of the eye; near the tarsal cartilages, with the arteries of the external surface of the eyelids. In some cases of intense simple conjunctivitis, these small vessels may be seen extending more or less on the cornea.

The sclerotic receives but a small number of arteries, nearly all of which are supplied from the muscular branches. These vessels present but few ramifications; they communicate, in their course, with the arteries of the conjunctiva and those of the interior of the eye, and at their termination contribute to form the vascular circle round the cornea, which we are about to examine.

The ciliary branches are the only arteries supplying the interior of the eye, to which I shall direct your attention; their mode of termination, on arriving at the ciliary circle, should be attentively studied. Some of these arteries pass outwards, and then, becoming reflected, anastomose with those of the conjunctiva and sclerotic; others, passing inwards, supply the iris, whilst a few, following their primitive direction, reach the cornea. The circumference of the cornea may, therefore, be termed the conflux of the arteries of the eye, as it is the seat of the vascular communication which exists between the exterior and the interior of that organ. The existence of this kind of external conflux bears so directly on the pathology of the eye, that it is indispensable you should be perfectly acquainted with the arteries by which it is formed.

The venous circulation of the eye is of but little importance with regard to the study of ophthalmology. The distribution of the veins, moreover, being nearly the same as that of the arteries, I shall not detain your attention any longer on this subject, but enter at once into the examination of the inflammatory affections of the eye, beginning by those of the external or mucous surface.

Conjunctivitis.

The ocular and palpebral conjunctiva being formed of the same anatomical elements, are consequently subject to the same forms of inflammation, with the exception of those inflammatory affections which attack the free margin of the palpebræ. The symptoms, however, are much more decided, much easier recognized, when the mucous membrane of the eye is inflamed, than when that of the palpebræ is affected.

The division we adopted for blepharitis will, therefore, in a great measure, be ap-

plicable to conjunctivitis or inflammation of the ocular conjunctiva. The affections which this general term comprise are the following:—

1. Simple Conjunctivitis.
2. Conjunctivitis with Chemosis.
3. Papular Conjunctivitis.
4. Granular Conjunctivitis.
5. Purulent Conjunctivitis.

This division is not arbitrary, as some persons might feel inclined to suppose; it is founded on an attentive and lengthened observation of disease, and you will see that its utility is not merely theoretical when we arrive at the treatment of conjunctivitis. Those of you who follow the practice of this hospital, must be well aware that these forms of disease are frequently met with; indeed we have now in our wards patients on whom you may observe each of the affections I have mentioned. I will, in the first place, describe the anatomical and physiological symptoms of each form of inflammation, and then examine at length the various agents we can employ in their treatment.

Simple Conjunctivitis.

This form of inflammation—the mildest we shall have to examine—is also the most frequent. The anatomical characters by which we may recognise it are the following:—the conjunctiva becomes of a deep or pale red colour; the redness, however, is not constant, being sometimes modified by a yellow, purple, violet, or brick-red tinge. On the surface of the eye we distinguish a great number of small vessels of variable calibre, interlaced in many directions. Their mobility—the ease with which they are displaced, on pressing the eye with the finger, through the medium of the lower eyelid—shew plainly that they belong to the conjunctiva. The nearer to the cornea you examine these vessels, the smaller and the less moveable you find them. They either terminate imperceptibly near the circumference of that membrane, or, becoming inflected, anastomose with the vessels of the eye. When the inflammation is intense, we sometimes see a few arterial filaments, reaching the cornea, advance more or less on its surface. The white colour of the scleroticæ is still easily perceived through the injection of the conjunctiva.

To these, the anatomical symptoms, we must add those which are entirely functional. The secretion of mucus, which is much increased, varies considerably in its physical characters: in some instances, clear, limpid, and transparent, it flows, more or less abundantly, over the eyelids, often producing an eczema of the parts over which it passes; in others, on the contrary, it is opaque, and being detained

by the cilia during sleep, concretes on the free margin of the eyelid, so that when the patients awake, they find their eyelids glued together. The mucus, also, sometimes accumulates in the inner angle of the eye.

The secretion may be entirely suppressed, in which case the mucous membrane becomes dry, and presents a shining appearance. This symptom deserves particular attention, as there is reason to fear its being the commencement of a very serious disease, *xerophthalmia**. A circumstance which is also worthy of remark is, that in simple conjunctivitis we meet with neither photophobia nor shedding of tears. Several ophthalmologists of merit, M. Jungken for instance, have asserted that these symptoms are generally present; their opinions, however, on this subject are incorrect, and must have been founded on cases presenting some other lesion. The visual functions are not in the least disordered in simple conjunctivitis, or, indeed, in any of the forms of inflammation we are now examining, unless there be chemosis to such an extent as nearly to conceal the cornea. This circumstance should be kept in mind, as it may be extremely useful in establishing the diagnosis. The pain felt by the patient is slight, and seems merely to consist in the peculiar sensation of an extraneous body on the surface of the eye, which we have already met with in mucous blepharitis.

Conjunctivitis with Chemosis.

When the inflammation runs high, the symptoms we have just described become more intense, and chemosis sometimes supervenes, in which case the eye assumes a most peculiar appearance. The conjunctiva is uniformly of a deep violet colour, and the injected vessels which give rise to the vascularization are no longer to be distinguished from one another. The tissue of the conjunctiva is considerably thickened, and the cellular layers on its internal surface, which separate it from the scleroticæ, become infiltrated with blood, so that the white colour of the scleroticæ is completely hidden from view. The surface of the eye, of a fungous consistence, and a livid hue, presents a peculiar dotted appearance, similar to what we meet with in the cerebral substance after congestion of the brain. The conjunctiva thus tumefied, thus thickened, more or less elevated above the usual level of the globe of the eye, forms a complete

* In the 16th number of "*La Presse Médicale*," Feb. 1837, will be found an interesting article, by M. Jeanuime, on this affection, the cuticular conjunctiva of Mr. Travers. M. J. gives a detailed account of several cases which have occurred in the wards of MM. Velpeau and Sanson, and has thus thrown additional light on the nature of a disease to which pathologists have hitherto paid but little attention.

circle round the cornea; indeed the chemosis is sometimes so great as to cover a great portion of the cornea, and consequently to greatly impair the visual functions of the eye. Chemosis is not only interesting as a morbid symptom, but also in an anatomical point of view; for although the limitation of the swelling of conjunctiva does not incontestably prove that the mucous membrane of the eye terminates at the circumference of the cornea, it nevertheless establishes, as an undeniable fact, that in this region it becomes extremely adherent to the subjacent tissues.

This, the inflammatory form of chemosis, may be compared, in many respects, to the phlegmonous erysipelas of other parts of the body, and might be termed the phlegmonous variety of chemosis—the tumefaction and swelling of the conjunctiva, which constitute this disease, not being always the result of violent inflammation, as most authors have asserted. It is, indeed, now generally admitted that chemosis is not, properly speaking, a disease, but merely a morbid symptom, generally the result of intense inflammation, sometimes, however, to be attributed to altogether different causes. The subconjunctival cellular layers may become infiltrated with serosity, and that not only in persons of a lymphatic constitution, but also in those who are young and robust, although the inflammation has been but very slight. The mucous membrane becomes tumefied by the accumulation of a serous fluid in the lamellæ of its tissue, without, however, presenting the characters I have described as accompanying the inflammatory form. The colour, instead of being of a dark-red or violet hue, is white, inclining to yellow; and the swollen tissues do not present the tense, elastic, turgid appearance we before noticed. The conjunctiva may, it is true, become considerably tumefied; but its tissue is flaccid, partly retaining the impression of the finger. In the phlegmonous form of chemosis there is often violent pain, caused by the compression of the eye by the chemosis; in this, the serous or edematous form, there is, on the contrary, little or no pain.

These two forms of chemosis are evidently distinct, and ought not to be confounded; you will now, however, I think, be able at once to distinguish them.

Partial Conjunctivitis.

The inflammation does not always attack the entire ocular conjunctiva; it may occupy a portion only of its surface. When this, the partial form of conjunctivitis, is not caused by external injury, it is generally to be met with near one of the angles of the eye, more especially near the

external angle, and has consequently been called angular conjunctivitis. The inflamed surface is more or less circumscribed, and forms a kind of triangle, the basis of which is turned towards the cornea, and the summit towards the angle of the side affected. The appearance it presents might not inaptly be compared to that of a slight ecchymosis, presenting small moveable tortuous vessels, some of which extend beyond the limits of the inflammation. I shall not enter into any further detail respecting this affection, as, with the exception of the peculiar appearance, it is in every other respect similar to simple conjunctivitis.

Papular Conjunctivitis.

Accompanying inflammation of the conjunctiva, we sometimes observe on the mucous surface a kind of small papula, which has been generally confounded with ulceration of that membrane. We have now in our wards several patients presenting this form of the disease, and we have frequently cases of a similar nature. Were you to examine them attentively, you would find that the abnormal appearance is not to be attributed to the presence of ulceration, but is occasioned by small aphthæ, analogous to those we meet with on the mucous membrane of the mouth. The mucous tissue which covers these papulæ would necessarily be destroyed were ulceration to exist; this, however, is not the case; there is no ulcerated surface, but merely small circumscribed tumefaction of the conjunctiva, which, by the friction they exercise on the internal surface of the eyelids, give rise to the peculiar sensation I have so frequently alluded to—that of an extraneous body between the eye and the eyelid—and are, as long as they remain, a source of continual irritation to the eye.

Granular Conjunctivitis.

Most of the characters which I gave when speaking of granular blepharitis, may be applied to granular inflammation of the conjunctiva. There are, however, some few symptoms peculiar to this affection, which I must not omit to mention. The inflammation of the mucous follicles—for they are evidently the seat of the disease—may be either acute or chronic. It is impossible to deny the existence of the acute form of this disease, although the chronic is by far the most frequent. We have had, indeed, lately, several patients in our wards presenting the former or acute form of inflammation; and many of you, no doubt, will remember perfectly well having seen them: and why, I ask, should not the follicles of the mucous membrane of the eye become primitively

inflamed, as well as the follicles of other tissues of a similar nature?

The more prominent characters by which we may recognise this affection are the following:—The mucous surface of the conjunctiva is of a paler red, and the vessels are less distinct, than in simple conjunctivitis; the colour is also, in most instances, uniformly the same. On examining minutely the conjunctiva, we find it covered with an immense number of granulations, of variable size, which are sometimes congregated together, as it were, on one portion of the mucous membrane, sometimes more or less separated from one another. When the disease persists, the conjunctiva assumes a velvety appearance. As in granular blepharitis, the mucous secretion varies in its physical properties. Sometimes it is increased, and then it may be limpid, opaque, and thick, or purulent; sometimes, on the contrary, the secretion is diminished, or even entirely suppressed; and should this suppression continue during any length of time, we might fear its being a symptom of incipient xerophthalmia. There is neither photophobia nor shedding of tears, these two symptoms, as I have already remarked, being absent in every form of conjunctival inflammation, unless accompanied by keratitis or iritis. The visual functions are not at all disordered. The sensation of foreign bodies on the surface of the eye is, as might be expected, extremely well marked.

This form of conjunctivitis appears identical with the disease described by German authors under the name of *catarrhal ophthalmia*, although many of the symptoms they mention are common to the various forms of conjunctivitis we have already examined. I shall not, however, discuss this question now, as we have agreed to defer the examination of "specific affections" until a later period.

Such are the different forms of conjunctivitis which attentive observation enables us to distinguish. Generally speaking, these affections are combined with one another; indeed, the cases in which you find them isolated are comparatively rare, as we have already seen it to be the case with the various forms of blepharitis.

I have yet to speak of purulent conjunctivitis, to complete the description of the inflammatory affections of the mucous membrane of the eye. As, however, the only resemblance between this disease and those we have just examined is in the seat of the inflammation being the same in both cases, I will first give you the treatment of the different forms of conjunctivitis we have passed in review.

CLINICAL REPORTS

OF

DIFFICULT CASES IN MIDWIFERY.

By ROBERT LEE, M.D., F.R.S.

Physician to the British Lying-in Hospital, and
Lecturer on Midwifery at St. George's Hospital.

[Continued from p. 670.]

SECOND REPORT.

Cases of Accidental Uterine Hemorrhage.

CASE XXXII.—Mrs. Lassiere, Oxenden Street, June 4, 1836, a patient of the late Mr. Saunier's, was, on three different occasions, attacked with dangerous uterine hæmorrhage immediately after the birth of the child. During the last of these attacks, which had nearly proved fatal, I was called to see her after the placenta had been extracted; and the discharge of blood was checked with great difficulty, by the introduction of ice into the vagina, the application of cold water to the nates, external parts, and thighs, and the use of the pad and binder.

On the 3d of June, 1836, this patient being at the full period, and labour commencing, Mr. Saunier consulted me respecting the treatment which ought to be adopted, to prevent the recurrence of such a dangerous accident. I advised him immediately to discharge the liquor amnii by rupturing the membranes, and not to wait for the dilatation of the orifice or the pains becoming stronger; to apply the binder round the abdomen, and tighten it as the labour advanced; to leave the expulsion of the child entirely to nature; to avoid the use of stimulants; and preserve the apartment cool.

This was done, and the uterus contracted after the delivery of the child, and the placenta was expelled without assistance in less than an hour; and so little hæmorrhage followed that it was easily restrained by the application of a napkin, soaked in vinegar and water, to the parts.

I have repeatedly employed the same practice, with the most satisfactory results, in other individuals who had been repeatedly exposed to the greatest danger from hæmorrhage after the expulsion of the child and placenta. The exhibition of the ergot of rye is also indicated in these cases, towards the end of the second stage of labour.

CASE XXXIII.—At one o'clock in the morning of the 23d March, 1829, I was called, by Mrs. Finlay, to a Dispensary patient, residing at No. 10, Great Earl Street, who was attacked with uterine hæmorrhage in the first stage of labour. The orifice of the uterus was widely dilated, the pains had entirely gone off, and there was great faintness and collapse of the features. I immediately forced my finger through the membranes, held up the head, that all the liquor amnii might flow out, and compressed the uterus above, and gave some stimulant internally. Strong labour-pains soon came on, and a dead child was expelled. The placenta followed, and no hæmorrhage afterwards took place. Nothing could answer better than did rupturing the membranes in this case.

CASE XXXIV.—Mrs. Brodrick, 33, Tyler Street, a patient of the St. George's and St. James's Dispensary, 28th June, 1824, at 4½ A.M. without any accident, was seized with uterine hæmorrhage and slight pains. At 2 P.M. several pints of blood, in a coagulated state, had escaped. The os uteri slightly dilated, and little affected by the pains. I ruptured the membranes, which had now become tense during the pains, and were protruded a little through the orifice. The flooding immediately ceased, the pains became much stronger, and at 7 P.M. the child was expelled alive. A great flooding followed, but it ceased on the removal of the placenta, the application of cold water to the external parts, and the binder firmly round the abdomen.

CASE XXXV.—On the 4th September, 1834, I was called to see a woman in the ninth month, who was attacked with uterine hæmorrhage after a violent quarrel. The os uteri was rigid, and very little dilated. The membranes could be felt all round. The vagina had been plugged, and several doses of the ergot of rye given. She was extremely faint. The membranes were ruptured, and she did well.

CASE XXXVI.—On the 22d June, 1837, Mr. Walker, of Marylebone Street, called me to see a patient who had a profuse discharge of blood from the uterus very soon after the commencement of labour. The hæmorrhage always increased when the pains went off; she

was faint and restless, and was constantly throwing the arms about, and yawning. The upper part of the vagina was filled with clotted blood. The os uteri was soft and considerably dilated, and the membranes were felt all round, and no part of the placenta. The hæmorrhage ceased immediately after rupturing the membranes; and in an hour the child was born, and the recovery was rapid.

CASE XXXVII.—On the 24th August, 1837, Mr. Gosna requested me to see a private patient, who, after a slight fall, had been seized with a flooding in the eighth month. As the discharge was not very profuse, and the pulse was little affected, I recommended rest in the recumbent position, and other means, to be tried before rupturing the membranes. The placenta was not felt at the neck of the uterus.

The hæmorrhage went off for about a week, and then returned to so great an extent, that Mr. Gosna discharged the liquor amnii, and the labour was happily completed in a few hours.

CASE XXXVIII.—About the same period I was called by Mr. Wise, of Princes Street, to a case of flooding in the first stage of labour. I immediately ruptured the membranes, and the child was soon expelled, without any return of the discharge.

CASE XXXIX.—On the 30th June, 1837, Mr. Balderson requested me to see Mrs. H., who was attacked with uterine hæmorrhage in the ninth month of pregnancy. The placenta did not present. I ruptured the membranes at 8½ P.M., when the os uteri was very little dilated. A dead child was expelled at 11 o'clock; and the placenta, which had been wholly detached, immediately after descended into the vagina. A violent rigor and great faintness followed the birth of the child, but she recovered in the course of a fortnight.

CASE XL.—On the 20th November, 1837, a lady, who had been repeatedly delivered by the late Dr. Hugh Ley, was, without any premonitory symptoms, attacked with a violent flooding at the commencement of the ninth month of pregnancy. I found the os uteri soft, and a little open. There was a sense of weight and dull pain in the region of the uterus, but no regular ute-

rine contractions. The hæmorrhage was going on when I ruptured the membranes. It immediately after ceased, and in about two hours a dead child was expelled, with the umbilical cord round the neck.

I considered this to have been the cause of the detachment of the placenta, as it probably was in some of the other cases related in this report.

CASE XLI.—At $4\frac{1}{2}$ A.M., 13th May, 1830, I was called to Mrs. P., æt. 25, residing at 23, Gresse Street, Rathbone Place, by Mrs. Wright and Mrs. March, the midwives in attendance. About eight o'clock the preceding evening, this patient being in the ninth month of pregnancy, began to have slight labour pains, and a considerable discharge of blood from the uterus. The pains continued during the night feeble, and recurring at long intervals. At 2 A.M. the flooding increased, and a large quantity of blood was lost. She did not appear, however, greatly exhausted when I first saw her, at $4\frac{1}{2}$ A.M. There were no labour pains; the os uteri was slightly open, and dilatable. I passed up my finger into the os uteri, removed the clots of blood adhering to it, and ruptured the membranes. On the discharge of the liquor amnii the flooding ceased. By pressing with the finger all round the os uteri, strong pains came on, and the head of the child was soon forced down into the pelvis and expelled; it was alive. A broad binder was placed round the abdomen before the expulsion of the child, and was afterwards tightened. The placenta came away without difficulty, and the uterus contracting firmly, no hæmorrhage followed. The patient suffered little after from the great loss of blood she had sustained.

CASE XLII.—A private patient of Mr. Gardiner's, Foley Place, was attacked suddenly in the night with a most alarming hæmorrhage from the uterus. She was in the ninth month, and was in perfect health the previous day, and had been exposed to no accident. I saw her three hours after the flooding commenced; the pulse was extremely feeble, and there was great faintness, with laborious breathing. The os uteri was very little dilated, and on passing the finger I felt the smooth membranes all round. I ruptured the membranes, and gently dilated the orifice with two

fingers. The hæmorrhage immediately ceased, and the pains becoming strong and regular, the child was expelled dead in an hour and a half. The placenta being wholly detached, followed the child; and a hæmorrhage, which had nearly destroyed the patient, again took place. Strong compression of the abdomen, and the vigorous application of cold to the external parts and nates, with stimulants, soon arrested it, and the patient was soon perfectly restored to health.

CASE XLIII.—At 5 A.M. on the 29th November, 1833, a female, aged 30, and eight months pregnant, was attacked with uterine hæmorrhage. At 11 A.M., when I first saw her, about two quarts of blood had been discharged, and she was pale and very faint, and the pulse could scarcely be felt.

The os uteri was dilated only to the size of a shilling, and the edge thin and soft. The membranes were felt all round, and tense. The flooding continued, with slight irregular pains. I applied the binder round the abdomen, and immediately ruptured the membranes and discharged the liquor amnii, after which strong pains came on, and the flooding ceased. The child, which presented naturally, was expelled dead in less than an hour. The binder was tightened, and in two minutes the placenta, with a great mass of dark coagulated blood, was expelled. A stream of florid blood suddenly began to flow from the vagina, and the most alarming degree of prostration of strength followed all at once. For several hours she was in a state almost of insensibility, without any pulse at the wrist, and at one time seemed beyond the reach of recovery. The discharge being, however, effectually checked by the introduction of ice into the vagina, and the dashing of cold vinegar and water over the external parts, and the strength supported by stimulants, she eventually did well.

An immense quantity of blood was lost in this case, yet the health was not permanently injured.

CASE XLIV.—On the 9th September, 1836, at 10 P.M., I was called to Mrs. —, residing at Little Chelsea, who was eight months pregnant, and had fallen down stairs a week before. Hæmorrhage to a great extent had taken place last night, which caused faintness.

The discharge ceased, and returned again this afternoon, and it has continued till the present time. The medical gentleman in attendance had examined, and thought the placenta was over the orifice of the uterus; but the membranes were felt all round, and I could touch no part of the placenta. The orifice of the uterus was considerably dilated; the head presented; slight pains; face pallid; pulse extremely weak; flow of blood continues.

On rupturing the membranes a great quantity of liquor amnii escaped. The binder was next applied, and the orifice of the uterus gently dilated during the pains. The child was soon expelled, with the cord twisted tightly twice round the neck; it breathed for a few seconds, and then died. The placenta being detached, was soon after extracted, as the flooding still continued. By firm pressure over the fundus uteri, the external application of cold and stimulants, it was at last arrested, but not till the strength of the patient was almost completely exhausted. Twelve hours after the extremities were cold, the respiration laborious, and the pulse could scarcely be felt. The circulation was restored in other twelve hours, and she recovered perfectly well.

I would interfere earlier in a similar case, and not trust so confidently to rupturing the membranes.

CASE XLV.—An out-patient of the British Lying-in Hospital was attacked with flooding about the middle of November, 1835, when seven and a half months pregnant. The discharge was not very great, and it produced no great effect upon the constitution. On the evening of the 17th December, 1835, it returned in a much more formidable manner, and continued through the night; and on the following morning, when I first saw her, she was faint and pale, and the blood was still flowing profusely from the vagina. The whole of its upper part was filled with coagulated blood, which led to the supposition that the placenta presented, which was not the case. The os uteri was soft, thin, and dilated to the size of a crown or more. The smooth membranes were felt all round, and the head presented. When a binder had been applied firmly round the abdomen, I ruptured the membranes, which I found difficult, from their never being put

upon the stretch by the pains. Regular labour pains soon came on after the membranes were ruptured, though the flooding was not entirely suppressed, and in two hours the child was expelled dead. The umbilical cord was round its neck. A large portion of the placenta was covered with a thick dark clot of blood. The structure of this portion of the placenta presented nothing peculiar.

It would have been better had this patient been delivered twelve hours earlier, by turning or craniotomy. She was so greatly exhausted by the loss of blood, that for some days it was doubtful if she would recover.

CASE XLVI.—On the 11th November, 1837, Mrs. Richards, 17, May's Buildings, was suddenly attacked with uterine hæmorrhage when near the end of the ninth month of pregnancy. A quart of blood escaped in a few minutes, which produced a disposition to syncope. I found the os uteri soft and dilatable, but little opened; the head presented; no uterine contractions; faintness gone; pulse 90, and not very weak. The horizontal position, cold applications, &c. were recommended, and I left the case to nature, and did not rupture the membranes, which I now think ought to have been done.

Regular labour pains commenced soon after my visit, and continued all the evening till midnight, when the delivery was safely effected, without artificial assistance of any kind. The small portion of placenta which had been detached, and had given rise to the flooding, was seen covered with a firm layer of coagulated blood.

CASE XLVII.—1828. A lady in the eighth month of pregnancy, while dressing for dinner, was alarmed with a profuse discharge of blood from the uterus; it continued till she fainted and fell down insensible on the floor. The pulse soon after was full and frequent, and the attack was preceded by a sense of weight and uneasiness in the hypogastrium. Twelve ounces of blood were drawn from the arm, ice in a bladder was laid over the region of the uterus, and she was kept in a state of rest, in the recumbent position, for several days. The discharge ceased, and she went to the full period, and was delivered of a healthy living child; but after the expulsion of the placenta a dau-

gerous hæmorrhage followed, which was checked with difficulty by pressure and the application of cold water externally. She recovered, and was able to suckle her child.

[To be continued.]

CLINICAL OBSERVATIONS
ON
THE USE OF THE AIR-DOUCHE IN THE
DIAGNOSIS AND TREATMENT
OF
DISEASES OF THE EAR.
BY T. WHARTON JONES, ESQ.

[For the London Medical Gazette.]

No. II.

In the case which I related last week, the increase of the hearing power manifested from day to day was a warranty to persevere in the same treatment, until improvement should, under its influence, go no further, or until the cure should be complete. The result was, that the hearing rose to the common natural standard; the means of diagnosis becoming at the same time the means of cure. In the following case, the treatment by the air-douche was persevered in until the hearing on one side was raised to the natural standard, and on the other improvement would go no further.

CASE II.—*Some affection of the auditory passages—Opacity of the left membrana tympani—Clogged state of the tympanic cavities from accumulated mucus—Eustachian tubes pervious.*

Master C. D., betwixt 12 and 13 years of age, was brought to me by his mother, in the beginning of March, 1838, who stated her son had just been sent home from school, being no longer able to go through his exercises on account of increasing deafness. The deafness, I was informed, had been first observed to come on after the measles, about four or five years ago. Is subject to catarrhal attacks in the nose and throat; has been under treatment without advantage.

The young gentleman could hear my watch with both ears at a distance only of an inch and a half. Thick lips; the nose broad at its root, and the state called epicanthus, *i. e.* folds of skin extending from the sides of the root of the nose over the inner canthi; together

with an habitually loaded tongue and enlarged tonsils, were points in the constitution of the patient worthy of being noted.

On examining the auditory passages, I found them not stopped up, but scales of unhealthy wax adhering to their walls, and projecting into their interior, so as to prevent my obtaining a view of either membrana tympani.

Auditory passages directed to be syringed out every second night, and a solution of the acetate of lead (gr. iij. to ʒj.) to be poured in two or three times a day.

Mrs. C. D. being anxious that her son should not be kept from his studies, especially as it was now so near the Easter holidays, when he should, of course, be at home for some time, he was allowed to return to school with the above prescription. Under its use the hearing improved so far that the scholastic exercises were gone through without marked impediment, which induced the master to write home, saying his pupil's hearing was restored.

Thursday, 12th April.—Has just returned from school, to remain at home during the Easter holidays.

On examining the auditory passages, I found them free; but at one or two places there was a small scab. The membrana tympani of the right side was pretty natural—perhaps only a little red. The membrana tympani of the left side was quite opaque, and presented large dark-coloured varicose vessels streaming through its substance. It was still sensible to the touch of a probe.

Saturday, 14th.—The hearing distance is now eight inches on the left side, and five inches on the right.

Introduced a catheter into the Eustachian tube of the right side, and blowing simply with the mouth, found it admitted the air. The hearing distance was immediately raised to seven or eight inches. The Eustachian tube of the left side impervious to a stream of air blown from the mouth.

Monday, 16th.—In consultation with Sir James Clark. Having stated the results of my examinations of the case, and that I believed there existed an accumulation of mucus in the tympana, which would require the employment of the air-douche to disperse, it was resolved, before having recourse to that,

to exhibit some general remedies calculated to improve the state of the mucous membranes. The throat and tonsils being red and swollen, but not affected with any acute inflammation, were ordered to be pencilled daily with a solution of lunar caustic.

Friday, 20th.—Hearing distance on right side nine inches; on left side eight inches.

Sunday, 22d.—Throat improving.

Monday, 23d.—Hearing distance on right side one foot and a half; on left side eleven inches and a half.

On another day in the course of this week the hearing distance had, on the left side, risen to one foot one inch and a half; but on the right side fallen as low as three inches and a half.

Saturday, 28th.—Hearing distance on both sides eleven inches and a half. To leave for school on Monday.

Saturday, 23d June.—Returned from school for the Midsummer holidays. Hearing distance of the right ear about six or seven inches; of the left about twelve or thirteen inches.

Has had since last report, while at school, several attacks of ear-ache in the right ear.

To rub tartar emetic ointment behind this ear.

Monday, 2d July.—Hearing distance of the right ear about one foot; of the left ear fourteen or fifteen inches.

Friday, 6th.—Sent in a stream of air, by means of the air-press, through a catheter introduced into the right Eustachian tube, whereupon the hearing distance was raised to one foot eleven inches. Threw in a stream of air on the left side also, after which the hearing distance was increased to one foot eight inches and a half.

During these applications of the air-douche, I found that, on the left side, the air penetrated less freely, and with more gurgling, than on the right side.

The good result of the first essay with the air-douche in this case confirmed the diagnosis I had ventured to draw from my previous observations, especially from the examination made by blowing air through the catheter with the mouth simply, and emboldened me to pronounce a favourable prognosis, qualified only by this—that, considering the extent to which the left ear had suffered from inflammation, as indicated by the opaque and thickened

state of the membrana tympani, it was not likely to be so much improved as the right, in which no marked organic change could be detected. This prognosis, though verified by the event, had like to have been contradicted by the unfavourable turn the case took during the three following days.

Saturday, 7th.—Had an attack of ear-ache in the right ear this morning, in consequence of which the hearing distance has fallen to fourteen inches. The left ear, however, has still further improved, viz. to two feet and a half.

Sunday, 8th.—Ordered to day six or eight leeches, to be applied around the right ear; and the tartar emetic ointment, as prescribed on the 23d June, to be continued. Sweet oil to be dropped into the ear, which is to be syringed with lukewarm water at bedtime.

Monday, 9th.—The leeches have been applied, and the cheek is swollen in consequence. No return of ear-ache, but the hearing distance has fallen on the right side to three inches, and on the left side to eight inches.

Introduced a catheter into the Eustachian tube of the left side without causing any pain, and applied the air-douche. The air entered with a rushing sound at first, and on increasing the force of the stream, with a gurgling sound. After this the hearing distance was, on the left side, ten inches.

Friday, 13th.—No longer any tenderness of the ear. Hearing distance on the right side, fourteen inches; on the left side, one foot nine inches.

Applied the air-douche to the right ear, after which the hearing distance was raised to two feet.

Monday, 16th.—Right ear, two feet and a half; left ear, two feet.

Applied the air-douche to the left ear, by which the hearing distance was raised to two feet eight inches.

Tuesday, 17th.—Right ear, two feet eight inches; left ear, three feet.

Applied the air-douche to the right ear, after which the hearing distance rose to three feet nine inches and three-quarters.

Wednesday, 18th.—Right ear, four feet two inches; left ear, two feet ten inches.

Applied the air-douche to the left ear, without any change in the hearing distance immediately resulting.

Thursday, 19th.—Right ear same as

yesterday; left ear, three feet three inches.

Applied the air-douche to the right ear. The stream was allowed to be a little more powerful than usual, which caused some pain. A rushing sound was first heard, until the force of the stream was increased, when a gurgling noise became discernible. After the application of the air-douche, the hearing distance of the right ear was found risen to six feet.

Friday, 20th.—Right ear, six feet three inches; left ear, four feet eight inches.

In consequence of some tenderness of the left external ear, the air-douche was not applied to-day.

Monday, 23d.—Tenderness of the left external ear gone.

Hearing distance on the right side, seven feet seven inches and a half; on the left side, five feet eleven inches.

Applied the air-douche to the left ear, and immediately found the hearing distance only four feet eight inches; but on trying it again, in the course of a few minutes it was found to have risen to seven feet and a half.

Tuesday, 24th.—Right ear, seven feet eight inches and three-quarters; left ear, eight feet one inch and a half.

Applied the air-douche to the right ear. When the air enters the tympanum with moderate force, a rushing sound only is heard; but if with greater force, a gurgling noise is perceptible. A few minutes after the air-douche, the hearing distance was found to be nine feet four inches. On trying it again, after an interval of a few minutes, it was found to be almost twelve feet.

Wednesday, 25th.—Right ear, twelve feet eleven inches; left ear, nine feet one inch.

A few minutes after the application of the air-douche to the left ear, the hearing distance was eleven feet four inches. After an interval of five minutes from the first trial, the hearing distance was found risen to thirteen feet one inch and a half.

Thursday, 26th.—Right ear, fourteen feet three inches; left ear, ten feet and a half.

Applied the air-douche to the right ear. At first there was a gurgling, as if there was in the cavity of the tympanum thin loosened mucus. A rough rushing sound was afterwards heard, as if something vibrated within the tym-

panum, or as when one blows on a bit of gold-beater's skin, stretched between the fingers. This sound appears to be owing to vibration of the membrana tympani.

Hearing distance on the right side was now fifteen feet and a half, and in the course of five minutes had risen to sixteen feet five inches.

Friday, 27th.—Right ear, seventeen feet and a quarter; left ear, eleven feet eleven inches.

After the application of the air-douche to the left ear, the hearing distance of it was twelve feet five inches.

Saturday, 28th.—Right ear, eighteen feet four inches and a half; left ear, fourteen feet one inch and a half.

Air-douche applied to the right ear. The patient now hears the ticking of the watch distinctly, from one corner of the room to the other, a distance of about twenty-five feet.

Monday, 30th.—Hears with the right ear the watch, from one corner of the room to the other; left ear, fifteen feet and a quarter.

After the application of the air-douche to the left ear, the hearing distance was found risen to about eighteen feet.

Tuesday, 31st.—Left membrana tympani, though still opaque, does not appear so much thickened as before. It glistens more naturally than it did. The handle of the malleus may now be seen. The appearance of the right membrana tympani is pretty natural.

Hears the watch with the right ear distinctly, from one corner of the room to the other. Hearing distance of the left ear, fourteen feet five inches.

After the air-douche to the left ear, the hearing distance was about seventeen feet.

Thursday, August 2d.—Hears the watch distinctly with the right ear, from one corner of the room to the other, but did not hear it with the left ear at quite such a distance as the day before.

Applied the air-douche to the left ear without much change, the hearing distance remaining at only about fifteen feet.

Friday, 3d.—Right ear continues good; left ear hears the watch at the distance of sixteen feet four inches.

Saturday, 4th.—Dismissed cured, and is to go back to school on Monday. To guard against a relapse, it was di-

rected, in addition to the general instructions regarding diet and regimen, which were obviously indicated, that in the event of ear-ache coming on again, leeches should be freely applied without loss of time, the ear fomented with warm water, and warm sweet-oil dropped in.

Saturday, 18th. — Received a letter from Mrs. C. D. to-day, in which she says her son is quite as well as when I saw him last; and although he had had a slight cold since, it had not in the least affected his hearing.

REMARKS.—In this case, the principal cause of the deafness was accumulation of mucus in the tympanic cavities. There was no particular obstruction of the Eustachian tubes; it merely appears, that at first the Eustachian tube of the left side was impervious to a stream of air blown from the mouth; and that at the first application of the air-douche, the air penetrated less freely and with more gurgling than on the right. That the affection of the auditory passages had some share in the production of the deafness, was shewn by the circumstance, that, when they were restored to a more healthy state, the hearing distance was raised a few inches, and the susceptibility to the human voice very much improved; but, unlike what occurred in the preceding case, the clogged state of the tympana prevented improvement to any considerable extent. The increasing ratio in the progress of improvement, under the use of the air-douche, illustrates well both the nature of the principal cause and the efficiency of the means adopted for its removal. That hearing was not so fully restored on the left side as on the right, was owing to the opaque and thickened state of the membrana tympani, and possibly to a similar state of other parts of the ear not accessible to view.

As to the origin of the state of the ears.

The deafness, it is said, was first observed to come on after the measles. Both the eye and the ear, it is well known, are particularly obnoxious (especially in scrofulous constitutions) to what is called the *dregs* of the measles, as well as of the other exanthemata. Ophthalmia tarsi, scrofulous ophthalmia, chronic dacryocystitis, &c.—all diseases involving tegumentary structures, are very often excited by the measles, &c.

The accessory parts of the ear being in like manner chiefly composed of the tegumentary tissue, readily participate in the various affections of the skin. In the case before us, I believe we have a counterpart of the diseases of the eye, excited by the same cause. The tegumentary lining of the auditory passages, with the ceruminous glands, were affected. Now this resembles, in many respects, that disease of the eye called ophthalmia tarsi. In both cases the structure affected being a tegumentary tissue in the transition from skin to mucous membrane; in the one connected with the ceruminous glands, and in the other with the Meibomian follicles.

But in addition to the affection of the tegument of the auditory passages, there was some affection of the mucous membrane lining the cavity of the tympanum, giving rise to the accumulation of mucus; an affection which might be compared to the scrofulo-catarhal ophthalmia, or to chronic dacryocystitis, diseases, as above mentioned, often excited by measles, and often existing along with ophthalmia tarsi.

This comparison of the pathology of the case under consideration with morbid states of the accessory parts of the eye, excited by the same cause, indicate the propriety of employing the same general means of cure; but, as was pointed out in my former communication, in regard to some parts of the local treatment, what is of easy application to the eye requires a complicated apparatus for the ear.

Unfortunately, cases such as the above have a great tendency to relapse, either in consequence of the membrane—the seat of the disease—not being restored to a healthy action, and thus giving rise to a reaccumulation of mucus, or in consequence of a new attack of inflammation to which the part will continue as liable as at first, or more so. This is not to be surprised at when we reflect on the difficulty of completely curing a chronic conjunctivitis, a chronic dacryocystitis, or even a chronic inflammation of the mucous membrane of the nose and throat; or the liability of these diseases, when cured, to fall back from the slightest causes.

Master C. D. came under my care again eight months after he was dismissed cured, for a renewal of deafness, brought on by repeated attacks of ear-ache while at school. No measures

having been taken immediately to subdue the inflammation, the cautions and advice given when he was dismissed having been entirely neglected, the membrane lining the tympanum has, I believe, become much changed in texture, so that the character of the disease is considerably different from what it was before.

The further history of the case will be given along with others treated with the vapours of acetic ether thrown into the tympanum.

EXTRAORDINARY CASE OF MELANOSIS OF THE SKIN IN A WOMAN,

IN WHOM THE GREATER PART OF THE SURFACE BECAME OF A DARK COLOUR.

By DR. GILLKREST,

Deputy Inspector-General of Army Hospitals,
Gibraltar.

(Communicated by Sir JAMES McGRIGOR, Bart.)

MARIA ANGLE, aged 28 years, a native of St. Lucar, in the province of Cadiz, was born of healthy parents. The father died from the consequence of a fall at the age of 50, but her mother still lives, and enjoys perfect health.

This woman came to reside at Gibraltar in the year 1828, and married three years afterwards, at the age of 21 years.

Previous to her arrival at Gibraltar, she passed through the small-pox, measles, and scarlatina; she also states, that at Cadiz, in 1819, she had an attack of fever, which she considers as having been the yellow fever.

She is the mother of three healthy children, all nursed by herself; their ages, respectively, are 6 years, 3½ years, and 14 months.

From the age of 13 menstruation has not been interrupted, except from natural causes, and no particular phenomena have occurred during periods of gestation, or in the course of her accouchements.

Previous to her marriage, Maria Anglen gained her living by needle-work.

Her temperament is bilious, and, like most Spanish women of her class, she is a brunette.

Previous to her present illness she was rather *embonpoint*. She has not been in the habit of taking any food dif-

ferent from what most others of her class take.

Her dwelling, for the last two years and a half, has been in a room on a first floor, in a small closed court (called here a "Patio"), in which several other families live. The room is badly ventilated, and the situation altogether, one would say, *à priori*, unfavourable to health; but it is to be remarked, that hundreds live here in the enjoyment of good health for years in these closed courts, of which there are great numbers in this garrison.

In the month of August 1838, this woman discovered, on placing her hand on the region of the liver, a small tumor, which she described as having been about the size of a pigeon's egg. To this, however, she paid little attention at the time, but she went to the Civil Hospital in a few days after, where she was directed to apply some leeches to the part. Fearing that she should be again ordered leeches, and there being no pain in the part, she did not return to that establishment. This tumor disappeared after some time, without any particular treatment.

Towards the end of October an attack of ophthalmia took place, which lasted for nearly a month.

About the 22d of October, after a dinner of beef, made into soup with a little ham, and cooked in an earthen vessel which had been several times before used for the same purpose, she was attacked with vomiting, a disposition to which continued for a considerable time afterwards. The same thing took place, in a more or less degree, in the case of her mother, and also in her three children, who had partaken of the same dinner. She consulted an apothecary about this vomiting, which was accompanied by tenderness of epigastrium and debility; and he gave her three pills and a powder; the former were retained on the stomach, but the latter immediately rejected on being taken. The pills produced bilious evacuations, and pyalism followed in a few days. The vomiting continued unabated, the sensibility of epigastrium became increased, and great thirst set in. On the 20th of December she consulted a Spanish physician, who found her greatly reduced in strength; there was a good deal of cough, with severe pains in both sides of the thorax; the pulse very quick and small; she was advised

to wean the child, now more than twelve months old; leeches were applied to the sides and epigastrium, mucilaginous drinks were ordered, and, under this treatment, the irritability of the stomach was allayed; but the cough continuing, a blister was applied to the sternum. Tartar emetic ointment was also applied between the shoulders, and under this management the cough ceased, and she was able to sit up in the first days of January.

About this time she observed a little swelling of the feet, accompanied with a pricking sensation, which annoyed her a good deal. The vomiting having returned without any manifest cause, she was again obliged to take to her bed, when leeches were again applied to the epigastrium, followed by a sinapism. The vomiting, however, continued, with a dry cough, diarrhoea, and violent palpitation. After a few days' treatment the cough and palpitation yielded; but the other symptoms persisting, leeches were applied to epigastrium. Her state now was in some respects ameliorated, the dejections, which had been lately dark and streaked with blood, having become natural; but the state of the feet mentioned became worse, and she now complained of pain and heat in them. The hands also now began to be affected in a similar way.

It was at this period that her physician perceived that Maria Anglen's skin had become darker, the change being very remarkable on the neck, trunk, and nates; the skin of the face and extremities having preserved its natural colour. Under the use of Seltzer water, and a mixture containing the acetate of ammonia, temporary relief from the vomiting was obtained. Cerebral symptoms, which soon afterwards occurred, were relieved by the application of leeches; and the application of another blister to the stomach was followed by an almost total cessation of the vomiting. In the meantime the pains in the hands and feet increased, so as to be very distressing; and the colour of the skin in the parts mentioned became darker. The thighs and upper part of the arms were now of a dark colour, but in a much less degree. During this time the conjunctivæ preserved most perfectly their natural colour.

On the 16th of February last a consultation took place, at which I was

present. The pain in the feet and hands was very distressing, and disabled her from moving in her bed; much emaciated; described the pain as extending from the feet along the back of the legs; conjunctivæ natural; pulse small, and 140; tongue moist; appetite moderate; passing very bad nights, from the severe pain in her feet, distressing cough, and palpitations; relieved during the day-time from the cough and palpitations, but not from the pain of the hands and feet, which, however, was then always less severe. Urine, carefully examined, presented nothing remarkable; dejections pretty natural, and usually an evacuation two or three times a day.

On inspecting the surface, all were greatly astonished at the colour of the skin on the parts already mentioned; and were we not previously informed of the case, we would not have believed, on seeing those parts only, that we had not a negress before us. This dark colour became gradually lighter down the thighs and arms; and, with the exception of slight traces about the toes, did not exist on the feet or hands.

On examining the skin where the greatest intensity of colour existed, numerous granulations, varying from the size of a section of a small pea to the size of a pin's head, were discovered; no traces of these being to be found in the legs or fore-arms.

On examining carefully the region of the liver, with a view to ascertain whether there existed any traces of the tumor which existed when she was seen at the Civil Hospital some months before, nothing was to be seen, and considerable pressure caused no pain.

In a few days afterwards I saw this poor woman, in whom I found no change except that the pulse had fallen to 112. With a view to ascertain how far any change might have taken place in the blood, $\frac{3}{4}$ ss. was taken from a vein in the foot; this separated into serum and coagulum, in the usual proportion, both being of the colour of ordinary blood.

A blister about the size of a half-crown was applied to the side, not with a view of relieving any symptom, but for the purpose of ascertaining whether there were peculiarities in the raised cuticle, or in the serous collection under it. The latter was as transparent as is usual in ordinary cases; but the cuticle,

with whatever of the cellular tissue which might have been adhering to it, was rather dark, but not to the degree which might have been expected from its previous appearance; and the subjacent surface presented nothing different from what usually takes place in ordinary cases after a blister.

Under a course of treatment (including a few mercurial frictions to the spine) to which I am not disposed to attribute any effect further than, perhaps, soothing her occasionally, this woman has gradually got better, desquamation having proceeded during April and May, but, until lately, not accompanied by corresponding relief from the pains in the hands and feet; the former, during the greater part of the time, having the fingers bent as in persons who have cramps, and the feet as in persons affected with paralysis; while there existed a morbid sensibility in all those parts, so that the slightest touch increased her torments.

On visiting Maria Anglen on this day (June 4, 1839), the improvement in her condition is very remarkable. The desquamation of the original dark layer is almost complete, and a further desquamation of another *brown* layer, which had succeeded to it, is in many places in progress, so as to display the natural colour of the surface of those patches.

The distressing pains of the extremities have nearly ceased, and she has the use of her hands once more. She has still, however, very little power over her feet, in which there is also still an excess of sensibility. She takes nourishment freely, is cheerful, and the functions are regularly performed.

The records of medicine abound in cases of melanotic tumors, differing vastly in size, and varying in consistence, in almost every organ of the body; and we are equally well furnished with evidence of the frequent deposition of a melanotic fluid in lymphatic glands, on mucous, but still often on serous surfaces, and the subjacent tissues. Laennec, Breschet, Andral junior, Alibert, Carson, and Cruveilhier, need but be consulted upon this subject. But on looking over the observations of the foregoing writers, as well as the works of other physicians of great research, we perceive how seldom an affection of this kind, to any extent in the skin, is spoken of. This has proba-

bly arisen, as Dr. Rochoux conjectures, from the disease having been sometimes confounded with the "melas-icterus;" decided distinctions, however, existing; the conjunctivæ in the latter, partaking of the change of colour, which is also pretty uniform over the whole surface: whereas, in melanosis of the skin, the contrary is always found to take place. Dr. Rochoux might, I think, have added, with great truth, that the colour in both must be considered as differing greatly; that of the skin of the woman whose case is related above, having been quite as dark as soot, to which the colour of the skin in other instances of this disease has been likened by authors.

It is to be presumed, that the case of Maria Anglen will not be considered as in any manner similar to those cases where a peculiar colour is given to the skin by the internal use of nitrate of silver.

It is in the work of Rayer, on the Diseases of the Skin, that I have been able to discover cases (and they are but few) at all approaching to the above. That quoted from Lecat, 1765, is very remarkable, where the head of a lady became "*du plus beau noir, excepté les yeux et les bords des lèvres*," on three successive occasions, about the seventh or eighth month of pregnancy; the natural colour returning soon after each accouchement. It appears that no desquamation took place in this case. He quotes a case from Rostan, where the greater part of the surface of the body of a woman presented the appearance of a negress. The disease was, in this instance, the sudden effect of a fright. The woman died from the consequences of an attack of pneumonia several months after, and the post-mortem examination shewed no trace of a melanotic tumor. The skin preserved the same intensity of colour until twenty-four hours preceding her death, when it became paler.

In no case do I find the disease described as being accompanied with the distressing pains in the extremities, or ending by desquamation, as in the above case of Maria Anglen.

OBSERVATIONS

ON

THE FUNCTIONS OF THE GREAT SYMPATHETIC NERVE.

IN REPLY TO MR. WELLS.

To the Editor of the Medical Gazette.

SIR,

YOUR Dublin correspondent, Mr. T. J. Wells, in the *MEDICAL GAZETTE* of the 27th ult., has recorded the result of an experiment designed to exhibit the physiological action of the great sympathetic nerve, in certain cases of poisoning. The experiment is thus recorded:—

“After making a wound on the inside of the thigh of a rabbit, I applied to it six drops of a solution of hydrocyanic acid. The animal was dead in four minutes. After some unsuccessful attempts, I succeeded in dividing both sympathetic nerves in the lumbar region of another rabbit much about the same size and age. To a similar wound on the thigh, I then applied the same quantity of hydrocyanic acid. No effect appeared to be produced for nearly ten minutes, when, some slight convulsion coming on, I repeated the application; but it was not till sixteen minutes from the time I applied the first quantity that the animal was dead.”

It is to be regretted that the experimenter was not more explicit in noticing the apparent mode by which death was produced, or, in other words, the sequence of symptoms consequent upon the administration of the poison; as it is impossible, in the absence of sufficient data, to form from an isolated case an hypothesis which may not be subverted by future observation. It unfortunately happens, too, that our knowledge of the functions of the great sympathetic nerve is exceedingly limited, pathologists, to whom abundant opportunities have occurred, having in a most unaccountable manner neglected to notice the appearances assumed by the ganglionic system in diseases, upon the nature of which the state of the visceral nerves might have thrown great light. In the deductions also, from experiments which have been instituted, there appears to exist a great discrepancy, so that conclusions of an opposite tendency have been drawn from experiments almost identical in their nature.

Sir Benjamin Brodie imagines that

direct sedative poisons (or those which, like hydrocyanic acid, produce an instantaneous extinction of life without previous excitement) act through the media of the nerves of sensation upon the brain, producing their specific effect upon the parts supplied by these nerves, which effect is the result of a direct impression which immediately exhausts them of their susceptibility of receiving external impressions. He found that the motor nerves were but little affected by the primary action of the poison, the organs of respiration continued their functions, the irritability of the heart remained unaffected, and the peristaltic action of the intestines continued for some time after the sensitive life of the animal had been destroyed.

Dr. Krimer, on the contrary, a physician, of Aix-la-Chapelle, states, from numerous experiments, that, notwithstanding the rapidity with which hydrocyanic acid acts in destroying life, it is nevertheless taken into the circulation; and that when the arteries and veins of a part are tied, the nerves being left entire, and the acid introduced into a wound, it does not act, but takes effect the instant the ligatures are removed from the blood-vessels.

These statements show the caution requisite to be observed in such intricate examinations which involve deductions of so adverse a nature.

To come more immediately to the case cited by Mr. Wells: the cause of the retardation of death is, I imagine, on both the above hypotheses, obscure. The theory of Brodie, which constitutes the sentient nerves the prime agents in conveying the specific effect of the poison to the sensorium, and rejects absorption, will not aid us, because, as we have already seen, the ganglionic system is affected by a secondary action only, the vegetative life, as it has been termed, of the body, continuing for some time after the sensitive has become extinct. So, also, from that of Krimer we do not gain much ground, unless, indeed, we take into consideration the important part which the great sympathetic plays in the economy of the vascular system, and suppose that by arresting the supply of nervous energy we thereby prevent the speedy extension of the poison, and consequently retard its secondary action upon the expanded extremities of the ganglionic nerves.

The subject, however, is one of extreme interest; not the less so, perhaps, from the obscurity which now overwhelms it. If it were possible to obtain a correct knowledge of the pathology of the internal ganglionic system, I am convinced, from observations which I have been able to make, that the nature of many disorders, whose origin is not now even suspected, would be perfectly demonstrable; and, as it is, although we cannot satisfactorily explain the *modus operandi* of internal irritation acting upon the intercostal ganglia, and causing remote disturbances, yet we are enabled, from the nature of certain sympathetic affections, and of the therapeutical agents employed with success for their removal, to trace with tolerable accuracy these disorders to their source. This is the great end to which all physiological investigation should be made subservient; and I confess, were it not for the unconquerable aversion I entertain for vivisections, that I should be delighted to pursue a subject which promises such abundant results.—I am, sir,

Your most obedient servant,

R. H. ALLNATT, M.D.

Wallingford, August 5, 1839.

ALLEGED DISCOVERY OF VARICOSE CAPILLARIES.

To the Editor of the Medical Gazette.

SIR,

THE following advertisement appeared on the cover of your journal of last week:—

"In August will be published, illustrated by plates, a Treatise on Varicose Capillaries, as constituting the Structure of diseased Hepatic Ducts: to which is added, an Account of the new form of the Pus Globules. By Thomas Gordon Hake, M.D., late Physician to the Brighton Dispensary, Orphan Asylum, &c. London: Taylor and Walton, Upper Gower Street."

Dr. Hake had repeatedly seen the greater number of my preparations illustrative of the anatomy of cancer; I had told him that I had other preparations illustrative of the mode of development of every description of growth: he had repeatedly asked me to show him *those* preparations, and to commu-

nicate my views to him, promising me that he would not divulge any thing I might communicate to him. Having no reason to doubt his honour, I complied with his request; and within the last month (and fortunately in the presence of Mr. Powell, the well-known optician, and, I think, on the evening of July 13th), I showed him, and fully explained to him, a preparation of "Varicose Capillaries." He has now the audacity to claim what I then communicated to him as a discovery of his own; founding his claim on the fact of his having "worked during several hours for several days, and re-discovered" what he calls "my secret;" admitting, however, that he first saw "varicose capillaries" at my house, and in my preparation; but stating that "*had I not shown them to him, he should have discovered them himself.*" Convinced, no doubt, by his laborious investigations, continued perseveringly "during several hours for several days," Dr. Hake assured me, with the utmost gravity of tone and manner, that "my opinions were quite correct:" it is for Dr. Hake now to explain how he could have ascertained the correctness of my opinions if I had not communicated them to him. At the conclusion of my interview with Dr. Hake, I told him, that as I should be sorry to have any misunderstanding with him, I was willing to leave the matter in dispute between us to the decision of a third person. Instead, however, of even attempting to arrive at an amicable conclusion, or of holding any communication with me, he speeds to your office with his advertisement; and when, after waiting nearly four days (and by which time his advertisement had appeared in the *Lancet*, though I did not see it either in that journal or in yours until Tuesday last), I requested him, by letter, to inform me what he intended to do respecting the subject of our conversation, he informed me that "the course he intended to take was to make public what he had discovered."

All that Dr. Hake knows of "*varicose capillaries*" he has learned of me; and the discovery which he claims forms the ground-work of a paper "*On the Anatomy of Cancer*," on which I have been almost uninterruptedly engaged during the last five years. Under these circumstances I request the favour of your

insertion of the following letters in the next number of your journal.

I am, sir,
Your most obedient servant,
F. KIERNAN.

33, Beaumont Street,
Aug. 8, 1839.

33, Beaumont Street,
Aug. 8, 1839.

Dear Sir,—You and Dr. Hake passed an evening with me about a month ago. On that occasion I showed Dr. Hake a preparation, which he examined during a considerable time with the microscope. Dr. Hake now claims what I then showed him as a discovery of his own, and is about to make it public. Will you oblige me by stating, to the best of your recollection, what passed with reference to the preparation?

I am, dear sir,
Very truly yours,
F. KIERNAN.

Mr. Hugh Powell,
24, Clarendon Street, Somers Town.

24, Clarendon Street, Somers Town,
August 6th, 1839.

Dear Sir,—In answer to your letter requesting me to state what took place on the evening I met Dr. Hake at your house, I beg to inform you that I will do so to the best of my recollection, though, not being acquainted with anatomical preparations, I am able to recollect but few of the many observations that were made.

After we had been using the microscope for some time, you produced a preparation which we all examined. During the time (which was about an hour and a half) that Dr. Hake was examining it with the microscope, you pointed out several different parts to him, one of which you said was disease in its most incipient state. Dr. Hake said he could sit and look at it all night, and wondered you had not published it. He thought if you did not soon do so it was likely some one would do it before you; and he added, that he would be as silent as the grave. Dr. Hake observed to me, as we walked home, that he thought you were too careless about it, and that some one would certainly publish an account of the same subject before you. From what you have stated to me in your letter it is evident that Dr. Hake would not have been long in

guessing the person that was likely to attempt to anticipate you.—I am, sir,

Yours truly,
H. POWELL.
F. Kiernan, Esq.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abréger.”—D'ALEMBERT.

Retrospect of the Progress of Surgical Literature, for the Year 1838-9. By MESSRS. NEWNHAM, W. WICKHAM, and SALTER. Read June 13, 1839, before the Annual Meeting of the Southern Branch of the Provincial Medical Association, and published at its request. London, 1839. 8vo. pp. 47.

THE following are the principal points touched upon in this useful Retrospect:—Vaccination and revaccination; Dr. Macartney's work on inflammation; the respective merits of amputation by a circular incision, and by the flap operation; adhesion of stumps and incised wounds by hare-lip pins and the twisted suture, and also by using platina-wire inserted with the common needle; lithotomy and lithotritry; the work of Bourguery and Jacob, on surgical anatomy; Blandin's *Anatomie Descriptive*; and Dr. Phillips's *Amputations dans la contiguité des Membres*. Dr. Phillips prefers the torsion of arteries as the means of arresting hæmorrhage, while Malgaigne thinks it better to bruise the internal coats of the vessel with suitable pincers, and speaks favourably of M. Bouchacourt's experiments, where a moderately heated iron was applied to the ends of the divided vessels. Both these plans, however, have been tried only on animals. Vidal prefers ligatures.

“The dissertation on dislocations by both these authors is most valuable; but your reporters must only notice a recommendation of Malgaigne, for avoiding injury to the female breast, where counter-extension is required—viz. to interpose the hand of the surgeon or assistant, so that the pressure of the bandage may be borne chiefly by it; and a suggestion of Vidal, which has succeeded admirably with himself, and is very simple—that is, in dislocation

of the humerus, to make the patient sit upon the ground, and taking hold of his wrist, to raise the arm strongly towards the head, at the same time, if possible, distracting his attention from the muscles, and then allowing it to drop suddenly, when the dislocation will be reduced."

The reporters next speak of Mr. Gardner's account of partial dislocation of the upper extremity of the radius, given in the *MEDICAL GAZETTE* for September 1837; the treatment of fractures by the immoveable bandage; the treatise of Vidal, on extra and intra-capsular fracture of the neck of the femur; the pamphlet of Malgaigne on fracture of the ribs; the compendium of diseases of the periosteum, by Maisonneuve; and a treatise, by Gerdy, on the removal of the articulating extremities of bones; as well as an article in the new edition of Cooper's *Surgical Dictionary* on the same subject.

They then mention Mr. Gulliver's memoir on necrosis, in the twenty-first volume of the *Medico-Chirurgical Transactions*; the use of tartar emetic in dropsy of the joints; and the works of Recamier, Guérin, Scoutetten, Dieffenbach, Vidal, and Daval, on "affections of the motor powers;"—except Dieffenbach, however, they have all confined themselves to club-foot. Mr. Dodd and Mr. Duke, of Chichester, have operated for club-foot this year, with success.

The introduction of air into the veins during surgical operations; the employment of warm air in the treatment of wounds; the application of cold water to dislocations, fractures, and contusions; and the advantages of platina needles, are the next topics.

Next come the advantages of bandaging and compression in some diseases; the radical cure of hernia, and the sketch of its anatomy, by Malgaigne; the treatment of hydrocele; the work of M. Beniqué, on retention of urine; a combination of extract of lettuce and camphor, for the relief of spermatorrhœa; a new bougie, made of ivory softened by acids; a treatise on inflammation of the prostate gland, by Verdier; and the treatment of varicocele, which "has received considerable attention during the past year, especially from Landouzy."

Our authors mention the works of Humann, Ricord, and Giraudeau, on

syphilis; Dr. Rognetta's treatise on ophthalmology; M. Maunoir and Sir David Brewster's observations on cataract; Mr. Wharton Jones's paper on staphyloma of the cornea, in the *MEDICAL GAZETTE* for February 1838; Mr. Tyrrell's remarks on acute inflammatory chemosis, in the last volume of the *Medico-Chirurgical Transactions*; Mr. Pileher's treatise on the anatomy and diseases of the ear; M. Helot's experience in twenty cases of varices; M. Bouchacourt's memoir on erectile tumors; and Mr. Hawkins's paper on malignant diseases of the skin of the face, in the twenty-first volume of the *Medico-Chirurgical Transactions*.

They further notice the work of Dr. Edward Zeis on plastic surgery; the opinion of Sir Charles Bell, that ranula does not always arise from obstructed salivary ducts; electricity as a remedy for tetanus; M. Hatin's newly proposed plan of tying polyp in the pharynx; a case of poisoning by arsenic, successfully treated by M. Deville, with the hydrate of the tritoxide of iron; the employment of ergot of rye in paralysis of the bladder; and M. Blandin's memoir on amputation of the foot, at the articulation of the os calcis and astragalus with the scaphoid and cuboid bones.

"Aware of the objection urged against this operation, on account of the retraction of the heel, M. B. relates his having performed it *eleven times*, without any such consequence, and thinks it would very rarely occur if sufficient care were taken to preserve the divided tendons long enough."—P. 35.

The reporters then say—"In a retrospect of surgical science for the year by-gone, it is impossible to pass over without notice the treatise of Esquirol, supported as it has been by many other contributions to mental diseases."—P. 35.

Assuredly, if it was impossible in a surgical retrospect to pass over a treatise on insanity, it ought to have been equally impossible to leave out all the books which have appeared on phthisis, gout, or dysentery. But they add, still more strangely—

"Till within a few years, the subjects of insanity, instead of being looked upon as objects of the highest interest, have been contemplated with a sort of alarm, which it is difficult to define; and the design has been to exclude them

from society rather than restore them to *health*, and to all the powers and privileges of the social compact. It is most extraordinary that disease which attacks the organ of the highest consequence to the existence of man, which spares neither rich nor poor, and is so frequently found among the highly-gifted, should have been so long left in obscurity, and should even now possess so large a domain of unexplored territory."—P. 35.

We readily admit that the treatment of madness has improved, like every other part of medicine; but no great leap seems to have been made within the last few years; and even the coarsest methods of treatment were designed to restore the patients to health.

We do not know whether Esquirol published any thing new last year, but the five reasons for confining the insane, which the reporters quote from him, are to be found in a work of his published at least six years ago*.

In midwifery, the reporters point out the treatises of Maigne, Moreau, and several others; Mayor's pessary, made of iron-wire covered with oiled silk, or silk dipped into a solution of caoutchouc; Hull's utero-abdominal supporter; and the hour-glass pessary recommended by Malgaigne for the cure of vaginal rectocele.

The subject of cancer has been discussed by Colombat de l'Isère and Dupareque. Their conclusions are, "that cancer is originally dependent upon chronic inflammation of the organ, from local congestion or ulceration, susceptible of cure in the first instance by judicious treatment; that it is in its primitive nature purely local (and this opinion is supported by the history of cancer of the face, at p. 33 of the present Retrospect); that it is, indeed, capable of involving the entire constitution in its progress, but also susceptible of arrest, by relieving the early pathological conditions, of which, in general, cancer is but the unhappy consequence. Unfortunately, practitioners are too apt to be led away by phenomena which are apparent, and do not give themselves the trouble of inquiring into the state of the organs which have furnished those phenomena. Thus, for instance, they

are told of pains in the loins accompanied with leucorrhœa, and they are contented to prescribe for these symptoms without inquiring after the cause, of the existence of which these are only the expression."—Pp. 39, 40.

The employment of ergot of rye and ammonia "in uterine hæmorrhage from congestion, with feebleness of the uterine fibre," and of the *cura famis* in hypertrophy of the uterus and other forms of chronic inflammation ultimately terminating in cancer, are mentioned with approbation.

On the amputation of the cervix uteri, the testimony of the year has been conflicting. The nitrate of silver is very useful in ulcerations about the cervix, when not of a malignant character.

"In chronic inflammation of the uterus, and in cases threatening to degenerate into cancer, Treille particularly advocates the use of cold baths for several hours, night and morning, and the frequent irrigation of the diseased organ with cold water."—P. 41.

The remaining points discussed, are vesico-vaginal fistula, lacerated perineum, diseases of the ovary, and tapping the head in chronic hydrocephalus. Finally, the reporters give a list of nearly fifty works referred to in the Retrospect. This Report does the authors great credit, and will furnish every member of the profession with useful hints for practice, as well as almost endless topics of inquiry.

The Surgical Anatomy of the Groin, the Femoral and Popliteal Regions.

By THOMAS MORTON, formerly one of the House Surgeons of University College Hospital. Illustrated with Lithographic Plates and Wood Engravings. London, 1839. 8vo. pp. 127.

THIS is another part of the work which we recommended to our readers in our number of May 25th. The former volume was on the perineum; the one now before us, on several other important regions, does Mr. Morton great credit, and affords some very favourable specimens of the perfection which coloured lithographic plates have attained. We would particularly point out the seventh and eighth plates, from drawings by J. Mæclise, Esq., as worthy of admiration. The former represents the dissection of the large vessels and nerves on

* Observations on the Illusions of the Insane, and on the Medico-Legal Question of their Confinement. Translated from the French of M. Esquirol, &c. By Wm. Liddell. Lond. 1833.

the front of the thigh, after the fascia lata has been removed from the muscles; the latter represents the popliteal region when the dissection of the muscle, and vessels which it contains within its limits, has been completed.

The grooving of the fibres of the sartorius, gracilis, adductor magnus, and adductor longus muscles, in plate vii., is a triumph for the powers of colouring.

Mr. Morton intends to complete the work by a similar treatise on inguinal hernia, the axilla, and bend of the elbow; and another on the head and neck,—making in the whole, four parts. We cordially wish his book every success.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

MEDICAL EXAMINATIONS.

THE questions set by the Examiners in the University of London, which we published in some of our last numbers, afford another proof of the great improvements that have lately taken place in the style and standard of the chief medical examinations. They are evidently losing all those faults which, but a few years since, so much diminished their utility. There are fewer of those stock questions which are, as pupils say, "sure to be asked;" and the most captious critic cannot assert that the subjects inquired into are limited to a few dull settled points of almost household knowledge, or to the crotchets of the examiner. All this is as it should be; the average knowledge of medical practitioners will always be proportionate to that required of medical pupils by their examiners: as the pupil passes his examination, so the practitioner will generally pass his life—either shuffling through it with vague uncertain notions of a few loose facts, and totally powerless in indepen-

dent reasoning, or with a sound conception of the truths that form the basis of his art, and the ability to meet any new circumstances that may occur in his practice.

Within certain limits, too (and they have not yet, so far as we know, been ever attained), the candidates for diplomas or for other honours will readily acquire whatever is demanded of them; the zeal of the pursuit being here, as in many other cases, directly proportionate to the difficulty of attaining its object. In the University of Cambridge, for example, the number of competitors for honours has regularly increased with the increasing difficulty of the examination; and this not only in consequence of the afflux of graduates being far greater now than some years since, but also from the greater emulation that is excited among them; for of the same number of graduates, the proportion who go out in honours is every year increasing. It is the same with the candidates for common degrees, who, since the standard of examination was raised, have neither decreased in number nor appeared less able or willing to acquire the full amount of knowledge required of them. In short, all experience affords the same result, and it may be taken as a fixed fact in planning schemes of examination, that pupils will do every thing that they can do, and much more than they like to do, if their doing it be essential to their obtaining their degree or diploma.

Whatever mode of learning a subject may be thought best, it is thus in the power of examiners to determine how much of it shall be learned, and in what kind and form it shall be acquired; and they have, therefore, in the end, complete power over both teachers and pupils, for the former must supply what the latter want. This being the case, every improvement in medical examinations is the sure prelude to an equivalent improvement in the general average of

medical knowledge; and every time that the intellectual price of a diploma is increased, the security of the public against ignorance is augmented. It is, indeed, chiefly through this medium of examinations that the public are benefited by the improvements effected by a few in medical science. The important and practical facts which the use of the stethoscope affords, are as yet hardly made available to the public good, only because the majority of medical students are scarcely, if at all, examined on its applications; and so of all the more recent improvements in pathology, of which the public will feel the full benefit only when the knowledge of them is made an essential step in obtaining the diploma.

We cannot, therefore, but look with great satisfaction on the improvements which have been made very lately in nearly all our medical examinations. At the College of Physicians, the abolition of the system of holding the examination in Latin alone has given more room for difficulty in questioning, and accuracy in answering, by removing the obstacle which before lay in the way of both examiner and candidate, who could only ask and reply to those things that they could extemporaneously put into Latin; and the adoption of printed questions has insured a much greater preciseness, and a more close searching into the real merits of the candidates, than is possible in any *vivâ voce* examination. The character of the questions, too, is highly creditable; the papers which we have seen are such, that any man who can fully and accurately reply to them, cannot but possess sufficient knowledge to insure security and success in his practice.

At the College of Surgeons the examinations, though still in most cases entirely conversational, have been lengthened and rendered more difficult, each student passing in succession before four examiners, by each of whom

his knowledge is scrutinized for upwards of a quarter of an hour. Actual demonstrations, also, are generally required; and we were glad to hear that, in the recent competition for the first appointment to the College studentships, the candidates were all set to perform actual dissections of different parts in animals, and that the decision was founded almost entirely on the ability which they severally displayed in their work*. This is the plan which should be followed in all cases; no student can possibly be *ground* to dissect with correctness or facility; he can only acquire this by practice; and by testing his ability in dissection, or in the performance of some operations, his examiners would ascertain whether he possessed not merely a verbal knowledge of anatomy, but the practical acquaintance with arrangement and structure, and the manual dexterity which would really authorize them in letting "all men know by these presents," that he is "fit and capable to exercise the art and science of surgery." Till they insist more generally than they do at present on practical examinations, we fear, however much their system may have already improved, that they will still sometimes bestow their diploma unfitly. One cannot test a man's fitness for a manual undertaking by his verbal aptness, any better than one could his intellectual attainments by his mechanical dexterity. A surgeon needs both head and hands, and ought to be required to possess both by those who give him a legal title to the name.

At the Apothecaries' Hall, though general improvements have taken place gradually, much room is still left for more; and an advance is the more urgent as its Examiners form the only board before which the large ma-

* The Committee appointed to examine the fitness of the candidates have recommended to the Council Mr. Crozier, a gentleman who was lately a student at St. Bartholomew's Hospital.

majority of students are compelled to appear, and might therefore be the means of preventing all ignorance, except that which displays itself in the brazen armour of utter quackery, from imposing upon the public. If what we have said of the influence of examinations in determining the average attainments of practitioners be true (and no one that can either see or think can for a moment doubt its truth), it is evident that the Apothecaries' Company have more power to improve the general condition of medical practitioners than any other existing body, inasmuch as they alone can prevent the greater part of students from practising till they are positively fit for the undertaking. But though we willingly admit that they have improved their examinations, they have not yet *nearly* attained to the right and advantageous exercise of this power, nor, indeed, do they yet afford much hope that they ever will, unless with considerable change in their plans of examination. The Examiners themselves, though excellent private practitioners, yet being neither teachers, nor placed in responsible public situations, have scarcely a sufficient inducement, to keep themselves *au courant* with the improvements of medical science; and are, therefore, not qualified to lead the rising generations upwards, nor to keep them at that level of knowledge which the public have a right to expect. The chief error, as we have often shewn, lies in the multiplicity of the subjects, of which only a superficial and ephemeral knowledge can be acquired within the scanty time bestowed on the education of the majority of their candidates. The apothecaries of the present are not like those of the olden time, mere dispensers and man-nurses, but practitioners, in whose hands the lives of the great mass of the population are placed; they are now, in fact, if not in name, physicians and surgeons, and many

of them worthily and well perform the duties of both. But the public ought to be secured that none others than are good should practise upon them; and this can only be done by raising the fence of examination over which impudent ignorance now too often leaps.

At the University of London, which now having commenced business in good earnest, will always claim consideration in plans of medical improvement, the first examinations deserve in general a full share of praise, and the fact, that of twenty-six candidates only sixteen were competent to pass them, proves that the questions set are *bonâ fide* demands upon the understanding. The standard of knowledge required for the complete answers of the questions is (as far as it is possible to judge by a single example) about equal to that set by the examination for the Bachelors' degree at Cambridge, and for the Licence of the College of Physicians; but the result of this first examination indicates that in the London University a return is expected, which shall be more justly proportioned to the demands than that which is sufficient at the other ordeals. In this they have judged rightly; examinations, like men, "should be what they seem;" and the Council may depend on it, that they will not in future have to reject so large a proportion of the candidates as on the first occasion. If we are not much mistaken, they will find, as all others have done, that they may have whatever they like to ask for.

The examination papers, and the results of this first examination, afford a better prospect of success than any thing that has hitherto occurred in the new University. We have often expressed the opinion, that their only chance of obtaining favour with the public would be to establish for their graduates a reputation for practical ability, without any regard to the extent of

their extraneous acquirements, or superficial general knowledge; and we readily confess that, though their whole scheme of education was directly opposed to the attainment of such a reputation, the character and result of the examinations are favourable to it. If the spirit which animates the Examiners could but spread to the Council, the University of London might yet hope to hold up its head among its competitors, and to obtain a solid reputation. Let only half the subjects to be learned be struck off, and the same accuracy of examination in the remainder be observed, and the public will not fail to repay the benefit of which they will soon be partakers.

PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

THIS society held its anniversary meeting at Liverpool, on Wednesday and Thursday, the 24th and 25th of July. Dr. Jeffreys, of Liverpool, was in the chair, and Dr. Symonds, of Bristol, delivered the retrospective address. We shall endeavour to make room for a detailed account of the proceedings in our next number.

UNIVERSITY OF LONDON.

DOCTOR OF MEDICINE.—1839.

PASS EXAMINATION.

Monday, August 5.—Morning, 10 to 1.

ELEMENTS OF INTELLECTUAL PHILOSOPHY, LOGIC, & MORAL PHILOSOPHY.

MORAL AND POLITICAL PHILOSOPHY.

Examiner, Mr. THIRLWALL.

1. What is the general distinction commonly drawn between physical and moral science with respect to their objects? Examine the grounds of this distinction, and point out the limitations which it may seem to require. What is the meaning of the term *law* as applied to each of these subjects?

2. State the general nature of the questions that have arisen on (*a.*) the origin of moral sentiments, (*b.*) the criterion of morality, (*c.*) the ground of moral obliga-

tion. To what branch of philosophy does the first of these questions properly belong? Mention the most eminent philosophers of ancient and modern times by whom they have been discussed.

3. What English philosophers have contended for instinctive moral principles? Mention the different forms which may be given to this doctrine. State the pernicious consequences, in theory and practice, which its advocates and opponents impute to the systems which they respectively reject.

4. What appears to be the bearing of the history of society and civilization on the question of the moral sense? Mention any considerations which may seem to lessen the weight of the arguments against it founded on the diversity of customs observed in savage tribes.

5. Analyse the ancient quadripartite division of virtue, defining each member, and comparing it with any other you may be acquainted with. How would you show that it includes every kind of virtuous disposition, or that any is omitted in it? Wherein did the Stoics make virtue to consist? What modern systems come nearest to their views in this respect?

6. Explain Hume's distinction between natural and artificial virtues. To which class, and for what reasons, does he assign justice? Explain the meaning and application of his maxim, "that no action can be virtuous, unless there be in human nature some motive to produce it, distinct from the sense of its morality."

7. What, according to Reid, constitutes the virtuous quality of an action? What is meant by the epithet *indifferent* as applied to actions with respect to their morality? Is there any sense in which it may be properly said that some actions are morally indifferent, except so far as all may be said to be so?

8. State and account for the difference between the ancients and the moderns in their views of the relation between moral and political philosophy. What are the objects and limits of the science called the law of nature and nations?

9. Mention some of the most remarkable hypotheses which have been formed as to the state of nature, and the inferences which philosophers have drawn from them with regard to the rights of rulers and the duties of citizens. What are the limits assigned by the laws of human nature to the power of every government?

10. Enumerate the principles of human nature on which the continuance of every social order depends. What practical inconveniences arise from the supposition of an original social contract?

11. State the advantages of hereditary

royalty over the elective, and of the irresponsible over the responsible. By what contrivances in modern constitutions is irresponsible royalty prevented from degenerating into despotism without the necessity of resistance?

Monday, August 5.—Morning, 10 to 1.

INTELLECTUAL PHILOSOPHY AND LOGIC.

Examiner, J. H. JERRARD, D.C.L.

1. What is meant by the phrase "Laws of Nature"? How does Bacon briefly show the impossibility of discovering these laws by *a priori* reasoning? What are the four kinds of "Idola" which he points out as obstructing the mind in its pursuit of truth? Give an instance of each of them. What means does he propose for freeing the mind from their influence?

2. What is the true method of Induction as laid down by Bacon? Whence arises our conviction of the truth of the conclusions arrived at by this method? Why is it applicable to mind as well as to matter? What are the peculiar difficulties which attend the investigation of mental phenomena?

3. How does Brown prove that a close connection exists between the progress of the science of mind and of the other sciences; and what remarkable error in the Logical Theory of the Schoolmen does he bring forward in confirmation of this view? How does Locke illustrate the importance of our knowing the extent of our intellectual powers?

4. What kind of knowledge of Body and of Spirit are we capable of acquiring? How does it appear that the real essence of each is wholly unknown to us?

5. Point out the fundamental distinctions between the great modern schools of Intellectual Philosophy.

6. Locke, in endeavouring to account, conformably to his system, for the origin of our ideas of Space, Time, Infinity, Personal Identity, Substance, Cause and Effect, and Good and Evil, is charged, by one class of his opponents, with confounding the antecedents or consequents of these ideas with the ideas themselves: how is this charge supported in the instances of Personal Identity, Substance, and Cause and Effect? What, according to Cousin, is the source of our knowledge of the existence of an external world?

Monday, August 5.—Afternoon, 3 to 6.

MEDICINE.

Examiners, Dr. BILLING and Dr. TWEEDIE.

Case for Commentary.

A. B. æt. 60. Three years after an attack of pleuro-pneumonia from which there was complete recovery, the breathing became somewhat oppressed, to which

swelling of the extremities succeeded twelve months afterwards. In the course of the next two years he frequently suffered from pulmonary catarrh; the dyspnoea increased, and when medical aid was resorted to, the following symptoms were present,—dyspnoea, slight cough without expectoration, dull sound on the left side of the chest posteriorly, from the inferior angle of the scapula to the base of the thorax, with distinct ægophony and bronchial respiration. The sound on percussion and the respiratory murmur over the other parts of the chest were natural. The action of the heart, though diffused, was without undue impulse, but there was a distinct bruit in the præcordial region, at the lower end of the sternum, and under the clavicle. The pulse was not accelerated, but remarkably small and intermittent. The state of the skin was natural. Blood taken from the arm to relieve the dyspnoea was neither buffed nor cupped. During the succeeding night, delirium came on, the pulse rose in frequency, and was still small and intermittent. The delirium disappeared on the following morning; but the pulse did not diminish in frequency, and, for the first time, the expectoration was viscid and tinged. A crepitous râle was detected on some points of the right side of the chest posteriorly. The physical signs on the left were unchanged. Blood drawn from the arm exhibited the buffy coat, but the symptoms were not relieved by the venesection. On the two following days the breathing was still rapid, and the expectoration unaltered: the crepitous râle, without dullness of sound, on the right side continued: on the left, the sound was more dull, but the ægophony less distinct. The delirium, which had been transient, was now constant: the strength declined, the pulse became more feeble, and on the following morning death took place.

State the nature of the organic lesions in this case, and the morbid appearances you would expect to find on dissection. Detail the symptoms on which the diagnosis of the different lesions may be deduced, and the treatment to be adopted.

Translate the following passage into English:—

Celsus de Re Medica, lib. iii. cap. 23.

Tuesday, August 6.—Morning, 10 to 1.

1. What are the causes by which the Heart may be displaced?

2. Specify the different forms of Paralysis, and the lesions on which each form depends.

3. What is the nature of Purpura? Detail the states of the system with which it may be accompanied, and the appear-

ances observed in the internal organs in fatal cases. Give an outline of its treatment.

4. Detail the symptoms, diagnosis, and causes of Delirium Tremens. How should it be treated?

5. Detail the general symptoms and terminations of Pneurionia. State the physical signs which indicate its different stages, and the appropriate treatment of each.

6. Describe the paroxysm of Angina Pectoris. Specify the derangements of the system, functional and organic, with which it may be connected.

7. Specify the various functional and structural lesions which give rise to Ileus. Describe the progressive changes that take place in the intestinal canal in cases in which an invaginated portion is discharged.

8. State the varieties of Small Pox. Detail the symptoms and treatment of Confluent Small Pox.

Tuesday, August 6.—Afternoon, 3 to 6.

1. What are the symptoms by which granular degeneration of the kidneys may be recognized? What is the condition of the urine in this disease? Mention the secondary lesions which occur in its progress.

2. Specify the nature of the internal lesions with which Rheumatism is frequently complicated.

3. Detail the symptoms, diagnosis, and terminations of Schirrus of the Pylorus.

4. State the various causes by which Puenmo-thorax may be induced. Detail its physical signs and diagnosis, and give an outline of its treatment.

5. What are the symptoms of Diabetes? Detail the mode of treatment, remedial and dietetic.

6. Give the general symptoms and physical signs of Emyema. State the general measures to be adopted with the view of promoting the absorption of the fluid, and the circumstances which render the evacuation of the fluid by tapping expedient.

7. What are the symptoms, causes, and treatment of Scurvy?

8. Describe the external characters of the Scrofulous Diathesis, and the prophylactic treatment of Tuberculous Cachexia.

SPONTANEOUS HÆMORRHAGE INTO THE PERITONEUM

FOLLOWING SUPPRESSION OF MENSTRUATION.

MADAME ROUSSET, æt. 29, of good constitution, felt for several weeks a painful sensation of tension and fullness in the um-

bilical region; but as she had ceased to menstruate, and had already had two children, she supposed that she was again *enceinte*, and did not take any medical advice. In the evening of the 13th of October last, after having been washing the door-steps, the pain, from having been slight, suddenly increased, and acquired, in the course of two hours, an alarming character. Her face was pale, her skin covered with a copious cold sweat, and she soon died with vomiting, diarrhœa, and frightful convulsions.

On examination, forty-eight hours after death, except for its excessive pallor, the body presented externally nothing abnormal. The autopsy, however, left no doubt as to the seat of the disease; it was in the abdomen. About two *pots* of black and livid blood were effused into this cavity. The mesentery presented on its front surface several clots *en nappe*, and so did the mesocolon.

The heart, the principal arterial trunks, and all the principal trunks of the abdominal aorta, were carefully examined, and found healthy; the mesenteric vessels, traced as far as possible, were remarkable only for their size; but no rupture nor any trace of inflammation was discernible.

The uterus contained no embryo; its volume was less than that usually found in women who have borne children; it was even rather atrophied. There seemed no reason to doubt that the amenorrhœa produced excessive engorgement of the mesenteric vessels, from which hæmorrhage, without visible rupture, had taken place after laborious exertion in a position in which they were dependent.—*M. Lecheptois, in Arch. Gén. de la Médecine, Juin 1839.*

ON THE DIVISION OF CERTAIN MUSCLES IN THE

TREATMENT OF LATERAL CUR- VATURES OF THE SPINE.

By M. JULES GUERIN.

THE author of this paper announces that he has already practised twelve times successfully on subjects affected with this deformity—an operation which consists in the division of certain muscles of the back and vertebral column.

The muscles which he has hitherto divided are—the trapezius, the rhomboideus, the levator anguli scapulæ, the sacro lumbalis, the longissimus dorsi, and the semi-spinales.

I have long established, he says, that the greater number of articular deformities are the result of convulsive muscular con-

traction, dependent on an affection of the brain or spinal cord, or of the nerves themselves which are distributed to the muscles. This opinion naturally led me to the two following results for the diagnosis and treatment of these deformities, viz.—1st. That the various forms which each of these varieties is capable of assuming are the products of this contraction, differently distributed in different muscles; and 2d. That the active treatment of each of them must consist in the division of the tendons or the muscles, to whose contractions the special form of each is subordinate.

The following are, he adds, some details of the applications which I have made of this new method of treatment:—I have employed it on subjects of both sexes, and of different ages: the youngest was 13, the eldest 22 years old. All the curvatures were in the second or third degree, with twisting of the column, and gibbosity in proportion. In some a single division of the contracted muscles was sufficient; in others I was obliged to make two or three: in all I obtained immediately after the operation a marked degree of straightening of the column; and in one young man of 22, whose curvature had been submitted to mechanical treatment for eighteen months, I obtained, by dividing the longissimus dorsi and the semispinalis, an immediate removal of the whole curvature. In others I have been able to pursue the treatment by mechanical means with complete and constant success. In none of the twelve operations have I met with the least accident; neither hæmorrhage, nor fever, and but little pain is produced; and with one exception immediate union of the wound has taken place. I may add, that though delicate, this operation may be performed almost as easily and by analogous means to those employed in the neck for torticollis, and about the foot for club-foot. — *Comptes-Rendus*, Juin 24, 1839.

BLACK AND WHITE.

THE offspring of a white man and black woman is a *mulatto*; the mulatto and black produce a *sambo*; from the mulatto and white comes the *quadroon*; from the quadroon and white the *mustee*; the child of a mustee by a white man is called a *mustee-fino*; while the children of a mustee-fino are free by law, and rank as white persons to all intents and purposes. I think it is Long who asserts that two mulattoes will never have children; but, as far as the most positive assurances can go, since my arrival in Jamaica, I have reason to believe the contrary, and that mulattoes

breed together just as well as blacks and whites; but they are almost universally weak and effeminate persons, and thus their children are very difficult to rear. On a sugar estate one black is considered as more than equal to two mulattoes.—*Journal of a West India Proprietor*, by M. G. Lewis.

A FAIR OFFER.

At the last sitting of the Phrenological Society, a discussion having arisen on magnetism, M. Bouillaud offered a prize of 1000 francs to any magnetizer who should be able to shew him a somnambulist reading when her eyes are covered by a bandage. M. Bouillaud insists only on two conditions—1st, that he is to put on the bandage himself; 2dly, that the experiment is to take place before twelve persons not interested in the question.—*Gaz. des Hôpitaux*, July 27, 1839.

We learn from the *Gazette Médicale* of Aug. 3, that at the sitting of the Academy of Medicine on the 30th of July, M. Burdin announced that he would give the prize of 3000 francs that he had promised on easier conditions than before. He will be satisfied if the magnetized person can read through a piece of cloth or calico, or even a sheet of paper; and he extended the time from October 1839 to October 1840.

SIMPLE METHOD OF TREATING DISLOCATION OF THE CLAVICLE.

To the Editor of the Medical Gazette.

SIR,

THE following method of treating dislocation of the clavicle may appear to you, perhaps, not less worthy of notice because it is simple. A collier, while at work in a coal-pit near this town, received a large quantity of material upon his shoulders; the consequence was dislocation of both extremes of the left clavicle. The usual means proving insufficient to retain the sternal end (which projected over the sternum more than half an inch) in its proper situation, the *back-board* suggested itself, and on trial was found to answer the purpose most satisfactorily. It is unnecessary to add, that it would not be less useful in cases of fracture.—I am, sir,

Your obedient servant,

Jos. THOMAS, M.R.C.S.

Wrexham, July 29, 1839.

NOTE FROM MR. LYON.

To the Editor of the Medical Gazette.

SIR,

MAY I beg the favour of your inserting the following communication in your valuable journal, at your earliest convenience.

I have the honour to be, sir,

Your obedient servant,

I. LYON, M.R.C.S.L.

25, Montague Street, Russell Square,
August 5, 1839.

In some of the articles which have lately appeared in your journal respecting the unfortunate case of the late Joseph Hall, it has been assumed that the surgeon who injected the Eustachian tubes had not sufficient anatomical skill and knowledge to perform the operation, and thence a chain of reasoning has been attempted to account for the death. To shew the fallacy of this mode of argument, I shall refer to two operations of great magnitude performed by me, and recorded in the MEDICAL GAZETTE of the 12th October, 1833, and 22d February, 1834. These were cases of tumors situated directly upon and in contact with the common carotid arteries, both of which had a successful termination. One of these tumors was considered by the celebrated surgeon, Mr. Liston, of sufficient interest to be placed in his collection of morbid anatomy; the other is in my own collection. The operation of injecting the Eustachian tubes is considered by aurists of eminence as one of the minor operations of surgery. Mr. Pileher, in his prize essay on Diseases of the Ears, states, at page 308, that "a little experience renders the introduction of the catheter through the nose one of the *easiest* of the *minor* operations in surgery." I shall leave the profession to judge whether a surgeon capable of performing the operations above alluded to was not also capable of performing one of the *easiest* of the *minor* operations of surgery.

BOOKS RECEIVED FOR REVIEW.

The Cyclopædia of Anatomy and Physiology, edited by Robert Todd, M.D. F.R.S. &c. Part XVII. containing Hybernation, by Dr. M. Hall; Hip-Joint (Normal Anatomy), by H. LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.
BY DR. VENABLES.

Cystitis.—Inflammation sometimes attacks the mucous membrane of the bladder, and has been divided into the acute and chronic forms. The acute form is attended with a burning pain, with a sense of throbbing, and there is a feeling of tightness and constriction in the hypogastrium. The pain is much increased upon pressure, and speedily extends to the parts in the neighbourhood. There is a constant desire of making water, but after violent and continued efforts the patient passes about a tea-spoonful, or at most a table-spoonful. Whatever urine is passed is of a deep red colour, and very high specific gravity—from 1025 to 1030. It is not perfectly transparent, but somewhat opaquish, generally depositing a sediment, which is frequently mixed with blood. In some cases the absolute quantity of urine passed is below the natural proportion; but even if this is natural, or even exceeds the healthy quantity, yet there is still the frequent desire, with scanty micturition; this depends upon the mode of secretion. The urine is constantly secreted by the kidney, and is always flowing through the ureters into the bladder, so, perhaps, that not more than a drop or two may enter the bladder at a time. From the highly irritable state of the mucous membrane, the moment any urine enters the bladder it irritates the mucous lining, and causes

excruciating pain. The irritation is extended by the stimulus of *contiguity* to the muscular coat of the bladder, and it is thrown into violent and laboured contractions; but there being as yet but a few drops of urine, this cannot be expelled; but when the quantity increases to about a table-spoonful, the contraction of the bladder expels it, and there is both a painful and scanty micturition.

The pulse is frequent, hard, and wiry, sometimes full. As the disease advances it becomes irregular, the skin is dry and hot, and there is most distressing thirst. The disease still proceeding, the pain now extends to the other viscera, and particularly to the rectum. Hence there arises tenesmus, or a constant desire of going to stool, with a total inability of passing any thing. At the same time there is great restlessness, anxiety, sickness, and even vomiting. If the disease be not relieved, the abdomen becomes tense and tumid, almost as in peritonitis, to which succeeds twitching of the muscles. To these succeed painful tumefaction of the loins, with rigors, coldness of the extremities, or cold clammy sweats, watchfulness, and delirium. At length the urine dribbles away involuntarily, convulsions come on, in which the patient generally expires.

The inflammation, it is said, generally occupies the lower part and neck of the bladder, in which case the symptoms will vary somewhat. Thus, if the inflammation be so situated, there will be a retention of urine, the sphincter being spasmodically contracted, and refusing an exit to the urine. If a catheter be introduced, the moment it enters the bladder the pain is almost intolerable. In other cases the inflammation is seated in that part where the ureters enter. In this case they may become involved, their coats thickened, and their mouths closed up, so as to prevent the urine flowing into the bladder, producing an apparent suppression, with

all its consequences. In this case it is that the pain is most severe on pressure of the hypogastrium. When the posterior part of the bladder is the seat of the inflammation, then the rectum becomes sympathetically engaged, and there is the tenesmus, as already described.

The appearances on dissection shew that not only the mucous lining is affected, but that the inflammation spreads to the other parts of the bladder, and the peritoneal covering has been found participating in the disease; and hence the bladder is often found agglutinated to the parts in the neighbourhood, more particularly the rectum. However, the severest signs of disease are generally observed about the neck. The mucous coat is sometimes a complete tissue of redness, while the natural appearance is pale. "The inner membrane of the bladder," says Wilson, "has not in the natural state many vessels large enough to contain red blood; but when inflamed, the trunks enlarge, and the minute vessels are then found to be sufficiently numerous to impart a florid red appearance to the whole surface. When the inflammation runs high, the muscular coat may be affected, and sometimes the peritoneal also; but as the inner membrane is loosely attached to the muscular, the inflammation is often prevented from extending from the one to the other*." Ulceration and tuberculated induration of the bladder may occasionally result from acute inflammation, but they more frequently result from the chronic form. I once saw an instance in which, during the acute stage of inflammation, enormous quantities of pus were secreted and thrown off by the mucous coat of the bladder, similarly to what takes place in acute bronchitis. The patient sunk, and on dissection the mucous membrane appeared as one red mass, covered with pus, without any ulceration. Sometimes gangrene has been observed after acute inflammation; it will certainly prove fatal.

Dr. Prout mentions a species of inflammation attacking the bladder in gouty persons who have suffered from urinary derangements, he says, ultimately involving the whole system. This affection is not strictly inflammatory, the circumstances attending it differing altogether from those of common inflammation. It occurs after or during attacks of irregular gout, commencing with slight rigors, followed by feverish exacerbations, attended with unusual prostration of strength and mental depression. The constitutional symptoms soon become more severe, the pulse becomes excessively frequent, the skin hot and dry, with nausea

or actual vomiting, and there is delirium, with all the symptoms of irritative fever of the severest kind. Up to this period the urinary system is not, apparently, much affected, and the patient, even on inquiry, makes no complaint of this sort, and even bears pressure without inconvenience. The symptoms, however, increase in spite of every remedy; at length there is retention of urine, and a tumor is observed in the hypogastrium. The patient sinks rapidly; lividity of the whole urinary organs, and of the contiguous parts, speedily ensues, to which death soon succeeds.

The nature of this affection is obscure; some, perhaps, may think it of a gouty character. Dr. Prout thinks the inflammation more closely resembles the diffuse or erysipelatous kind. The appearances, however, after death, have not been much examined.

Causes.—The causes are those of inflammation in general, as also certain others of mechanical operation, derived from the functions of the bladder. Of this kind we may more particularly mention the presence of calculi, which, by the mechanical irritation which they produce, may excite inflammation. External injuries, blows in the hypogastric region, violent exercise, protracted retention of urine, exposure to cold and damp, &c., may be ranked amongst the exciting causes of cystitis. Gonorrhœa suddenly suppressed by astringent injections, or stimulating remedies, before the inflammation has been reduced, may give rise to inflammation of the bladder. Indeed, the severest instance I ever saw was brought on by an immoderate use of cubebs to speedily suppress gonorrhœa. Not only the bladder, but the kidney and testicle were very violently inflamed in this instance; nor was the inflammation subdued till the patient's health had suffered, and his strength was greatly exhausted. Repelled gout, the exanthemata, the sudden cessation or suppression of habitual discharges, more especially of blood, as of the hæmorrhoids, acrid and highly stimulating diuretics, cantharides, turpentine, high-seasoned foods, the immoderate use of strong wines or ardent spirits, may excite acute inflammation of the bladder; and, perhaps, we may add to these, the but too frequent abuse of catheters, bougies, and other urethral instruments.

Diagnosis.—Acute inflammation of the bladder is to be determined not by a single symptom, but by the aggregate of all the circumstances. Thus, if we have an acute and burning pain in the hypogastrium, much increased upon pressure, dysuria, with frequent and scanty micturitions, and tenesmus, we may safely pronounce the disease inflammation. In the more

* Lectures on the Urinary Organs.

obscure cases, sounding will generally decide the presence or absence of a calculus.

Prognosis.—Acute inflammation of the bladder is a very dangerous affection. Even in the young, healthy, and vigorous, if subdued, it often leaves behind consequences which harass the patient for a time, undermine the health, and ultimately prove fatal. In the old it is apt to terminate fatally; but should this not be the case, the evils it superinduces are of the most distressing nature. The most common result is, such a state of the mucous lining as renders the bladder at all times extremely irritable, and an almost insurmountable tendency to repeated attacks of catarrhus vesicæ. In all circumstances, therefore, inflammation of the bladder is to be looked upon with suspicion, and if it occur in the old, the prognosis can hardly ever be favourable.

Treatment.—The general treatment is much the same as in the other phlegmasiæ. Bleeding largely, and in quantities proportioned to the violence of the symptoms and the urgencies of the case, is the first object to be accomplished. Some of the French practitioners recommend the blood to be drawn from the foot; but it is probably of little moment from whence the blood be taken, provided it can be abstracted in sufficient quantity and with sufficient rapidity. The general treatment should be followed by local bleeding, by means of cupping, leeches, &c. applied over the hypogastrium, and to the perineum. The bleeding should be promoted by warm fomentations, the semicupium, and emollient clysters. The bowels should be opened by the milder aperients, as castor oil, infusion of senna, and laxative enemata. To relieve the irritability of the bladder, hyoscyamus or opium should be given in sufficient doses. The bowels also should be kept open by mild aperients and laxative clysters, and care should be especially taken that no fecal accumulation take place near the rectum. In this, as in nephritis, it is recommended to give calomel combined with opium; but I would observe upon this, as before, that mercury, if its specific effects be excited in the system, has generally appeared to me to do harm in the inflammatory diseases of the urinary system; therefore, they who employ this remedy will be cautious in the use of it, and watch its effects.

As the pain and irritation of the bladder are greatly aggravated by the acrimony of the urine, we should endeavour to render this as bland and as dilute as possible. Hence, mucilaginous drinks may be taken in abundance, and perhaps none are preferable to the *mistura amygdalæ*, already mentioned. Colchicum also has appeared

to me to exert a very beneficial effect in all forms of cystitis, and may therefore be given with some one or other of the medicines. We should also attend to the state of the urine, and if there be any tendency to alkaliescence, this should be corrected by the limited use of the phosphoric acid. When the more urgent symptoms have been subdued, counter-irritants may be applied to the hypogastrium—a mustard cataplasm, for instance. Blisters are questionable, and when used should be kept on only for a short time, and the discharge kept up by proper dressings. Sometimes, in consequence of the irritation, a spasmodic action of the sphincter vesicæ takes place, thus giving rise to a most distressing retention of urine. In such cases it may be necessary to draw off the urine by the catheter; but in doing this great care is required, to avoid increasing the pain and sufferings of the patient. Some of the French practitioners recommend injecting the bladder with mucilaginous fluids, to correct or protect it from the acrimony of its contents; and if all other means fail of affording the necessary relief, this method may be adopted with considerable advantage. By the above means we may often succeed, in favourable circumstances, in relieving, or indeed in wholly subduing, the inflammation; but in many instances a diseased condition of the mucous membrane, ultimately terminating in the affection next to be considered, is left behind.

Cystirrhœa, or catarrhus vesicæ.—This affection is sometimes the consequence of acute inflammation of the bladder; but it frequently comes on suddenly, and without any obvious cause. In some instances the attack is preceded by oppression of the stomach, with spasm, and an extreme degree of relaxation of the bowels. The patient also complains of sharp piercing pains, with a sense of burning and spasms in the hypogastrium. A weight is felt in the perineum, and there is a tendency to piles. As the disease becomes more completely established, there is a frequent and urgent desire, with inability, to pass the urine; and this at the beginning appears to depend upon spasm at the neck of the bladder and in the urethra. The urine is found to contain a quantity of mucus of a more or less adhesive character, and which subsides to the bottom of the utensil. For the most part, at the beginning there is slow fever, with great weakness of the back and loins; the patient complains of great thirst, which cannot be satisfied, and his rest is completely broken. This, the irritation, and the unnatural drainage from the system, causes, if the disease be protracted, great exhaustion and emaciation; and the patient is either cut off by

the disorganization excited, or he dies of the extreme exhaustion.

The urine varies in its characters according to the circumstances. In incipient or slight cases, the urine when first passed appears of a whitish colour, somewhat opaque and turbid, and after standing for a few minutes minute flocculi are seen floating about in it. On remaining at rest for a sufficient time, a mass of adhesive mucus will be found deposited at the bottom of the vessel, and the urine above either perfectly transparent or nearly so. In these cases, tested by litmus paper, the urine has an acidulous reactivity, that is, reddens the litmus; nor is it otherwise very unnatural. The mucus itself is generally alkaline, but occasionally neutral. In some cases the specific gravity of the urine is high—1.025 and upwards—and then it will be found to contain urea in excess, and if allowed to stand soon becomes alkaline.

The mucus itself also varies in different cases, or even in the same case at different times. In some the mucus is uniformly diffused through the urine, subsiding only after a time, and may be again diffused through it by agitation; in others it is so viscid and tenacious, that once it has been allowed to collect into a mass, it cannot again be mixed with the urine. In the severe cases, too, the quantity is sometimes enormous. In a case which came under my observation at Chelmsford, the quantity averaged about eight pints for several days. The pain and desire to pass the urine were incessant, and the mucus was so tough and partially concreted into coagulums, as to prevent the passage of the urine, giving rise to a most painful distension of the bladder. It was at first suspected that the symptoms arose from a stone in the bladder, but the surgeon, on sounding, could not discover any calculus; and when the catheter was introduced, to relieve the retention by drawing off the water, only a few drops passed, the perforations of the instrument being immediately closed up by the viscid mucus.

After repeated and very painful efforts, sometimes a greater quantity of urine is passed; and, on pouring off the fluid portion, a great quantity of mucus, sometimes extremely tough and stiff, is often found at the bottom of the utensil; and this is so tenacious that it adheres even though the vessel be inverted. When the mucus undergoes this sort of imperfect coagulation, it seems to depend upon the admixture of a considerable proportion of fibrin. The mucus generally has a somewhat opaque appearance, sometimes quite so, and even becomes dark. In the more advanced stages, it becomes of a yellow or greenish colour, and assumes the charac-

ters of pus. Frequently it is found mixed with blood; the urine at the same time loses its transparency, becomes coagulable from containing serum, and will now be found so alkaline as to redden turmeric paper immediately on being evacuated from the bladder.

Catarrh of the bladder, when occurring in old people, or when long protracted, is generally complicated with disorganizations; frequently ulceration of the bladder and the prostate, if not affected from the beginning, soon becomes involved. If the bladder be ulcerated, there are often severe hæmorrhages, and if the urine be very unnatural, we may presume that the kidneys have become more or less affected.

The more severe forms of this affection may be considered as principally confined to old persons. The patients in whom I have seen it most severe, have been approaching to or upwards of sixty. The patients, too, were gouty subjects, and who had suffered from repeated paroxysms of this disease; and there either is or has been a tendency to cutaneous eruptions of various characters. In such, if they have lived freely, have been much addicted to venery, have suffered from gonorrhœa, strictures, and similar irritations of the urinary organs, there is a strong tendency to severe attacks of catarrh of the bladder. Irritable and scrofulous habits, too, in advanced life, are subject to this disease; and it seems induced by mere exposure to cold or damp; during which periods, persons subject to it suffer much more severely in cold weather. Among the exciting causes may be enumerated stimulating or acrid diuretics, severe exercise on horseback, hæmorrhoids, &c.; but very often it comes on, in those predisposed to it, without any obvious cause.

This disease, when once completely established, may be considered as of a very obstinate character; and, from its being so constantly associated with organic disease of the bladder, mostly incurable. In many, however, it assumes a mild character, occasionally appearing and disappearing at intervals, in the intermitting form, especially when the patient is troubled with hæmorrhoids or with certain cutaneous affections. If long protracted, it may occasion paralysis of the bladder. On dissection after death, the bladder shews various morbid appearances. The mucous coat always is turgid, with enlarged blood-vessels presenting a perfectly red appearance, and in some cases it seems as if in a completely varicose state. In one or two instances which I had an opportunity of examining, the bladder appeared as a completely red tuberculated mass, much thickened in all its coats,

and ulcerated in three places. It is evident, however, that the morbid appearances will be much varied by accidental circumstances. The disease, however, uniformly presents a diseased state of the vascular tissue of the bladder, and which has been in all probability erroneously looked upon as of an inflammatory character. But the morbid vascularity upon which these affections seem essentially to depend, appears to be of a very different nature.

Treatment.—When this disease occurs in younger subjects, or is the consequence of acute inflammation, the urine will be found to differ from that of the more inveterate forms. In such the urine is often decidedly acid, high coloured, and of medium specific gravity. Moderate antiphlogistic measures are suited to such cases, and therefore, cupping the loins, and the application of leeches, will be found serviceable. But in the more inveterate cases, and where the qualities of the urine are such as have been already described, these means will seldom be necessary, and even when requisite, should never be carried to the same extent. The first thing, however, will be to regulate the bowels, which must be effected by mild aperients and laxatives, as castor oil; and if this do not prove sufficiently active, it should be assisted by enemas. At the same time gentle astringents should be given, together with sedatives. The *ura ursi* is, perhaps, one of the most valuable of the class, and it may be given either in extract or infusion. As an extract, it may be given in the form of pills, combined with the sedatives*.

The urine, in the severe forms, as already stated, is alkaline, and then the irritation of the bladder is much increased. We must, therefore, endeavour to alter the condition of the urine as speedily as possible. This is best effected by the administration of some of the indestructible acids and the hydrochloric; or, what perhaps is preferable, the phosphoric acid should be administered internally, for which purpose we cannot do better than combine it with one of the urinary astringent infusions†. Those

most celebrated are *buchu* (*Diosma crenata*), *pareira*, *Alchemilla arvensis*, or *parsley* breakstone. Hydrochloric acid checks the secretion of mucus, but, it is said, increases the irritation in the bladder. "The muriatic acid, on the contrary, assisted by plentiful dilution, has sometimes, in a remarkable degree, the effect of checking the mucous secretion; but it is also liable to increase the irritation of the bladder, in which case it may be necessary to lay it aside altogether*." The phosphoric, again, not only corrects the chemical condition of the urine, but also hold this mucus in solution, which is precipitated by alkalies. "At first," says Marcet, "this mucous secretion is probably only a consequence, but it soon becomes a concurrent cause of urinary concretions. The use of alkalies unfortunately tends to increase this inconvenience, by precipitating from the urine the mucus which is held in solution by the redundant phosphoric acid†."

By these means, unless in the most obstinate cases, we shall generally succeed in relieving the patient from at least a great portion of his sufferings. Some, indeed, recommend balsamic remedies and other urinary stimulants; but I have never seen them do any good, but often, on the contrary, a great deal of harm.

But in some cases of a very inveterate description, more especially if the treatment has not been judicious at first, or has been too long delayed, the mucus gets so coagulated that it will not pass off with the urine, and, forming masses in the bladder, causes much irritation and distress to the patient. It is in such cases that the injection of the bladder with the phosphoric acid, largely diluted with distilled water, does so much good. I have already mentioned the case of an old gentleman to whom I was called, and who was suffering very severely from this disease. The mucus was so viscid and tough that it choked the perforations of the catheter, and hence the urine could not be drawn off. As the bladder became dis-

* Marcet on Calculous Disorders, p. 175. Dr. Marcet's observations apply to the mucus secreted during the calculous diathesis; but in the inveterate forms of catarrhus vesicæ, I have never found the hydrochloric acid produce irritation; on the contrary, by correcting the chemical condition of the urine, it has mostly produced a soothing effect. In slight or recent cases, perhaps a long-continued use of the acid might be attended with some slight degree of irritation.

tended, the urine kept dribbling from the urethra in drops, and began to produce excoriation of the cellular tissue. Under these circumstances I had the bladder injected with the phosphoric acid; and after two or three times, with the means directed above, the mucus became much more fluid, and was passed in very great quantity; and in about three weeks the patient was relieved from all the symptoms of his disease. But in another case, in which there was a scirrhus state of rectum, neither injection of the bladder nor any thing succeeded, and the patient died comatose or apoplectic; indeed, it should not be lost sight of, that such patients are always liable to die suddenly apoplectic.

When we have succeeded in evacuating the existing mucus, and in controlling the future secretion, we may proceed to give some tonic. Perhaps there may not be any grounds for preference; but, from my own experience, I should say that I think the tinctura ferri sesquichloridi the best. I have been in the habit of using it, and mostly with very good effect. Upon occasions, especially if the urine appears to be getting natural or manifests any tendency to alkalescence, we may add a few drops of the hydrochloric acid.

The regimen, both during the prevalence of the disease and during the convalescence, should be strictly attended to. The bowels should be properly regulated by mild aperients; the diet light, nutritive, easy of digestion, and free from all stimulating condiments. Moderate exercise will be beneficial, but severe or fatiguing exercise may bring on relapse; therefore riding in a carriage upon rough roads, or upon horseback, should be avoided, as also exposure to cold and damp, especially in winter, during which season the patient should protect himself from the agency of cold by sufficient and warm clothing; and, if possible, residence in a milder climate during this season would be advisable.

Strong stimulating drinks also will be bad; but if any thing of this sort be necessary, some of the light acescent wines may be permitted. As the state of the urine will often afford evidence of an approaching attack, I need hardly observe that this should occasionally be carefully examined.

VELPEAU'S CLINICAL LECTURES ON OPHTHALMIA.

By J. HENRY BENNET, B.L. & B.S.

Sorbon.

ON THE TREATMENT OF INFLAMMATION OF THE CONJUNCTIVA.

Treatment of conjunctivitis—Simple conjunctivitis—Conjunctivitis with chemosis—Partial conjunctivitis—Papular conjunctivitis—Granular conjunctivitis—Purulent conjunctivitis—Gonorrhæal conjunctivitis—Purulent conjunctivitis of Egypt.

Treatment of Conjunctivitis.

THE treatment of conjunctivitis, like that of all other surgical diseases, may be either general or local. The general treatment is regulated by the constitution of the patient, and the symptoms to which the malady may give rise. The local treatment, on the contrary, is directed against the lesion itself. In conjunctivitis, as, indeed, in all the various inflammatory actions we have yet to study, local treatment is more especially to be depended upon. I do not mean to assert that general remedies, such as bleeding, purgatives, &c. should be banished from the treatment of these diseases; you must be well aware that circumstances too numerous to be mentioned render them often useful, and in some cases even necessary. I wish you, however, to understand that the action of these agents is indirect, that they undoubtedly assist in effecting a cure, but in most instances are not sufficient to produce it of themselves. My ideas on this subject have not been formed *a priori*, but are founded on numerous facts and experiments, which have led me to the conclusion that local remedies ought to occupy the first place in the treatment of ophthalmia.

On examining the local agents which we can employ in the treatment of these affections, we shall find that, as in blepharitis, astringent applications are to be preferred. The treatment of the several forms of conjunctivitis, although not essentially different, presents, nevertheless, modifications of sufficient importance to induce me to treat separately the remedies applicable to each.

Simple Conjunctivitis.

When the inflammation is slight, you will often find that bathing the eye with some emollient liquid, such as an infusion of marsh mallow or linseed, or even with

tepid water alone, will in a few days dissipate every inflammatory symptom. If, however, the inflammation is intense, these means no longer suffice, and you must have recourse to astringent applications, under the form of collyria. The substances generally employed by practitioners are, sulphate of zinc, acetate of lead, or nitrate of silver. The different preparations of the nitrate of silver, which you see me use so frequently, and to which I wish more especially to draw your attention, are by no means modern remedies. The ancients recommend the nitrate of silver, but only as a caustic, in cases of chronic conjunctivitis. Now you must have observed, that in our wards this remedy is principally used as a collyrium or ointment in cases of acute inflammation, and that the success attending this practice is really surprising. Regent, Janin, and Scarpa, who speak in high terms of the nitrate of silver, appear only to have employed it as a caustic. I cannot, however, admit that it acts as a caustic only; its action, in many cases, is certainly resolute, and the rapidity with which it arrests the progress of inflammation in intense conjunctivitis is a decided proof that I am warranted in making this assertion. You have, indeed, seen numerous instances this year, in which the inflammation has been thus rapidly arrested.

Whatever may be the mode of action of the nitrate of silver collyrium, it deserves the decided preference of practitioners. The experiments I have made to ascertain its efficacy are so numerous that I have no hesitation in speaking thus decidedly. I must, however, add, that it is more especially in simple conjunctivitis that the effects of the nitrate of silver are rapid and undeniable. I generally commence with a solution, containing half a grain to an ounce of distilled water, for children, and a grain or a grain and a half to the same quantity of water for adults; the proportion is afterwards gradually increased. When the solution has been used for a short time it should be laid aside for two or three days, and then again employed as before; and the treatment should be thus continued until the inflammation is entirely subdued.

During the first few days you employ the collyrium, the inflammatory symptoms are often exasperated, and this might create doubts in your mind respecting the efficacy of the remedy—the more so, as when its use is suspended, the inflammation diminishes, and the disease appears to progress rapidly towards a favourable termination. The patients themselves, indeed, are generally inclined to think that the treatment they have undergone has done them more harm than good;

but a well-informed medical practitioner will never entertain such an opinion, as the above mentioned phenomena are in perfect accordance with the laws of pathology.

The solution must be again employed after a few days' intermission, as I have already stated. Were it to be discontinued, from erroneous views respecting its action, the disease would, in all probability, return with greater intensity even than before.

I must also add, that the efficacy of the nitrate of silver collyrium depends, in a great measure, on the manner in which it is applied, it being absolutely necessary that every portion of the inflamed conjunctiva should be brought into contact with the solution. I need scarcely say, that it ought never to be employed as a lotion; two or three drops only should be introduced between the eyelids night and morning. To effect this, the patient must lean his head back, and then, separating the eyelids as far as possible, you allow two or three drops to fall from the phial on the eye. You should then immediately close the eyelids, and keep them in contact for a few seconds, at the same time directing the patient to move the eye in various directions.

I have entered into these details respecting the nitrate of silver collyrium because it is, without exception, the remedy on which we may place the greatest reliance, not only in the affections which we are now studying, but in several others of which I shall have to speak hereafter. We must not, however, forget, that in many cases local treatment alone is not sufficient, and that we are then obliged to have recourse to general means. Thus, if the inflammation is intense, and the patient of a plethoric habit of body, it becomes necessary to bleed. In some cases of this nature I have derived great benefit from bleeding *coup sur coup*, according to M. Bouillaud's method. If, on the contrary, there appear to be slight symptoms of gastric irritation, purgatives may be resorted to. In a word, general symptoms, whatever they be, when they exist, should be treated as in all other inflammatory affections.

Conjunctivitis with Chemosis.

I have described two forms of chemosis essentially different from one another; you will not, therefore, be surprised to hear that the treatment of each of these forms is also essentially different.

When you meet with the inflammatory or phlegmonous chemosis, you must at once have recourse to antiphlogistics, following up the treatment with greater or

less energy, according to the degree of intensity of the inflammation. In these cases bleeding from the arm *coup sur coup*, and leeches applied to the temples or to the mastoid region, are often attended with very favourable results: I have in many instances found this practice exceedingly beneficial. Direct applications have also been much employed in this, the acute form of chemosis. From the earliest periods, surgeons have attempted to bring about the resolution of the inflammation by scarifying the injected tissues. The ancients, you well know, performed this operation with barley-spikes. I am, however, inclined to think that scarification of the conjunctival vessels does not deserve the praise given to it not only by the ancients, but also in our own times by M. Demours, and by English practitioners, who, I believe, employ it pretty generally. M. Sanson says he has found scarification in some instances a valuable remedy. It may be so; as, however, my experience on the subject has not been very extensive, I do not feel warranted in giving a decided opinion. I must, at the same time, remind you, that we have in our possession a more efficacious, and certainly less dangerous remedy; I allude to leeches applied to the surface of the conjunctiva itself. In 1817 I made several experiments, at Tours, with M. Bretonneau, to ascertain the effects produced by leeches thus applied; and I must say we always found that the patient derived great benefit from their application.

I do not wish entirely to banish scarifications from the treatment of inflammatory chemosis, as cases may occur in which they ought to be resorted to; but these cases are rare; general blood-letting and leeches, applied as I have stated, are almost always sufficient to subdue the chemosis. I seldom have recourse even to leeches; not that they cause much pain, but from the trouble attending their application. They are not, it is true, long in filling themselves, but they have to be applied one by one, which makes it rather a tedious affair.

To resume, the following is the course I generally pursue. I begin by general and local blood letting, regulating the quantity of blood extracted, and the number of times the operation is repeated, according to the intensity of the inflammation and the constitution of the patient. If these general means are not sufficient to calm the inflammatory symptoms, I then apply leeches to the conjunctiva. When the tumefaction and inflammation have subsided, I have recourse to the nitrate of silver collyrium. By thus uniting general and local treatment, I frequently succeed

in subduing the chemosis in the course of a few days; and should you adopt this plan in your practice, I am convinced it will be followed by the same results.

The second form of chemosis—the serous or oedematous form—not being essentially of an inflammatory nature, it is no longer necessary to resort to general or local depletion. Purgatives seem to be the most useful remedy we can employ in this affection; and among them calomel, given in Rasorian doses, occupies undoubtedly the first rank. Here again, however, the nitrate of silver collyrium is the agent on which we must chiefly depend for a radical and definitive cure of the disease.

Partial Conjunctivitis.

The treatment is the same in this form of inflammation as in simple conjunctivitis. I shall therefore confine myself to a caution respecting the use of the nitrate of silver collyrium. It must be employed with rather more circumspection than hitherto, and applied, as far as possible, to the parts only which are inflamed, in order that the remainder of the mucous membrane should not be too much irritated.

Papular Conjunctivitis.

The nitrate of silver collyrium does not always prove sufficient to effect the cure of papular conjunctivitis. When this remedy does not succeed, the best plan we can adopt is that of cauterizing lightly the papulae with the solid nitrate. As soon as this has been done, it is advisable to drop a little cold water over the cauterized spot, with the view of preventing the parts of the conjunctiva you wish to preserve intact from being injured. During the two or three days which follow this slight operation, the symptoms are exacerbated, the intensity of the inflammation being apparently much increased. You have already seen that this is generally the case, even when the solution is employed. The patient, however, soon begins to feel better, the inflammation diminishes, and, when the papulae have been cauterized a time or two, entirely disappears. This form of conjunctivitis is much more obstinate than those we have already examined: this is a fact you ought always to bear in mind.

Granular Conjunctivitis.

After what I have said respecting the seat and the symptoms of granular conjunctivitis, you will not be surprised to find that it is the form of conjunctivitis which usually proves the most rebellious to therapeutical agents. The disease is not, however, incurable, a well-directed

treatment, continued with perseverance, being generally successful; more frequently, indeed, than in granular blepharitis. The treatment of this affection is exactly the same as that of granular blepharitis. I shall, therefore, to avoid repetition, refer you to what I stated in a former lecture, with regard to the treatment of this malady.

These are the considerations I have to offer you respecting the treatment of the various forms of conjunctivitis we have already examined. I shall now proceed to describe the purulent forms of inflammation.

Purulent Conjunctivitis.

All the morbid affections described by authors under the name of purulent ophthalmia may be reduced, as regards their primitive seat, to two principal classes:—

1st. Purulent blepharitis; that is, purulent blepharitis of new-born children, or purulent blepharitis of adults.

2d. Purulent conjunctivitis.

I have already stated my reasons for making this division; it would therefore be useless to repeat what I have said.

Purulent conjunctivitis is generally admitted to be contagious. The facts which can be adduced to support this opinion are so numerous, I scarcely consider it necessary to discuss the question; there can, indeed, be no doubt on the subject. The disease seems often to rage as an epidemic; and there are, perhaps, few countries where, at one period or another, it has not exercised its ravages. There are, consequently, many interesting treatises on this malady to be met with, nearly each epidemic having had its historian. Were you to form an opinion from the mere perusal of these treatises, you would admit numerous forms of purulent conjunctivitis. I am, however, inclined to think that the authors of these monographs, led astray, in some degree, by a minute appreciation of peculiar symptoms, perhaps also influenced by the charm of novelty, have considered the disease they had observed as a new affection, although, in reality, it had no claim to such a distinction. If we examine with care, and without any prevention, the descriptions they give, we cannot but acknowledge that there exists the greatest analogy between the various epidemics; an analogy which warrants my considering them as mere modifications of two principal forms of disease. The forms to which I allude, are—

1. Gonorrhœal conjunctivitis.

2. The purulent conjunctivitis of Egypt.

I do not intend to examine separately the numerous epidemics which have been witnessed and described in our own and

other countries; we have not time to devote to such a study. If any of you, however, doubt the correctness of these remarks, I would request you to draw a parallel between the different descriptions; you would then see immediately that these affections are, in reality, nearly identical. If you listen attentively to what I am about to say, you will, I think, be able to form a correct opinion respecting purulent ophthalmia.

Gonorrhœal Conjunctivitis.

Although numerous researches have been made to ascertain the nature of this affection, practitioners are far from agreeing with regard to its original mode of production.

Some look upon the disease as the result of a metastasis of the urethral affection to the mucous membrane of the eye; others attribute it to gonorrhœal matter being, by some means or other, brought in contact with the conjunctiva; some, again, attribute it to a general syphilitic infection of the system. Each of these opinions numbers many partisans, who bring forward numerous facts and arguments to defend their theoretical views. Indeed, any one of these opinions might be adopted, without any offence to reason, to the exclusion of the other two. Whatever may be the manner in which gonorrhœal conjunctivitis originates, no one in the present day can doubt its syphilitic nature; the facts which establish this point are too numerous to be denied, and this is quite sufficient to guide us in practice. We will now proceed to describe the symptoms by which the malady may be recognized.

One of the most striking features of this disease is the extreme rapidity with which it progresses. The rapidity is, indeed, so great in some cases, that it becomes impossible to follow the march of the complaint through its different periods. The eye may be lost in less than four-and-twenty hours, and that without its being possible for the surgeon to arrest the progress of the malady. This is not, however, always the case; the march of the disease may be sufficiently slow to enable us to study it in its different stages. These are the cases I shall take as models in the description I am about to give you. In either form, however, the affection is a most serious one, and one in which the surgeon must not temporize, but act at once, and with energy.

When gonorrhœal inflammation of the conjunctiva is moderate, the following are the symptoms which we observe:—The conjunctiva, at first of an uniform red cinnabar colour, soon becomes of a darker hue, and assumes a tinge similar to that

of wine-ices. The injected vessels are no longer to be distinguished from one another, and the tissue itself of the membrane, as well as the cellular layers separating it from the sclerotica, becomes gorged with blood and tumefied. The free surface of the conjunctiva, at first smooth and polished, soon assumes a velvety appearance, and presents a great number of granulations, the volume of which varies from the size of a millet seed to that of a large pea. This tumefaction of the conjunctiva gradually increasing, soon gives rise to chemosis with all the concomitant symptoms.

The tissues which enter into the formation of the palpebræ are generally more or less inflamed. The eyelids become much swollen, and the cutaneous surface is red and hot, the patient complaining at the same time of burning pain in this region. Sometimes the tumefaction of the upper eyelid is so considerable as to partly cover the lower one. Sometimes, on the contrary, there is ectropion, and then the velvety appearance of the globe of the eye is perfectly visible; the eye presenting a fungous, granular surface, in the centre of which we see the cornea, more or less concealed by the tumefaction of the conjunctiva. The most important character, however, the character which may be considered pathognomonic of this form of ophthalmia, is to be found in the thick greenish-yellow purulent mucus, which is continually discharged from the eye—mucus which may be compared in every respect to the discharge we meet with in gonorrhœa. If the eyelids are separated, the purulent fluid which is retained between the eye and the palpebræ by the tumefied state of these organs, flows in a stream over the face. In this affection, as in those we have already examined, the visual functions are not disordered unless the swelling be so great as more or less to conceal the pupil, and thus diminish the field of vision. The deep-seated pain felt by the patient must be attributed to the compression exercised on the globe of the eye by the inflamed and tumefied tissues.

These symptoms, if borne in mind, will always enable you to recognize gonorrhœal conjunctivitis. You must not, however, think that this affection is always met with as I have just described it, that is, in the simple inflammatory form, without complication. Unfortunately, the inflammation is seldom confined to the conjunctiva. In many instances it attacks the cornea, and it is to this complication I particularly wish to draw your attention. It is not always in our power to prevent the inflammation extending to the cornea, which is then often destroyed in the course of a few hours, although previously

perfectly healthy and transparent. In some cases, nevertheless, we are able to follow the progress of the disease after it has reached the cornea. When this is the case, we find that the symptoms are developed with extraordinary rapidity. The cornea loses its transparency and becomes of a whitish grey colour. Vision is also necessarily impaired, the patient complaining of a mist which obstructs the sight. The tissue of the cornea seems infiltrated with an opaque fluid; a kind of pultaceous matter covers the free surface, from which it is easily separated. Very soon, pus takes the place of the pultaceous matter, and an ulceration is seen, with perpendicular edges of variable size. This ulceration growing deeper and deeper, the cornea is at last entirely perforated, and the humours of the eye evacuated. The iris then becomes engaged in the perforation of the cornea; and the interior of the eye, which is the seat of intense inflammation, suppurates profusely.

I have often remarked in gonorrhœal conjunctivitis, that when the secretion of mucus is considerable, of a purulent nature, and by its acrid properties gives rise to slight inflammation of the skin over which it passes, the cornea remains perfectly sound; whereas, if the secretion is less abundant, of a whitish colour, of a creamy consistence, and does not irritate the skin, we often find that the cornea is perforated in the manner I described. This circumstance has also been noticed by other practitioners. You must not, however, look upon this as a general law; were you to do so you might often be led to entertain false hopes with regard to the termination of the disease.

Gonorrhœal conjunctivitis does not always terminate thus unfavourably. An energetic well-directed treatment will sometimes destroy the inflammation at the onset, and the cure may be thus completed by the local treatment I shall presently describe.

In the most favourable cases, when the disease terminates by resolution, the secretion of mucus becomes every day less thick and less abundant. The tumefaction also diminishes, and by degrees every tissue returns to its normal state. The resolution is, however, seldom complete, the conjunctiva retaining more or less of its vascular appearance, and the mucous follicles remaining voluminous and indurated. A glutinous, half-purulent matter continues to be secreted. When the eye is in this state the slightest cause will bring back the acute form of inflammation. The surgeon should, therefore, use every endeavour to subdue the inflammation which still exists in this, the subacute form.

Sometimes, after gonorrhœal conjunctivitis, the cornea presents opacities which interfere more or less with vision, according to their extent, and according to the part of the cornea they occupy. I merely allude now to these lesions of the cornea, as I shall speak of them at length when treating of keratitis.

Treatment of Gonorrhœal Conjunctivitis.

If all I have said respecting this malady has been well understood, you must, in some measure, be already aware of the nature of the treatment which ought to be pursued. At the very commencement of the disease, as soon as he is aware of its presence, the practitioner must attack it with energy. The least delay on his part, or the inefficacy of the agents he employs, is generally attended with fatal consequences to the organ affected. When the disease is a little farther advanced it is too late, the most powerful measures are then nearly always unable to arrest the rapid strides of the malady.

Purulent conjunctivitis is undoubtedly the form of ophthalmia which most imperiously requires general treatment. You must, therefore, at once have recourse to blood-letting, general and local. The practice of bleeding *coup sur coup*, to syncope, is often attended with very beneficial effects. I have several times resorted to this mode of treatment, and that with success; the intensity of the inflammation being, indeed, such as to warrant the most energetic measures. When, by copious and repeated bleeding, you have diminished the volume of the circulating fluid, you must endeavour, by the depletion of the inflamed tissues, to act more directly on the malady. The means by which this may be accomplished are various. Some recommend leeches applied round the orbit, on the mastoid region; others, the opening of temporal artery, or the scarification of the conjunctiva. Arteriotomy does not certainly deserve the praise which has been given to it by some. When other means fail to arrest the progress of the inflammation, I should not expect greater success from such an operation. As, however, it is a plan I have not very often tried, I will not speak very decidedly on the subject.

Excision of a portion of the conjunctiva, which has been recently extolled by M. Sanson, is often attended with serious consequences; we ought, therefore, to be careful how we make use of such a remedy. I should myself prefer repeated applications of leeches on the conjunctiva. By adopting this plan the end proposed is attained, and the disagreeable consequences which may follow the excision are avoided.

When you have subdued the inflamma-

tion by general and local depletion, to complete the cure you must have recourse to another plan of treatment. The measures to which I have just alluded are, it is true, indispensable, in the great majority of cases. Nevertheless alone, without the assistance of local applications, they would not restore the inflamed tissues to their normal state. Before I speak of topical remedies, however, I must say a few words respecting a special mode of treatment which has been proposed by some practitioners.

Reasoning on the supposed gonorrhœal nature of the malady, they consider it advisable to recall the discharge from the urethra; this is to be effected by various means. Some propose introducing into the urinary canal a bougie impregnated with gonorrhœal matter proceeding from another individual, or from the inflamed eye. Others assert that the presence alone of a bougie is sufficient to give rise to the discharge. There are, it is true, facts which tend to prove that on producing inflammation of the urethra, the intensity of the ocular inflammation has been diminished; but I must observe to you, that this plan of treatment can only be indicated when the gonorrhœal conjunctivitis is metastatic, that is, when it has occurred immediately after the decrease or the suppression of the urethral discharge. Again, prudence will scarcely, in my opinion, allow us to attack a disease so rapid in its progress by a treatment the action of which is comparatively slow.

The same theoretical views have induced some surgeons to employ the internal remedies which are used in gonorrhœa. The objections I have just made may be repeated here. The action of these medicinal agents is too slow for it to be prudent to employ them in the first or acute period of the disease; when the inflammation has in a great measure subsided, and then only, advantage may be derived from this method of treatment. In cases of subacute inflammation, I have myself found cubebs and the balsam of capivi, given in large doses, extremely beneficial.

The treatment I shall definitively recommend to you may be resumed in a few words. Copious bleeding should be resorted to during the first period of the disease, until the inflammatory symptoms are entirely subdued. Astringent collyria may then be applied to the inflamed parts, and a revulsive action set up in the intestinal canal. When the disease is to be attributed to metastasis, one of the methods I have described may be employed, with the view of recalling the urethral discharge.

By thus uniting general and local treat-

ment, I have succeeded in all the cases I have treated, when the cornea was not already affected at the time they came under my care.

When the inflammatory symptoms have abated, the disease may yet prove more or less rebellious to the remedies you employ; you need not, however, entertain any fear respecting the sight of the patient. In many cases granulations of variable size remain on the conjunctiva, and resist the action of all astringent collyria, one of which seem sufficiently energetic to destroy them. Recourse must then be had to cauterization with the solid nitrate of silver; and should it likewise fail, to the excision of the granulated portion of the conjunctiva. I would, however, advise you only to adopt this last plan of treatment when all other means have failed, as excision of a portion of the conjunctiva is sometimes attended with very unfortunate results.

The Egyptian Purulent Conjunctivitis.

On comparing the published descriptions of the epidemics of purulent ophthalmia which have been observed in various countries, I have found so much analogy between them and the Egyptian form of purulent inflammation, that I do not hesitate to describe them under the same head. If these descriptions are faithful, as, indeed, I am inclined to believe they are, the morbid symptoms are nearly always the same, as also the treatment. I cannot, therefore, see any really valid reason for treating separately of each of these affections. It appears, however, that the Belgian epidemic presents some symptoms which have not been noticed in other epidemics of the same nature. Thus it has been asserted that granulations are to be met with on the conjunctiva, and that these granulations have not been observed before in purulent conjunctivitis. Is it, however, certain that granulations did not exist in the Egyptian ophthalmia? Is it certain that they were not then overlooked by our surgeons, who do not, it is true, mention their presence? This is a question which deserves to be investigated; I myself am inclined to think that they exist in all cases of purulent conjunctivitis. We will now examine what are the characters of this disease, and you will then, I hope, have a clear idea of the various purulent forms of inflammation.

The contagious or non-contagious nature of the Egyptian purulent form of inflammation has been the subject of much discussion. Most persons now agree in considering it to be contagious; and this opinion, which is substantiated by numerous well-authenticated facts, has not been

shaken by the experiments performed on himself by Mackely, and quoted by Mackenzie in his treatise on Diseases of the Eye, page 184.

The etiology of this affection is extremely obscure. In Egypt, the reflection from the sand, the nature of the climate, &c. are quite sufficient to account for its presence. When, however, we find it appearing on the transports between Leghorn and Egypt—when we see it exercising its ravages in other countries, in England, in Belgium, and that with the same violence as in the country where it was first observed—we can no longer attribute its existence to these causes alone. If we admit the contagious nature of the malady, we can easily account for its attacking troops on their passage to Egypt; it is not, however, equally easy to prove that the epidemics, to which I have alluded, have been imported from that country, as some writers have asserted.

Other reasons have been given to account for the appearance of the disease. Thus the Belgian epidemic is attributed by M. Vleminckx to the soldiers wearing *schakos*, which are too heavy, to their washing their heads with cold water, and to the collar, which forms part of their uniform, being too tight, and consequently compressing the neck. These causes are not, most certainly, worthy of the attention they have met with. How is it, indeed, that the malady has only existed in the Belgian army for the last six or seven years, if its existence is to be explained by causes which have always been in action? M. Vanhonsbrooch is not much more rational in his attempt to explain the origin of the epidemic, when he attributes it to the irritating action on the eyes of the subcarbonate of lime which is used by the soldiers in cleaning their buffletery. Would it not be better to acknowledge at once, that in this instance, as in many others, we are unacquainted with the primary cause of the disease?

This form of purulent inflammation is similar, in many respects, to gonorrhœal conjunctivitis. It presents the same rapidity in the appearance of the symptoms, the same intensity, and is followed by nearly the same consequences. In the disease we are examining, however, the inflammation generally attacks both eyes at once, although, in some instances, one of them is affected some time before the other. In gonorrhœal conjunctivitis, on the contrary, generally speaking, one eye only is the seat of disease. When the progress of the malady is not too rapid to allow us to observe the various symptoms, we find they manifest themselves in the following order:—

The patient complains at first of intense itching in the eye; this symptom generally makes its appearance in the evening. The itching is soon followed by the peculiar sensation of which we have so often spoken—that of extraneous bodies placed between the eye and the mucous surface of the palpebræ. The conjunctiva at the same time becomes inflamed; its tissue, as also the cellular lamellæ on the internal surface, are gorged with fluid, and tumefied. The vascularization of the conjunctiva is from the commencement extremely well defined; the size of the caruncula lacrymalis is much increased. The parts thus tumefied are soft, rather elastic, and bleed easily. This is not, however, an unfavourable circumstance, as the slight hæmorrhage which is thus produced tends to diminish the swelling. Four-and-twenty hours after the appearance of the above symptoms, a slightly viscid and opaque mucus is secreted, and the inflammation then extends to the entire internal surface of the palpebræ. This mucus soon assumes a thick, yellowish, purulent appearance. The eyelids become very much tumefied, especially the upper eyelid, which often covers nearly entirely the lower one. When they are separated, a considerable quantity of the purulent secretion escapes from the eye, and, flowing over the face, excoriates the skin wherever it passes. The ocular conjunctiva may become of a fungous nature, and be swollen to such an extent as to separate the free edges of the eyelids, and protrude from between them. When this is the case, the conjunctiva being irritated by the contact of the air, the secretion is extremely abundant. It may, indeed, according to Dr. Vetch, amount to several ounces daily.

Such are the principal symptoms of the Egyptian purulent conjunctivitis. Unfortunately this disease terminates, in most cases, by the extension of the inflammation to the cornea, and the total loss of the eye. As we have examined this complication, when speaking of gonorrhœal conjunctivitis, I shall refer you to what I then said on the subject.

Besides the local symptoms which I have just described, there are also general symptoms, which must not be omitted. The pulse is small, sometimes hard; generally, however, it remains soft. The skin is hot; the appetite nearly always remains good. Should the disease continue for several months, the patient generally falls a victim to diarrhœa, dysentery, and marasmus.

I shall not enter into any details respecting the treatment of this disease. It is in every respect similar to that of gonorrhœal conjunctivitis, with which we

are already acquainted; with the exception, however, of those indications which are founded on the gonorrhœal nature of the disease.

CLINICAL REPORTS

OF

DIFFICULT CASES IN MIDWIFERY.

By ROBERT LEE, M.D., F.R.S.

Physician to the British Lying-in Hospital, and
Lecturer on Midwifery at St. George's
Hospital.

[Continued from p. 717.]

THIRD REPORT.

Cases of retained Placenta.

THE following report contains the histories of seven fatal cases of retained placenta, and thirteen in which more or less difficulty and danger were produced from portions of the placenta, or the entire mass, being left within the uterus beyond the usual period. The best method of preventing the occurrence of similar accidents, is to apply the binder immediately after the birth of the child; to make pressure with the hand over the fundus uteri at short intervals; and slight traction upon the cord downward and backward, in the direction of the hollow of the sacrum. By these means the upper part of the uterus usually goes on contracting till the placenta is detached and pressed down through the os uteri into the vagina. In all cases, whatever the cause of the retention may be, if the placenta at the end of an hour is not detached from the uterus and expelled, it should be withdrawn artificially, by passing the hand along the cord to its insertion, expanding the fingers and grasping the whole mass, or as much as can be seized and brought away. The difficulty of removing portions of placenta adhering with more than the natural firmness to the uterus is only increased by delay.

CASE XLVIII.—A woman who was delivered in the British Lying-in Hospital, in the month of March, 1829, was seized soon after with pain in the region of the uterus, quickness of the pulse, and respiration; and the skin assumed a peculiar dusky hue, and severe pains were experienced in some of the principal joints of the body. She died on the 26th day after her confine-

ment; and on inspecting the body, with Dr. H. Davies and Mr. Armstrong, we found a small portion of placenta adhering to the uterus, near the fundus, and the veins of the part distended with pus. The cartilages of the right knee-joint, which had become tender and swollen for some time before death, were seen ulcerated.

CASE XLIX.—A patient of a public institution was delivered on the 30th of August, 1831, and a large portion of the placenta was left within the uterus. I saw her on the third day after delivery, when there was foetid dark-coloured discharge from the vagina. The pulse was feeble, the countenance haggard, and there was constant vomiting and delirium. The orifice of the uterus was so firmly contracted, that two fingers could not be introduced within it, and the placenta felt. Thirty grains of ergot of rye were administered, but it only increased the vomiting and general distress. Another dose was given soon after, but without any good effect; and, on the evening of the fifth day after delivery, death took place, with all the symptoms usually observed when a putrid animal poison is introduced into the system. I inspected the body, and found a large portion of the placenta and membranes within the uterus in a black putrid state, and emitting a most offensive odour. All the coats and vessels of the uterus were apparently healthy. The placenta did not appear to adhere with more than the usual firmness to the inner surface of the uterus.

As there did not exist any morbid adhesion of the placenta to the uterus in this case, no portion of it would probably have been left within the uterus had the hand been introduced into its cavity within an hour after the delivery of the child, and before the cervix had contracted.

CASE L.—On the 18th June, 1834, with Dr. H. Davies, I examined the body of a woman who died eighteen days after delivery, from a portion of the placenta being retained and undergoing decomposition within the uterus. The orifice of the uterus contracted so much after the birth of the child, that the medical attendant found it impossi-

ble to remove the whole placenta. For five days she appeared to recover favourably; then the pulse rose to 120, and there were rigors, loaded tongue, sickness at stomach, and diarrhoea, with slight occasional cough and hurried breathing. She became more and more feeble, and died without any suspicion being entertained of the existence of disease of the lungs.

I removed the uterus and vagina, and, on laying open the latter, a portion of placenta in a sloughy state, like a piece of putrid flesh, was seen hanging through the os uteri, and filling the whole of the upper part of the vagina. The uterus was then laid open, and the placenta was found filling its cavity and loosely adherent to the fundus by the decidua. There was no morbid adhesion of the placenta to the uterus, as they were separated without any force. The portion of placenta within the uterus had undergone a slight degree of decomposition compared to that which hung through the orifice. There was a great quantity of pus in the veins of the uterus, and the lining membrane of the organ and muscular coat, where the placenta adhered, were soft, and as black as ink. The pleura on the right side was extensively inflamed. The right inferior lobe was hepatized, and there were several deposits of pus in the substance of this portion of the lungs. At one point, the pleura appeared to be destroyed by sloughing or gangrene.

CASE LI.—On the 23d October, 1835, the body of a woman was brought into the St. Marylebone Infirmary, who had died from retention of a portion of the placenta, which adhered with unusual firmness to the inner surface of the uterus. She was delivered on the 11th October, and a most alarming hæmorrhage took place soon after the birth of the child. Several unsuccessful attempts were made by the medical practitioner to extract the placenta, and it was uncertain at the time whether the whole had been removed from the uterus. A serious affection of the brain took place, and she died about ten days after delivery. The late Dr. Sims examined the body, and found the superior longitudinal sinus of the brain filled throughout a great part of its extent by a solid coagulum of fibrin, and all the veins on the right side, which

empty themselves into it, distended with fibrin. The veins on the left side were in the same condition, but to a less extent.

There was no trace of inflammation about the uterus; all its vessels were healthy.

On laying open its cavity, there was seen adhering to its fundus a portion of placenta, as large as a middle-sized orange. On examining more carefully the connection between the uterus and placenta, it appeared that they were united more firmly than natural at one part, which did not exceed an inch in diameter. So firm was the union in this case, that the substance of the placenta would have been more easily torn than the adhesion between it and the uterus. The portion of placenta thus adhering to the uterus, was harder than natural, and of a yellow colour.

CASE LII. — On the 14th of August, 1838, Dr. Hall, of Kennington, shewed me a uterus, with a portion of placenta, about two inches in diameter, firmly adhering to the upper part of its body. The placenta and uterus were so closely joined together that they seemed one substance; it was almost impossible to see the line running between them. Yet the placenta could be separated from the inner membrane of the uterus without much force being applied, or any laceration produced. In this instance the uterus might have been suspended by the placenta, without a separation between them having been produced.

The patient from whom this specimen of adherent placenta was removed, resided near Denmark Hill, and was attended in her labour by Mr. Cooke. The cervix uteri contracted so firmly soon after the expulsion of the head of the child, that Mr. Cooke was obliged to employ much force before he could extract the shoulders. No hæmorrhage followed the birth of the child. The os uteri closed so completely afterwards in a few minutes, that all attempts to remove the placenta were unsuccessful, and the umbilical cord was lacerated. Dr. Hall saw the patient some hours after, and as he could not succeed in getting more than one finger into the uterus, he gave up all attempts to extract it, and it remained for several days in the uterus without any un-

favourable symptoms taking place. A fætid discharge then began to escape from the vagina, and symptoms of peritonitis supervened. Seven or eight days after delivery another attempt was made to extract the placenta, and a portion of it was removed. A hook was introduced into the uterus, but it brought away nothing. The patient at last died with the usual symptoms of peritonitis.

CASE LIII. — On the 20th October, 1832, I was called to a patient, in a public institution, who had been delivered about two hours before, of a living child, at the full period, by the natural efforts. The placenta not being expelled in the usual time after, and hæmorrhage occurring, the hand was introduced into the uterus, and the cord was torn without any part of the placenta being brought away. The difficulty was believed to arise from hour-glass contraction of the uterus, and a large dose of laudanum was given. I found a portion of the placenta in the vagina, and the neck of the uterus firmly contracted around the remainder. Two fingers were gently insinuated through the os uteri, and the whole placenta was readily extracted. No hæmorrhage followed.

On the ninth day after delivery the pulse was very quick and feeble. The region of the uterus was slightly tender on pressure, and there was dyspnoea, with pain in the left side of the chest. The symptoms gradually increased, and she died a few days after. The upper lobe of the right lung was covered with a thick layer of false membrane, and hepatized; and there was a considerable quantity of fluid effused into both sacs of the pleura.

There was a considerable curvature in the upper part of the spine.

CASE LIV. — On the 4th May, 1839, a surgeon requested me to see a patient who had been delivered the day before, after a lingering labour, of a dead child. The funis was broken with the slightest touch, and the placenta could not be removed. There had been no hæmorrhage, but a great disposition to syncope. When I saw the patient, twenty-two hours after, the pulse was rapid, the discharge from the vagina was very offensive, and the neck of the uterus contracted, but not firmly. One

finger was passed after another, until the whole hand entered the cavity of the uterus. The placenta was felt adhering throughout to the uterus, and was separated with difficulty from it. Even after the mass had been grasped by the hand and detached, a small portion still adhered so firmly that it could not be removed, and was left behind. The hand was re-introduced, and as much of it taken away as was possible. No hæmorrhage, but great faintness followed. For a time she appeared to recover, but the pulse continued unusually rapid and feeble, and towards the end of May the lower extremities swelled; she became delirious, and had the usual symptoms of inflammation of the veins of the uterus.

She died, and all the femoral and pelvic veins were found plugged up with coagula. The uterus was twice its natural size and flabby. No portion of placenta was found within the uterus.

CASE LV.—On the 7th July, 1838, I was requested by a medical friend to see a lady who had been delivered of her sixteenth child on the 28th June. He had attended this lady in seven labours, which were all natural. On this occasion hæmorrhage took place soon after the expulsion of the child; and though the orifice of the uterus was not contracted, the placenta could not be brought away without considerable difficulty after the introduction of the hand, and had a lacerated appearance when extracted, and looked as if a portion had been left within the uterus.

On July 7th, the pulse was 120; great giddiness, and beating of the temples. The tongue was not much loaded, and the appetite continued, and there was no tenderness of the hypogastrium. There was a most offensive dark-coloured discharge from the vagina. The os uteri so open that a finger could be introduced, and a portion of placenta felt within, but it was impossible to take it away with the finger, and we did not consider it safe to employ any other instrument for the purpose.

Injectations of tepid water, with a weak solution of chloride of soda, were frequently employed, and occasional cathartics, with quinine, wine, and nourishing diet. This plan was continued for several days, when the retained por-

tion of placenta was expelled, and she speedily recovered.

CASE LVI.—On Saturday, 28th September, 1838, I was called to a patient, ætat. 23, residing near the Edgware Road, who had been delivered of her second child on the preceding Thursday evening, and the greater part of the placenta had been left within the uterus. Repeated attempts had been made by the medical attendant to extract it, but they were unsuccessful. A dark-coloured offensive discharge was flowing from the vagina. The pulse was rapid; tongue loaded; nausea, and great headache, and restlessness. I found a portion of the placenta protruding through the os uteri, and had little difficulty in drawing the whole of it into the vagina with the fore and middle fingers of the right hand. Tepid injections of milk and water were recommended.

30th.—Discharge diminished in quantity, and without the peculiarly offensive odour. Pulse less frequent; nausea, and inquietude, and headache gone. Repeated doses of the ergot of rye had been given without any effect upon the uterus.

CASE LVII.—28th July, 1838. At ten o'clock at night I was called by a surgeon to extract a placenta which had been retained eighteen hours after the birth of the child. The cord was torn off in attempting to remove the placenta. No hæmorrhage had taken place. I found the cervix uteri so closely contracted, that one finger only could at first be introduced, and it appeared very improbable that the hand could ever be passed into the cavity so as to grasp the placenta. By cautiously pressing one finger after another through the orifice, the resistance was, in the course of an hour, so much overcome, that I could feel a considerable portion of the placenta, though the whole hand had not passed through the cervix. By pressing backward with the fingers the portion of placenta within reach, I at last succeeded in removing the whole mass. No bad symptom followed. It was the first labour.

CASE LVIII.—On the 4th January, 1828, I was called to a case near Covent Garden, in which the placenta had not been expelled in the usual period after the birth of the child. Hæmorrhage taking place, the medical attendant passed

up his hand into the uterus to extract it, but found it impossible to reach the fundus uteri in consequence of the upper part of the cervix being firmly contracted. He pulled with some force upon the funis, and it soon broke off, near its insertion into the placenta. He then administered a dose of laudanum, and left an assistant with the patient to make firm pressure over the fundus uteri. I saw the patient soon after this; and the neck of the uterus being relaxed, I experienced no difficulty in removing it, as it was lying detached in the lower part of the uterus.

CASE LIX.—On the 22d September, 1828, I was called by the assistant-matron of the British Lying-in Hospital to a patient near Drury Lane, to extract the placenta, which had been retained four hours after the expulsion of the child. The cord and a portion of the placenta had come away in the efforts which were made to withdraw it. I found the vagina filled with clots of blood, and the neck of the uterus closely contracted. I had some difficulty in passing two fingers into the cavity of the uterus and gradually pressing the placenta down into the vagina. No hæmorrhage followed, and the recovery was favourable.

The whole hand could not possibly have been passed into the uterus, nor was it necessary.

CASE LX.—On the 4th January, 1828, I was called to a patient of the Westminster General Dispensary, residing in Whitcomb Street, with retention of the placenta, who had been delivered of a dead child three hours before, at the $7\frac{1}{2}$ month. The vagina and cervix uteri were very rigid and undilatable, but the resistance they gave was gradually overcome, so that I succeeded in introducing two fingers and the thumb of the right hand through the cervix, and with these extracted the placenta, which was lying loose in the cavity of the uterus. The whole hand could not have been passed through the cervix uteri in this case. No bad symptom followed.

CASE LXI.—On the 22d April, 1835, a woman who was delivered at the full period, in the lying-in ward of the St. Marylebone Infirmary, had retention of the placenta from the cervix uteri contracting very quickly and firmly after

the expulsion of the child. The cord was torn away at its insertion into the placenta. Although not more than four hours had elapsed from the birth of the child when I saw the patient, the orifice of the uterus was so firmly closed that I found it impossible to pass the whole hand, and I succeeded after a time in extracting the mass with two fingers. She recovered in the most favourable manner.

CASE LXII.—On the 26th July, 1835, I was called to a case in Charlotte Street, Portland Place, where the cord had been torn off, and the whole placenta had been left within the uterus from four o'clock in the morning till three in the afternoon. A profuse hæmorrhage had occurred. Frequent attempts had been made to remove the placenta, but they were unsuccessful. I passed the whole hand in a conical form slowly through the os uteri, and soon grasped the mass of the placenta and withdrew it.

Three drachms of the ergot of rye had been given to this patient during her labour.

CASE LXIII.—On the 22d August, 1835, I was called to another case of hæmorrhage and retained placenta, in Hedden Street, where the cord had been torn away. As a short period had elapsed in this case from the birth of the child, no difficulty was experienced in passing the hand and extracting the whole placenta. The flooding immediately ceased, and no bad symptom followed.

CASE LXIV.—Mrs. C—, residing at 3, Stacy Street, was delivered at nine A.M., on the 4th March, 1829, of a child at the $6\frac{1}{2}$ month. The umbilical cord being soft, was broken by the midwife in attempting to draw out the placenta. I saw the patient four hours after, when the parts had become so contracted that I could not introduce the hand without employing more force than was proper. The placenta was therefore obliged to be left within the uterus. The following morning a brisk cathartic was exhibited, and in the evening the whole placenta came away without any help whatever. No bad symptoms followed.

CASE LXV.—At ten A.M., August 13th, 1836, I was called to a married woman, residing in Dean Street, who

had been delivered of a dead child, at the full period, thirty-four hours before. The medical attendant had given several doses of the ergot of rye, and had made repeated efforts to extract the placenta, but without success. I found the os uteri closed, but not firmly. The discharge from the vagina was extremely fetid, which made me determine, if possible, to extract the placenta. The orifice of the uterus gradually yielded to the introduction of three fingers, with which I laid hold of the mass and withdrew it, without passing the whole hand within the uterus. The recovery was very favourable.

CASE LXVI.—On the 29th August, 1835, I was requested by Mr. Johnson, of Mortimer Street, to see a lady with retained placenta, who had expelled a dead fœtus, of six months, twenty-four hours before. Two drachms of the ergot of rye had been given to produce uterine contractions, but they had had no effect. I found the orifice of the uterus open, the margin thin, and the point of the finger readily touched a portion of hard placenta within the cavity. Two fingers were introduced, and the placenta seized; but it could not be made to descend into the vagina, and I was forced to leave it in the uterus. A cathartic draught was administered the following morning, which produced vomiting and purging, and during its operation the whole placenta was expelled in a yellow indurated state. No bad symptoms followed.

CASE LXVIII.—*Retention of the Placenta by a peculiar band or septum in the vagina.*

Oct. 10th, 1838.—Mrs. B—, æt. 20, No. 20, Great Chapel Street, was delivered of a dead child, at the end of the seventh month, three hours before I saw her. The placenta was soon after expelled from the uterus into the vagina; but though the cord was pulled forward as strongly as its strength would admit, by Mr. Babington, who was in attendance, the placenta could not make its escape from the orifice of the vagina. The difficulty was found to depend on the presence of a broad smooth band or septum, passing across the vagina, from the anterior to the posterior wall. One half of the placenta was pressed down on the left side of this band, out of the vagina; and the

other half, with the umbilical cord, on the right side. With a pair of scissors I divided the placenta into two portions, on the left side of the band, and it immediately after came away; and the septum, which had been greatly stretched and drawn forward, went up into the vagina.

On the 15th, I examined the vagina carefully with Mr. Babington, and we found it, near the orifice, divided into two canals, by a broad smooth band passing from the anterior to the posterior surface. It was perfectly smooth; and the parts of the vagina into which it was inserted were neither hard nor irregular, as they are found to be where cicatrices are formed after inflammation and sloughing of the vagina.

I considered this as resulting from an original malformation, and probably an instance of imperfectly formed double vagina.

She had been previously delivered twice without any difficulty; and since her last confinement there had been no inflammation of the parts. She stated, that from the first she had invariably experienced great pain during intercourse.

CLINICAL OBSERVATIONS

ON
THE USE OF THE AIR-DOUCHE IN THE
DIAGNOSIS AND TREATMENT
OF
DISEASES OF THE EAR.

By T. WHARTON JONES, Esq.

[For the London Medical Gazette.]

No. III.

CASE III.—*Chronic Inflammation of the Lining Membrane of the Tympanic Cavities, with accumulation of Mucus—No obstruction of the Eustachian tubes—Auditory passages natural.*

27th JAN. 1839.—The subject of this case was sent by Mr. Quain, of University College, with the following note:—

“My dear Sir,—Mr. E. F., the bearer of this, has been more or less deaf for a considerable time, and, from a short examination, I am inclined to think the Eustachian tubes at fault.

I shall be much obliged if you will be so good as to examine him and give

me your opinion. The tendency of my own opinion is, that the local means—catheterism, &c.—may be beneficial; yet, judging from his appearance, the diathesis, so to say, it is probable they will not alone be of any great utility.

* * *

I am, &c.

R. QUAIN."

Mr. E. F. is 19 years of age; had scarlet fever when he was six; after that the deafness came on. Is subject to attacks of ear-ache. His sister was born quite deaf, but after having scarlet fever she *acquired* hearing!

Skin coarse, with the sebaceous follicles of the face much developed; habitually costive. The climate in which he usually resides is very moist.

In September and October 1836, was treated in Paris, by M. Deleau, who applied the air-douche about fourteen times, but only with temporary benefit. Took iodine last summer, according to the prescription of Dr. Elliotson. During the last autumn, hearing improved of itself considerably, but has been diminishing since he came to London. It is now—left ear, 3 inches; right ear, 5 inches.

Left membrana tympani and handle of the malleus appear natural; the right also. The skin of the auditory passages slightly red and tender. The secretion of wax natural.

Applied the air-douche to both ears, as an exploratory means. On the left side the air entered freely, but with great gurgling; on the right side not so freely, and with less gurgling.

After the air-douche, the hearing distance of the left ear was nine inches, of the right ear seven inches. The hearing was further raised on both sides to one foot, by making forced expirations with the nose and mouth closed.

Tuesday, 29th Jan.—In consultation with Mr. Quain, and Mr. Gasquet of Burton Crescent. Hearing distance to day—on the left side, eight inches; on the right side, one foot.

After the application of the air-douche, the hearing distance on the left side was raised to one foot four inches, on the right side to one foot and a quarter.

To continue the treatment with the air-douche, and endeavour to improve the state of the constitution by attention to diet and regimen. To resume the use of the iodine.

Wednesday, 30th.—Left ear, one foot

one inch; right ear, one foot and three quarters. Some pain in the right ear last night, and still some tenderness.

Applied the air-douche to the left ear only: the air entered freely.

After the air-douche the hearing distance of the left ear was one foot and three quarters; that of the right ear, although not treated, was found increased also—from one foot and three quarters to two feet four inches and a half.

After some minutes, and after having forced air into the tympanum by attempting to expire with the nose and mouth closed, the hearing distance on the left side was raised to three feet, and on the right side to three feet and a quarter.

Thursday, 31st.—Left ear, from two feet to two feet and a half; right ear, three feet. After forcing air into the middle ear, by attempting to expire forcibly with the nose and mouth closed, the hearing distance of the left ear rose to three feet and a half, and that of the right ear fell to two feet and a half.

Applied the air-douche to the right side only. The hearing distance was diminished immediately after, but in the course of a few minutes it was found risen again to three feet.

Tuesday, 5th Feb.—Right ear, two feet and a half, at first trial, but after forcing air into the Eustachian tube, by attempting to expire with the nose and mouth closed, the hearing distance was found raised to four feet.

Left ear, one foot ten inches at first trial; three feet one inch and a half after the forced expiration. Some cold in the head, and tenderness about the external auditory passages. No air-douche today.

To apply leeches behind the ears.

Tuesday, 12th.—Leeches have not been applied. Left ear, one foot four inches; right ear, two feet. After a forced expiration, left ear, two feet five inches; right ear, three feet three inches.

Friday, 15th.—Ear-ache has shifted from the right to the left side. Has had some leeches applied behind the left ear.

To repeat the leeches.

Monday, 18th.—Has had ten leeches applied behind the left ear. Still some pain and tenderness of the left ear.

Tuesday, 19th.—No pain, but still

some tenderness. Fomented the ear last night with warm water.

To rub in tartar emetic ointment behind and below the left ear.

Thursday, 21st.—Left ear, one foot; right ear, one foot and three quarters. Still some tenderness of the left ear. Pain is excited when air is forced into the tympanum by attempting to expire with the nose and mouth closed.

Tuesday, 26th.—Right ear, two feet three inches; left ear, two feet one inch. No recurrence of ear-ache.

Wednesday, 27th.—Again some pain in the left ear. Hearing not so good today. Nasal catarrh continues.

Friday, 1st March.—Hearing very dull to day; no ear-ache. Air-douche applied to both sides. The air entered freely, but produced great gurgling. No pain during the application of the air-douche; but the Schneiderian membrane is so tumid that a very small catheter only can be passed along the nostrils without causing pain.

The cold is now going off; the mucus is therefore increased in quantity and becoming thicker, hence the greater degree of deafness.

After the air-douche, the hearing distance on the right side was one foot eleven inches, on the left side one foot six inches.

Saturday, 2d.—Right ear, one foot eleven inches; left ear, one foot nine inches and a half.

Right ear treated. The hearing duller immediately after the application of the air-douche.

Monday, 4th.—Right ear, one foot nine inches; left ear, one foot two inches and a half.

Left ear treated. Some obstruction to the free entrance of the air at first, but that was readily overcome, and then the air entered freely.

After the air-douche, the hearing distance of both ears was about two feet and a half.

Wednesday, 6th.—Right ear, two feet eleven inches; left ear, two feet five inches.

Right ear treated.

Friday, 8th.—Does not hear so well to day, but does not complain of ear-ache.

Monday, 11th.—Right ear, one foot three inches; left ear, one foot.

Applied the air-douche to both sides. After the air-douche, the hearing distance of the right ear was found raised

to two feet and a half, of the left ear to one foot eight inches.

Tuesday, 12th.—Right ear, two feet and a half; left ear, two feet.

Left ear treated. During the injection of the air, felt a sudden pain in the situation of the mastoid cells.

Wednesday, 20th.—Right ear, one foot four inches; left ear, only seven inches.

Air-douche applied to the left ear—great gurgling.

Thursday, 21st.—Right ear, one foot; left ear, one foot nine inches.

Air-douche applied to the left ear today again, the right nostril being too tender to allow the catheter to pass. During the application of the air-douche felt a sudden pain, as on Tuesday, the 12th.

After the air-douche, the vapour of acetic ether, diffused in air, was allowed to flow gently into the tympanum.

After this treatment by the air-douche and ethereal vapours, the hearing distance of the left ear was two feet and a half.

Friday, 22d.—Hears well to day, but has not time to be treated.

Monday, 25th.—Right ear, four feet one inch; left ear two feet seven inches.

Right nostril still too tender to admit of the introduction of the catheter.

Left ear treated by the air-douche and ethereal vapours. After this treatment the hearing distance was three feet four inches.

Tuesday, 26th.—Right ear, three feet seven inches. Left ear, one foot eight inches.

Left nostril so tender as not to allow of catheterism to day. The tonsils and uvula red and swollen. The mucous membrane of the nose also red and swollen.

To apply a leech within each nostril and to take a dose of jalap and rhubarb.

Wednesday, 3d April.—Right ear, one foot nine inches. Left ear, two feet.

Left ear treated.

Monday, 8th.—Right ear, two feet three inches. Left ear, three feet six inches.

Right ear treated. After the treatment heard the watch at the distance of six feet.

Wednesday, 10th.—Right ear seven feet three inches. Left ear, three feet four inches. Left nostril too sensitive to allow the passage of the catheter.

Right ear treated by the air-douche and the ethereal vapours.

Friday, 12th.—Right ear, seven feet and a half. Left ear, one foot and a quarter.

Left ear treated. A pricking sensation felt in the ear, from the ethereal vapours.

Has heard, yesterday and to day occasionally, sounds like the beating of a hammer.

Monday, 15th.—Right ear, seven feet six inches. Left ear, 4 feet ten inches.

Has not heard the beating since. Right ear treated.

Friday, 10th of May.—Has been in the country since the last report.

Right ear, 9 feet 2 inches. Left ear, 7 feet, 5 inches.

The hearing having improved so much of itself while in the country, I thought it advisable not to pursue the local treatment any further, but to wait and see what the powers of nature would do.

I have seen this patient twice since, when he complained that his hearing was becoming dull again.

REMARKS.—The result of this case has in some degree justified the anticipation of Mr. Quain. The scrofulous diathesis, with an unhealthy state of the tegumentary system in general, evident in this patient, was a great obstacle to permanent improvement. As in Case II, the disease of the ear was called into existence by an exanthema. It appeared to be confined to the middle ear, the mucous membrane of which was in a state of chronic catarrhal inflammation, alternately calming down and becoming aggravated. All that the air-douche appeared to do when applied by M. Delcau, as well as when I applied it, was to effect the dispersion of the accumulated mucus, and so improve the hearing for a time. The affected membrane, however, not being at the same time restored to a healthy action, the mucus was always re-accumulating; hence the constant tendency to relapse, and the comparatively small progress made by the treatment above recorded, until the membrane lining the tympanum was directly acted on by the vapours of acetic ether. After this, the improvement was more striking than before, and probably, if it had been persevered in, decided and permanent advantage would have been ultimately gained.

A point worthy of notice was the improvement in the hearing effected by forcible expirations with the nose and mouth closed. It has been long known, that by making a forced expiration with the nose and mouth closed, deafness is in some cases considerably relieved. With such facts, Delcau remarks, it is surprising that blowing air artificially into the tympanum in deafness was not thought of sooner. Archibald Cleland spoke of blowing air into the tympanum a hundred years ago, but his was a mere suggestion and I do not find that he meant the air should be sent in by any other means than by the operator blowing with his mouth through a flexible tube (the ureter of a large animal) attached to the catheter introduced into the Eustachian passage*. When the hearing is improved by merely forcing the breath through the Eustachian tubes into the tympanic cavities, it is in general a sign promising farther advantage from the air-douche. In recent cases of muculent obstruction of the tympanic cavities, without obstruction of the Eustachian tubes, very considerable improvement may in this way be obtained, as in the following:—

CASE IV. Friday, 26th April, 1839.—Master G. H. aged about 14. Hears the watch at the distance of nine inches on either side. The deafness has been occasional in occurrence for some time, and varied in degree. Has had sore throat lately, but is now better. The tonsils are somewhat enlarged, and the uvula long. A rather too copious secretion of wax, which appears at the very entrance of the auditory passages, though it does not stop them up.

On making the patient expire forcibly with the nose and mouth closed, the hearing distance was raised on the right side to four feet nine inches, and on the left side to five feet seven inches.

If the obstruction be of some standing, such an event does not so readily take place, but that more or less improvement

* Wathen's cases by aqueous injections are well known. Bussan (an absque membrane tympani apertura topica injici in concham possint. Paris, 1784. Haller, Collect. Diss. Chir. t. 2, p. 286) proposed to effect the discharge of fluids effused into the cavity of the tympanum by forcing vapours into the Eustachian tube. His proceeding was to fill the mouth with the vapours, close the lips and nose, and then make a long forced expiration, by which the vapour is driven through the Eustachian tubes into the tympanum.

may be obtained by it is shown in Case III. and Dr. Sims (Memoirs of the Medical Society of London) mentions a case in which forcing the breath into the Eustachian tube, with the nose and mouth closed, proved successful after the deafness had continued for more than a year.

The subject of Case III. took iodine, though not with any marked advantage. This medicine was first employed in deafness by Dr. Manson, of Nottingham, who however gave no particular diagnosis for the cases in which it proved useful. But as he also succeeded in curing chronic dacryocystitis by the same remedy, I am inclined to think that in Dr. M.'s cases the deafness was owing to affection of the mucous membrane of the middle ear, especially as I have shown that the membrane lining the tympanum and Eustachian tube, and that lining the lacrymal sac and nasal duct, strongly resemble each other, both in their structure and in their diseases. It is in children, however, and at the commencement of the complaint, that iodine has most influence in diseases of the ear.

In the course of Case III. it is several times mentioned that the hearing was diminished immediately after the air-douche: Dr. Kramer considers this a positive sign of nervous deafness. Whether it be so or not, the state of the middle ear in this patient was sufficient, in my opinion, to account for all his deafness, and the improvement gained from the application of the ethereal vapours bore too strong an analogy to the speedy and marked improvement, derived from a stimulating application in chronic catarrhal ophthalmia, to induce me to look deeper for a part which might be supposed to be that at fault, and therefore the one benefited by the remedy.

REMARKS ON

THE PHARMACOPŒIA OF THE ROYAL COLLEGE OF PHYSICIANS, EDINBURGH, 1839.

By RICHARD PHILLIPS, F.R.S. &c.

[For the London Medical Gazette.]

AQUA AMMONIÆ. *Diluted aqueous solution of ammonia.* "Density 960; nitric acid occasions no effervescence."

Whether nitric acid occasions effervescence or not, may depend entirely on the strength of the acid employed; for if it be not diluted, the effervescence of ammoniacal gas is extremely violent, owing to the heat occasioned by chemical action. Carbonic acid is, I presume, the admixture that the nitric acid is intended to detect; lime water, or a solution of chloride of calcium, are much better tests of the presence of this acid than nitric acid, even when properly diluted.

AQUA AMMONIÆ FORTIOR. *Concentrated aqueous solution of ammonia.* "Density 880: one fluidounce with three of water makes Aqua Ammoniacæ," meaning, of the density of 960, as above directed. This statement, however, is erroneous, for when a solution of ammonia is mixed with water, the density of the mixture is nearly the mean; so that one volume of solution of ammonia, of density 880, and three volumes of water, will have a density of 970 instead of 960: two, instead of three, fluidounces of water should have been directed to be added to one fluidounce of the stronger solution of ammonia.

ARGENTI NITRAS. *Nitrate of silver.* "Soluble in distilled water, with the exception of a very scanty black powder," which, however, does not occur when the salt has been properly prepared from pure silver.

BARYTÆ CARBONAS. *Carbonate of baryta.* "One hundred grains dissolved in an excess of nitric acid are not entirely precipitated with sixty-one grains of sulphate of magnesia." If, by sulphate of magnesia, the anhydrous salt be intended, then this statement is correct; but there is no indication of this, and it requires either calculation or experiment to discover a meaning which there are no grounds for suspecting to be hidden.

BARYTÆ MURIAS. *Chloride of barium.* "Ninety-nine grains in solution, acidulated with nitric acid, are not entirely precipitated by 49 grains of sulphate of magnesia." Why the solution is directed to be acidulated with nitric acid I cannot discover; if the salt be pure, it is perfectly soluble in water without any such addition.

I have just shewn that "sulphate of magnesia" means *anhydrous* sulphate, and I shall presently prove that "sulphate of magnesia" also means *crystallized* sulphate: hence, when crystalliza-

ble salts are mentioned, we are under the necessity of determining, by calculation or by previous trial, with what materials an experiment is to be performed. In this instance, the muriate of barytes and the sulphate of magnesia

may be crystallized or anhydrous, and it may require four calculations, or as many experiments, to discover the state in which the salts are intended to be employed: thus—

| | | | | |
|------|--|---|--------------|-----------------|
| 1st. | The muriate may be crystallized and the sulphate crystallized. | | | |
| 2d. | " | " | anhydrous | " crystallized. |
| 3d. | " | " | anhydrous | " anhydrous. |
| 4th. | " | " | crystallized | " anhydrous. |

In these four cases the quantity of each salt required is, in the

| | Muriate of Barytes. | | Sulphate of Magnesia. |
|------|-------------------------------|-------|----------------------------|
| 1st. | crystallized, 99 grains | | crystallized, 99·8 grains. |
| 2d. | anhydrous, 99 " | | crystallized, 117· " |
| 3d. | anhydrous, 99 " | | anhydrous, 57· " |
| 4th. | crystallized, 99 " | | anhydrous, 48·6 " |

Making, therefore, a slight allowance for the difference between the weights of the equivalents which the College appear to adopt, and those used by me, it is evident that, by the aid of repeated calculations or experiments, the inquirer may arrive at a correct conclusion as to the meaning which the College attach to the words "muriate of barytes" and "sulphate of magnesia."

It follows also, that, in this case, two meanings may be conveyed by the same term; whereas, under acetum destillatum and acidum aceticum, "crystallized carbonate of soda" and "carbonate of soda" have both the same meaning: whether to give the same name to two different substances, or two different names to the same substance, has the merit of being the less ambiguous, I shall not stop to inquire.

CRETA PREPARATA [PREPARATA]. *Chalk, finely pulverized by levigation.* "A solution of 25 grains in ten fluidrachms of pyroligneous acid, when neutralized by carbonate of soda, and precipitated by 32 grains of oxalate of ammonia, continues precipitable after filtration by more of the test." Under the head of acidum pyroligneum (this name being given to pure acetic acid) it is stated, that one hundred minims neutralized at least fifty-three grains of carbonate of soda, meaning, as I believe, in the state of crystals; ten fluidrachms, or six hundred minims, therefore, saturate 318 grains of the carbonate, equivalent to 110 grains of carbonate of lime: hence it follows that the acetic acid directed for dissolving twenty-five grains of chalk is capable of dissolving more than four times that quantity, and the excess requires 244 grains of carbonate of soda for saturation; so that before the lime of

twenty-five grains of chalk can be precipitated from solution by oxalate of ammonia, nearly ten times its weight of carbonate of soda is used to saturate the excess of acid employed in dissolving it.

MAGNESIE SULPHAS. *Sulphate of magnesia.* "Ten grains dissolved in a fluidounce of water and treated with solution of carbonate of ammonia, are not entirely precipitated by 280 minims of solution of phosphate of soda." I have shown in two cases that sulphate of magnesia means the anhydrous salt; it might therefore be very naturally concluded that the same meaning would in this instance attach to the same words; on making the experiment, however, with the crystallized sulphate, I found that the precipitation occasioned by the phosphate of soda when added a second time, was not nearly so considerable as it would have been if the anhydrous salt had been used. In this instance, therefore, sulphate of magnesia means the crystallized salt, as it must also do in the directions for preparing the carbonate of magnesia.

PULVIS ANTIMONIALIS. *A mixture chiefly of sesquioxide of antimony and phosphate of lime, with a little antimoniatic of lime.* "Distilled water, boiled with it and filtered, gives with sulphuretted hydrogen an orange precipitate: muriatic acid digested with the residue becomes yellow, does not become turbid by dilution, but gives a copious orange precipitate with sulphuretted hydrogen." Not only is antimonial powder not chiefly sesquioxide of antimony and phosphate of lime, but it frequently contains not a particle of the former; the antimony is mostly in the state of deutoxide or antimonious acid. A proof that it contains very little sesqui-

oxide, if any, is indeed given by the College in stating that the muriatic solution "does not become turbid by dilution." If this preparation contained sesquioxide chiefly, it would be almost entirely soluble in muriatic acid, for this oxide and phosphate of lime are very readily taken up by it.

It appears to me more probable that it is antimonite than antimoniate of lime, which the powder contains.

QUINÆ SULPHAS. *Sulphate of Quina.* "A solution of 10 grains in a fluid-ounce of distilled water, and two or three drops of sulphuric acid, if decomposed by a solution of half an ounce of carbonate of soda in two waters, and heated till the precipitate shrinks and fuses, yields on cooling a solid mass, which when dry weighs 7·4 grains."

Supposing that the sulphuric acid added amounts to six grains, and the sulphate to contain two grains, less than twenty-five grains of the carbonate would be sufficient to precipitate all the quina, instead of the 240 grains ordered.

I made the experiment with 10 grains of the sulphate of quina, 25 grains of the carbonate of soda, and three drops of sulphuric acid; I found that there was more of the alkaline salt than was required; the quina was readily separated by the filter, and it weighed when dry 7·1 grains.

POTASSÆ SULPHURETUM. "*A mixture of sulphate of potash with persulphuret of potassium.*"

This cannot be a correct description of this compound, which in p. 111 is called Potassii Sulphuretum, for, if it contains persulphuret of potassium, a considerable portion of carbonate of potash must also be present. This will appear from

the following statements:—480 grains of sulphur are heated with 1920 of carbonate of potash, of which one-fourth is converted into sulphate; the remainder, after deducting 16 per cent. of water, must contain 691 of potassium, requiring 552 of sulphur to convert them into bisulphuret; now, as the whole quantity of sulphur amounts to only 480 grains, of which 92 are converted into sulphuric acid, there remain only 388 grains to perform the office of 552; and this calculation is made without any allowance for the loss of a portion of the sulphur by volatilization.

I have now concluded such remarks, and detailed such experiments, respecting the *Materia Medica* and the chemical statements connected with it, as my time has permitted me to offer. On some future occasion I shall probably make some observations on what the College candidly admit to be their "patchwork" nomenclature. There are still some statements in the *Materia Medica*, which appear to me to require putting to the test of experiment; and, with respect to the different formulæ contained under the head of "Preparations and Compounds," there are some, of which I question the practicability, and more, of which I doubt the eligibility. These processes I intend to subject to trial as soon as I can find leisure.

I cannot, however, quit the *Pharmacopœia*, even at present, without pointing out what seem to be some typographical errors occurring in the *Materia Medica*.

The following list exhibits, as it appears to me, instances of the omission of capital letters, in cases in which they ought, according to the best authorities, to have been employed:—

Acorus calamus
Carum carui
Cinnamomum cassia
Anamirta cocculus
Citrus limonum
Humulus lupulus
Daphne mezereon
Strychnos nux-vomica
Juniperus sabina
Polygala senega
Aristolochia serpentaria
Taraxacum dens-leonis
Arctostaphylos uva-ursi
Amygdalus communis
Acacia catechu
Arcea catechu

instead of Acorus Calamus.
Carum Carui.
Cinnamomum Cassia.
Anamirta Cocculus.
Citrus Limonum.
Humulus Lupulus.
Daphne Mezereon.
Strychnos Nux-vomica.
Juniperus Sabina.
Polygala Senega.
Aristolochia Serpentaria.
Taraxacum Dens-leonis.
Arctostaphylos Uva-ursi.
Amygdalus communis.
Acacia Catechu.
Arcea Catechu.

In the following instances the College have varied their practice, in some

cases employing capitals, and in similar ones neglecting them:—

Aurantii oleum
Hydrochloric acid
Carbo ligni
Antimonium Tartarizatum
Cinnamomum Zeylanicum
Maranta indica
Rosæ Fructus
Calamina preparata [præparata]

Bergamotæ Oleum.
Hydrochloric Acid.
Carbo Animalis.
Ferrum tartarizatum.
Cinnamomum zeylanicum.
Cetraria Islandica.
Juniperi fructus.
Creta Preparata [Præparata].

The inaccuracies in the natural history part of the *Materia Medica*, are, however, of a much graver description than those which I have just pointed out.

“CASTOREUM. *Castor: a peculiar secretion from the præputial follicles of Castor fiber.*” Castoreum, or castor of the shops, is the præputial follicles with their contained secretion, of the Castor Fiber. According to the definition of it given by the College, apothecaries ought, of course, to use the secretion only, in making tincture of castor, throwing away the follicles themselves.

“CINCHONA CORONAE, *Crown-Bark.*”

“CINCHONA CINEREA, *Gray-Bark.*”

“CINCHONA PALLIDA, *Pale-Bark.*”

Much confusion has been here introduced. It might be naturally supposed that *crown*, *gray*, and *pale* barks were different kinds of Cinchona bark; whereas the fact is, that crown and gray barks are pale barks. The only other kind of pale bark known in English commerce, is ash bark, an inferior kind, of little value. Surely the College did not mean this? But if not, what is meant? Again, the College have translated the terms *gray* or *silver* Cinchona by *Cinchona cinerea*, which means literally, *ash-coloured Cinchona*, and which for shortness may be termed *ash Cinchona*. Now ash Cinchona of commerce is a very distinct and inferior kind of bark to that called “*gray or silver Cinchona.*” Further, why is the hyphen (-) put between the words *Crown*, &c. and *Bark*?

“ALOE INDICA.” What is meant here? Aloes produced in India? If so, none is found in English commerce. Does it mean aloes brought from some part of the world by way of India? If so, “*Aloe socotrina*” is “*Aloe indica.*”

“CALAMUS AROMATICUS” is obtained from *Andropogon Calamus aromaticus* (Royle, *Hist. of Hindoo Med.* p. 33.) The rhizoma of *Acorus Calamus* is a very different substance.

“ERGOTA. *An undetermined fungus developed in place of the seed upon Secale cereale.*” Decandolle’s opinion here adopted by the Edinburgh College has been satisfactorily disproved by the investigations of Phillipar, Phæbus, Smith, Quekett, and others. Both Fries and Berkeley evidently doubted its correctness.

“HORDEUM. *Decorticated seeds of Hordeum distichon (L. W. Spr.); Barley.*” The decorticated grains of Hordeum distichon form *Scotch or Pearl Barley*, but not “*Barley*,” as so called in England.

“GLYCYRRHIZÆ RADIX.” The substance meant is a *rhizoma*, not a *root*.

[To be continued.]

ON THE DECOMPOSITION OF IODIC ACID

BY URIC ACID AND BY ALBUMEN,

AND ON

THE VALUE OF IT AS A TEST FOR MORPHIA,
IN CASES OF POISONING BY OPIATE
PREPARATIONS.

To the Editor of the Medical Gazette.

SIR,

You will oblige me by inserting the following communication in the MEDICAL GAZETTE.—I am, sir,

Your obedient servant,

WM. DAVIDSON, M.D.

Lecturer on Materia Medica, and one
of the Physicians to the Glasgow
Royal Infirmary.

Glasgow, 1st August, 1839.

It was first shown by Serullas that iodic acid was decomposed by morphia, the latter combining with the oxygen of the former, while the iodine is set at liberty; and that it might be used as a very delicate test for this alkaloid. Since this fact was announced, iodic acid has been particularly noticed by many writers on chemistry and toxicology, and by some recommended as ex-

ceedingly delicate, capable of detecting 1-100th part of morphia. It is, therefore, important, as far as poisoning with opium is concerned, and more particularly morphia, to ascertain whether there be any constituent of animal bodies that possesses the same property; for, if there be, this reagent for morphia must lose the greater part of its value.

When making some experiments on the urine of a patient, several months ago, I observed that the addition of iodic acid to it, disengaged the odour of iodine, and that the fluid assumed a blue colour on the addition of gelatinous starch. This result led me to inquire, what constituent of the urine had this property; and on trying urea and uric acid, I found that the latter only possessed it; and that it might be indicated in the urine of diseased, as well as in that of healthy individuals. I next tried the effects of iodic acid on the serum of the blood, and found that a similar result was obtained, but more slowly, and the colour was less deep, than in the case of healthy urine.

I shall now describe the experiments which were had recourse to. When a grain or two of colourless uric acid is mixed with a small quantity of a tolerably strong solution of iodic acid, and well stirred together for a few minutes, the odour of iodine gradually becomes sensible; and on the addition of a little gelatinous starch, a purple tint is soon observed, which gradually assumes a deep blue colour. A similar result is obtained from calculi which contain uric acid as a predominating constituent. When iodic acid is added to healthy and recently passed urine, the odour of iodine is very speedily developed, and the addition of gelatinous starch causes a pretty deep purplish blue colour and precipitate. But if the urine be alkaline, either from decomposition or from the use of alkaline medicines, the action of the iodic acid is more slow; but it may be quickened by the addition of a little diluted sulphuric acid; although in this case the blue colour soon disappears. I have tried the urine of several healthy persons, as well as that of individuals affected with various diseases; viz. typhus fever, pneumonia, and pleuritis, and in every case a purplish blue colour has been developed on the addition of iodic acid and starch. When iodic and gelatinous starch are added to the serum of the blood (con-

tained in a small phial), no particular effect is sometimes observed for a considerable time; but by employing occasional agitation, and generally after the lapse of 20 or 30 minutes, a reddish tint is observed, which gradually deepens into a purple colour and precipitate, exhaling at the same time the odour of iodine. The colour of the fluid and precipitate is not permanent; but disappears in a few hours. When a little diluted sulphuric acid is added, the purple or bluish-purple colour is developed in a few minutes; but it very soon disappears, as in the case of the urine when similarly treated. Having obtained this result with the serum of the blood, it was natural to conjecture that it might be owing to the presence of uric acid, which is still, as far as I know, only a hypothetical constituent of this fluid. Before, however, any probable conclusion of this kind could be drawn, it seemed necessary to try some of the organic constituents of the blood, and the first that was experimented with proved the fallacy of the supposition. When white of eggs is beat along with water for some time, in about equal proportions, and afterwards mixed with iodic acid and gelatinous starch, in a phial, which is to be frequently shaken, the liquid, after the lapse of 5 or 10 minutes, becomes reddish, then purple, and finally deepens into a permanent indigo-blue colour and precipitate, exhaling strongly the odour of iodine. The same effects take place when the albumen ovi is diluted with thirty parts of water; but the colour with this proportion has a purple hue, and is more apt to be decolorized, apparently by an excess of iodic acid. This latter experiment seemed to me nearly conclusive that albumen possessed the property of decomposing iodic acid; but to render it more so, the following one was adopted. A portion of the serum of the blood was coagulated by heat, the fluid part of the clot was carefully pressed out from a cotton cloth, the coagulated albumen was then macerated in cold water for two or three days, and the water afterwards pressed out from it. The solid albumen was then put into a small phial along with iodic acid and gelatinous starch; frequent agitation was employed, and nearly the same purple colour, possessing similar characteristics, was developed, as when uncoagulated serum of the blood is employed. Every albumi-

nous fluid that I have tried has produced the same results, varying in the intensity and beauty of the colour; viz. serum from the brain of a typhus patient, the fluid evacuated from the peritoneum of a person who was tapped for ascites, hæmotosin carefully freed from serum and dissolved in a considerable quantity of water, and the serum of cow's milk. The serum of blood, even when diluted with 4 or 5 parts of water, produces, with iodic acid and starch, nearly the same purple colour, but more beautiful, as when employed in the undiluted state. It would appear from these results, that iodic acid is capable of being decomposed by substances which exist to a large extent as constituents of our food, or as component parts of the fluids and solids of the animal bodies; and that one of the secreted fluids, viz. urine, contains, as an ordinary constituent, an element capable of effecting the same change upon it. Hence, in analyzing the contents of the stomach, in a case of poisoning with morphia or opium, the certainty of encountering albumen, and the possibility of meeting with uric acid, would render the separation of the morphia from these two substances so difficult and complicated, that no precise conclusion could be drawn from the indications of iodic acid as a reagent.

CASE OF OVERDOSE OF COLCHICUM.

To the Editor of the Medical Gazette.

SIR,

As the following case of the result of an overdose of colchicum appears to place the effects of that drug in a new point of view, as to its power in diseases of the joints, if you think it worth a place in your extensively-read periodical, it is very much at your service.

I am, sir,

Your obedient servant,

T. A. HENDERSON,
Surgeon, &c.

39, Clifton Street, Finsbury.
July 31st, 1839.

Mrs. M. aged 33, residing in Worship Street, of a corpulent and gross habit of body, and occasionally addicted to drinking, having had some words with her husband, swallowed the contents of an ounce phial nearly full of tincture of colchicum, with the intention of poisoning herself. This was at 11 o'clock

on Thursday night. At about 2 o'clock on Friday morning, great pain at the stomach and vomiting came on. The matter first vomited was food taken the night before, and this was followed by a great quantity of thick yellow bile—several basons full. Severe purging now came on, also of bilious fluid. The matter vomited became thinner and less yellow, and ultimately (Friday evening) it was of a pale straw colour, containing a large quantity of small white shreddy particles; and a discharge of the same kind now came from the bowels. During the entire of Saturday, much of this was vomited up, but the purging ceased. About 10 o'clock on Friday morning, she felt a numbness of the feet and hands; and to this succeeded a prickling feeling, as if, so she expressed it, "they had been asleep." All the joints of the fingers and toes, and also the wrists and ankles, were very painful, and the toes and fingers were painfully flexed at times. Pain in the shoulder-joints succeeded, and, on Saturday, in the hips and loins. It was also increased in intensity, so that she said that she thought she should go mad. Ultimately, almost all the bones and joints were affected with pain, which was of a gnawing, dragging character. Just before these symptoms were at the height, very profuse sweats came on, and were of a very sour odour. I may mention, that to the pains in the limbs was added, on Sunday evening, great stiffness and pain in the back of the neck and occiput, which was aggravated by moving the head: there was also a feeling as of something tightly bound round the head; and on moving the tongue, and in swallowing, she experienced sharp pain about the root of the tongue. She asked me if she had not got rheumatic fever. Some females in the room were also struck with the similarity of the symptoms.

Such is the general account of the symptoms. As to the treatment, she had effervescing medicine to allay the vomiting, followed by castor oil; but as the pains in the bowels became severe, I took 14 oz. of blood, and had the bowels fomented several times, which checked the enteric symptoms, and allayed the pain; afterwards I gave her calcined magnesia and tincture of hyoscyamus, which seemed to quiet the stomach, and remained down when every thing else was returned immediately it was swallowed. But the other symp-

toms, and such as seem peculiar to the drug, and might be called the secondary effects of it on the system, followed quite unchecked by the bleeding, &c.; and these I look upon as the most remarkable features of the case, especially the intense rheumatic kind of pain in the hands and feet, which began first, and continued during the origin and progress of the affection, in the other joints and limbs, and was very severe on Tuesday, so much so that she could not bear me to press her finger-joints, nor to extend them from their semi-flexed condition.

Are we from these symptoms to infer that the utility of this drug in gout and rheumatism depends on its specific or secondary action on the joints, and not, as Dr. A. T. Thomson observes, by acting as a counter-irritant on the whole alimentary canal, and by emptying the liver? In this case the pains in the joints continued exceedingly severe long after the vomiting and purging had ceased; and, indeed, up to that period, it was not near so intense as it became afterwards. As I have not seen these rheumatic pains noticed as occurring after an overdose of colchicum, I should feel much gratified if any of your numerous readers, who may happen to meet with a similar case, would observe if such symptoms also make their appearance when the vomiting and purging are decreasing.

REGULATIONS OF THE COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

IN the last number of the *Lancet* I see a report of Dr. Webster, to the Association of which he is President, containing an account of his mission to the Meeting of the Provincial Medical and Surgical Association at Liverpool. At its conclusion he remarks, on a motion brought forward, and indeed carried, by Mr. Turner, of Manchester, respecting some regulations of the College of Surgeons having reference to country pupils.

Not to remark on other parts of Dr. Webster's report, I think I am right in saying, that a person reading this last part would conclude from it, that Mr. Turner's motion was in accordance with the feeling of the large majority of the members: this, I do not hesitate to say, was not the case.

I have allowed that the motion was carried, and consequently the petition to the College of Surgeons depending upon it must be presented; but the number of those who voted was small when compared with the number present, and even then, the majority in favour of it was so small that it has been questioned, had the votes been counted whether the motion would have been carried.

It was evidently Mr. Turner's opinion, nay more, I believe I am justified in saying, his direct assertion, that the provincial schools are capable of affording a pupil sufficient means of education, and consequently that there is injustice in requiring their pupils to spend any time in London before examination. At least one gentleman, attached to an hospital in his own neighbourhood, was found to differ from him in this opinion; and I could mention more than one respectable hospital medical man in another neighbourhood also differing from him.

And if the majority of the meeting did not (as I contend they did not) agree with him as to the policy of his measure, still less did they approve of the reflections he thought fit to make on the motives of the College of Surgeons, and the opinion he expressed respecting their feeling towards provincial practitioners.

I have been induced to trouble you with these remarks from the interest which, as a member, I feel in the success of the Provincial Association, and from my conviction that the chances of its success can never be increased by remarks tending to beget ill feeling between provincial and metropolitan medical men.

An association reckoning nearly twelve hundred must possess some influence; and the circumstance that the *Lancet* makes it the object of its abuse, is a proof that it possesses some respectability. There is, therefore, the greater necessity that it rightly direct the one; and, from a due remembrance of the second, never allow itself to be hurried into intemperate attacks on others, in the prosecution of its objects.

By giving this communication a place in your pages, at your earliest convenience, you will oblige, sir,

Your obedient servant,

JOHN BARRETT.

Bath, 17, Westgate Buildings,
August 6, 1839.

CASES OF ASTHENIA.

To the Editor of the Medical Gazette.

SIR,

THE two cases I have the honour to send you are descriptive of forms of disease not met with every day, and which, when they do present themselves, are often mistaken and mistreated. I shall feel much obliged, therefore, by your giving insertion to them, with some observations of my own, in the *MEDICAL GAZETTE*.—I remain, sir,

Your very obedient servant,
MELBOURNE B. GALLWEY,
Assistant Surgeon,
Royal Artillery.

Woolwich, August 1839.

Early in the spring of the present year, I embarked in a transport from Jamaica, in medical charge of two companies of artillery, and a proportionate number of women and children. We had not been many days at sea when the following case came under my notice. — Balneaves (the child of a corporal in the Royal Artillery), a stunted, delicate-looking little girl, about two years and a half old, was brought to me by its mother, with the ordinary symptoms of disordered bowels, viz. diarrhoea, pain in the abdomen, some heat of skin, white tongue, &c. Such affections, unhappily, are far from being rare in transports, where the vicious quality of the water, contaminated by being kept, through a short-sighted and miserable economy, in wooden casks in place of iron tanks, creates the disease, and by remaining in operation, as a perpetual exciting cause, opposes an almost irresistible barrier against the chances of a successful treatment.

“*Alitur vitium—vivitque tegendo.*”

On the present occasion I prescribed some castor oil and hyoseyamus, and a small dose of a mild preparation of mercury at night; desired the mother to allow it as little water as possible, and in place of the salt provisions with which it had hitherto been fed to substitute arrow-root and preserved meat or soup. Under this treatment the child soon became convalescent, and was removed from the sick list. Need I say, however, that this child, with an intestinal mucous membrane perhaps still in a state of abnormally exalted sensibility, and conse-

quently predisposed to take on an irritative action, was sent back from my hands to encounter the very same sources of evil as had proved so pernicious to it before! The poor little thing, like the rest of us, was reduced to the alternative of drinking its allowance of water or of drinking nothing at all. It did not, perhaps, consume very much, for we were all on a short allowance, which, considering its quality too, might have been rather an advantage than otherwise, though we did not think so, I remember, at the time.

Within a week the mother brought back her child to me again, with an aggravation of all its former symptoms. The stools now ran from it with very little intermission, day and night, and were greatly deranged from their healthy character. For three days I pursued a plan nearly similar to the former, excepting that I gave up during the last twenty-four hours the castor oil and mercury, and substituted chalk mixture and opium in their place, from a fear that the former might reduce my patient too much. At the end of this time, what with the disease and the doctor, the child was much enfeebled, but the diarrhoea had given way, and the alvine discharge assumed a natural appearance. Early on the morning of the fourth day I was summoned by its anxious mother to the bed-side of the child, to witness an entirely new train of symptoms, from the commencement of which I may date the true interest and importance of the case. Well may I say a new train of symptoms had arisen, for I have seldom seen, within a few hours, such a metamorphosis as this poor child now presented. I found her lying on her mother's lap, with the pallor of death on her face, her features greatly shrunk, and her eyes sunken deeply into their orbits. She whined and screamed incessantly, and was exceedingly impatient of my presence, screaming yet more loudly when I attempted to touch her. Her pulse was 140 and eminently feeble. The surface of her body was cold, and her hands and feet particularly so. Bowels had not been moved for twenty-four hours. Here was indeed an altered state of affairs; but on what did this state depend? I could perceive no sufficient cause to account for the present symptoms; and no one of them was especially prominent. I felt at a loss how to act, and determined therefore to

temporize for a while. Yet there was one striking feature in the case which spoke for itself. The child was manifestly below par, and in a condition which forbade any mode of treatment calculated further to depress it. I ordered it, accordingly, ten grains of rhubarb, and two of the extract of hyoscyamus, in a table-spoonful of port-wine, which I believed would moderate the action of the aperient, and prevent the exhaustion that might otherwise follow its operation. The medicine produced its effect very soon; but, I regret to say, that effect was less mild than I had anticipated. I omitted to mention, that I had the child put into a hot bath as soon as it could be procured, and bottles of hot water applied to its feet and abdomen when replaced in bed; besides which, I ordered the mother to give it occasionally a table-spoonful of hot wine and water, and, if it would take it, some preserved soup likewise.

At 6 p.m. my little patient bore evidence of yet greater exhaustion, and to its former symptoms was now added a state of decided coma; the pupils were, however, obedient to light, and not manifestly dilated; the pulse had risen to 150, and the child was tormented with a constant husky cough. All things wore a most unfavourable aspect, and foreboded, I believed, an early and fatal termination. But I now suddenly remembered the remarkable and very interesting history of an affection (to which the present case bore a close analogy) which had been described by Dr. Marshall Hall, and subsequently by Dr. Gooch, and which represented a disease of the head in children arising from exhaustion, which much resembled, and was generally treated as hydropcephalus.

From what I could recollect of the descriptions given by these physicians of the disease in question (for I had neither of their works with me at the time), I believed that the case of this child offered a very strong and striking illustration of the same. I regretted now the purgation I had subjected it to again in the morning, and determined to lose no time in attempting to snatch my patient from its impending fate, by the steady employment of stimulants and a nutritious diet. I commenced by prescribing a tea-spoonful of hot brandy and water every half hour; and a small

quantity of preserved gravy soup occasionally in the intervals. To rouse the energies and circulation of the brain, I applied a blister to the neck and ordered the child to be put at once into a hot bath, to be well enveloped in blankets when taken therefrom, to have the bottles of hot water continued, and on no account to be removed from the horizontal position. At 10 p. m. I went to see the result of this treatment. It had truly operated like a charm, the hands and feet had exchanged their former lifelessness for a uniform and comfortable glow, the surface of the body also and the cheeks were now warm. The child had lost much of its former irritability, and allowed me to feel its pulse without opposition, which had fallen to 110, and no longer galloped as before. It had slept occasionally, the mother informed me, during the last hour; but I attached not too much importance to this communication, as the sleep might still have partaken of its former comatose character, although the child now seemed lively and unclouded in its faculties. The parents had not failed to notice the striking improvement in their child. It was indeed remarkable in degree, and such as I could not have dared hope for in so short a space of time. Fearing the remedy might be carried too far, I desired that the brandy should be discontinued during the night, with the exception of a dose at midnight, and one early in the morning, before I should see the child.

At 8 a. m. the next morning, I found that the amendment was steady and progressive. My patient had slept refreshingly towards the morning, was now free from all appearances of coma, its face was warm and much less pallid than on the evening before. Pulse 98, soft and moderately full; the blister had risen well. I did not think it necessary to order the brandy now oftener than every four hours. The soup was continued, the child seeming to relish it much. The day after this, the improvement was so steady that I considered the child's state as no longer doubtful. Indeed, its recovery was progressive from this time, notwithstanding the disadvantages it had to contend with, of want of air, of proper food, and the perpetual uproar arising unavoidably out of the crowded scene around.

Dr. Gooch, in alluding to Dr. Mar-

shall Hall's account of this disease, observes—"The only difference between our experience seems to be this—that he attributes the state which I have been describing to the diarrhœa produced by weaning, or to the application of leeches for some previous complaint. In most of the cases I have seen, however, the child has had no previous illness, and the leeches have been applied subsequent to the drowsiness, and as a remedy for it."

The case I have myself now brought under review would appear to confirm Dr. M. Hall's description of the history of the affection, inasmuch as it presented too very opposite and distinct stages, and was ushered in by the symptoms of disordered bowels. "This morbid affection," says the latter physician, "has usually been first induced by some change in the diet, by which the stomach has been loaded or disordered, and the bowels perhaps affected with diarrhœa; and this latter state has frequently been exasperated by the untimely administration of an aperient medicine. The infant becomes irritable, restless, and feverish; the face flushed, the surface hot, and the pulse frequent; there is an undue sensitiveness of the nerves of feeling, and the little patient starts on being touched, or from any sudden noise; there are sighing, moaning during the sleep, and screaming; the bowels are flatulent and loose, and the evacuations are mucous and disordered."

"If, through an erroneous notion as to the nature of this affection, nourishment and cordials be not given; or, if the diarrhœa continue, either spontaneously or from the administration of medicine, the exhaustion which ensues is apt to lead to a very different train of symptoms. The countenance becomes pale, and the cheeks cool or cold; the eyelids are half closed, the eyes are unfixed, and unattracted by any object placed before them, the pupils unmoved on the approach of light; the breathing, from being quick, becomes irregular and affected by sighs; the voice becomes husky, and there is sometimes a husky teasing cough; and, eventually, if the strength of the little patient continue to decline, there is crepitus or rattling in the breathing; the evacuations are usually green; the feet are apt to be cold."

He goes on to say, that this state of

exhaustion is occasionally brought about by the abstraction of blood. "In both cases, leeches are sometimes again applied to subdue this new form of disease, under the erroneous notion of a primary cerebral affection. This measure infallibly plunges the little patient into imminent, if not irretrievable, danger."

Dr. Marshall Hall, it will be observed, portrays, in the above picture, an affection characterized by two stages. Of such, likewise, did the case I have detailed consist. But, although there is considerable resemblance in the latter to the description given of the disease by this physician, I do not consider there to have been, in the first stage of the case which fell under my own notice, any symptoms which contraindicated the use of aperients—which bespoke a disease partaking of the nature of exhaustion—or any which could have warned me of the state of things about to arise. I look upon it, indeed, to have been a simple case of disordered bowels, plainly traceable to a common cause, and presenting in its character no marked evidence of depression, or any thing foreign to such cases in general.

Having described the first stage of this disease, and as a prelude to the second, the same gentleman observes,— "If, through an erroneous notion as to the nature of this affection, nourishment and cordials be not given," &c. With great deference to this high authority, I much fear that few practitioners possess a discrimination sufficiently nice to enable them to detect in a retrospect of the symptoms detailed, as far as the passage I have just quoted, aught that could be looked on as the harbinger of an approaching affection of this description, or any thing in the symptoms themselves belonging to such a condition. "The infant," in the words of the text, "becomes irritable and feverish, the face flushed, and the surface hot." These, it will be remembered, are amongst the symptoms of a condition said by the author to be one of exhaustion. But in the next page I find my respected and distinguished friend observing,— "The condition of the cheeks, in regard to colour and warmth, may be considered as the *pulse* of very young infants, indicating the degree of remaining power or of exhaustion. In the present case, especially, there is no symptom so important, so distinctive. It is from the condition of the cheeks, in conjunction

with a due consideration of the history, that the diagnosis of this morbid state, and the indication of the appropriate remedies, are chiefly to be deduced. The general surface, and especially the hands and feet, also afford important sources of information as to the condition of the nervous or vital powers."

I have ventured to make these few observations by the way (allusive to the warning which Dr. M. Hall throws out to us, not to form an erroneous opinion of the nature of the first stage of the affection), from a belief that there is scarcely sufficient evidence in the picture he has given of it, that a state of exhaustion is at the bottom of the symptoms; and few men — few men without much experience, at least — would hesitate, I think, to combat such a state with aperients:—"the sighing, moaning during the sleep, and screaming," would certainly awaken attention to the necessity of not depressing unnecessarily the powers of life; but I fear they would do little more with the generality of practitioners: and whether Dr. Gooch is correct or not, in believing the affection from its commencement to dash at once, as it were, into what I have spoken of as its second stage — viz. the coma, heaviness of head, excessive pallor and exhaustion, &c., I cannot but fear that if there be a stage antecedent to this, it will seldom point out to the physician "the narrow path" which is to direct his treatment to the prevention of the subsequent very serious disease. The principal object to be desired, then, is that we should be enabled to understand the nature of the latter condition when presented to our notice, so that we may then bring all the means of a safe and correct treatment to bear upon it.

Dr. Gooch's history of the affection is so interesting in its detail, that I cannot resist giving a short quotation from it in this place.

"I am anxious to call the attention of medical men to a disorder of children which I find invariably attributed to, and treated as, congestion or inflammation of the brain, but which I am convinced often depends on, or is connected with, the opposite state of circulation. It is chiefly indicated by heaviness of head and drowsiness. The age of the little patients whom I have seen in this state, has been from a few months to two or three years; they

have been rather small of their age, and of delicate health, or they have been exposed to debilitating causes. The physician finds the child lying on its nurse's lap, unable or unwilling to raise its head, half asleep, one moment opening its eyes, and the next closing them again, with a remarkable expression of languor. The tongue is slightly white; the skin is not hot; at times the nurse remarks that it is colder than natural; in some cases there is at times a slight and transient flush. The bowels I have always seen already disturbed by purgatives, so that I can scarcely say what they are when left to themselves: thus the state which I am describing is marked by heaviness of the head and drowsiness, without any signs of pain; great languor, and a total absence of all active febrile symptoms. The cases which I have seen have been invariably attributed to congestion of the brain, and the remedies employed have been leeches and cold lotions to the head, and purgatives — especially calomel. Under this treatment they have gradually become worse, the languor has increased, the deficiency of heat has become greater and more permanent, the pulse quicker and weaker, and at the end of a few days or a week, or some time longer, the little patients have died with symptoms apparently of exhaustion."

In a paper I published in the *MED. GAZETTE* of October last, on the Nature and Varieties of Delirium, I attempted to direct the attention of the profession to the frequency of its dependance on adynamic causes—on causes the very reverse of an excess of action in the brain, deducing my conclusions principally from the works of the most eminent physicians who had written on the subject; and coma, which delirium often subsides into, may well be said to belong to the same family of symptoms as the latter, to result from similar causes, and to be dependent on the same pathological condition of the brain, viz. sometimes on plethora, sometimes on anæmia of the organ. Galen and Boerhaave notice the occurrence of such symptoms as the result frequently of other causes than hyperæmia of the brain. Nay, Hippocrates seems to have made some allusion to this fact, where he says, that diseases from an excess and a deficiency of power produce the same train of cerebral symptoms.

Sydenham, Cullen, Wilson Philip, Armstrong, Van Rotterdam, and others, have all in their turn urged these vital considerations on the notice of physicians. Though now revived, indeed, by the moderns, these head symptoms arising from exhaustion of the brain, are nothing more nor less than what compose the "*apoplexia ex inanitione*" of earlier writers. Celsus has observed, that bleeding sometimes appears to save, at other times to kill the patient, which is simply to be explained by the circumstance of this disease depending sometimes on an excess of blood in the brain, sometimes in a deficiency of the vital fluid. As coma, or an oppressed state of the brain, forms so important a symptom in this affection, I may quote what Dr. Adair Crawford says in the article Coma, in the *Encyclopædia of Practical Medicine*, on the diagnosis of this condition:—

"The temperature of the surface of the body may be considered one of the safest guides with respect to the propriety of blood-letting, together with the state of the pulse and the action of the heart. We have never, indeed, seen beneficial effects follow venesection when the animal heat has been very low, even although the strength of the pulse might appear to justify its being prescribed. The temperature of the body is, perhaps, a safer general criterion of the exact condition of the powers of life than even the pulse; for, do we not see the arteries pulsating and throbbing with great force and frequency in cases where there is an undoubted tendency to debility and sinking? This opinion relative to the degree of heat on the surface is that, it will be remembered, to which Dr. M. Hall attaches likewise so much importance."

Dr. Holland's admirable observations on "bleeding in affections of the brain," in his recent work, entitled, "*Medical Notes and Reflections*," contain much which belongs to the subject under review—viz. the dependence of coma, delirium, &c. on an exhausted state of the brain; and must be read with interest and advantage by every member of the profession. "In the ordinary use of the term coma," says this writer, "the notion of pressure is associated with it by most practitioners. But it is familiar to us also, as a concomitant and token of the last stage of debility, and is often expressly

induced by depletion and other depressing causes, as well as by those which are known to produce direct pressure on the brain. Even in children, we have express instances of a state having all the characters of coma, but which is proved by the precursory causes, as well as by the effects of medical treatment, to depend on general feebleness of circulation and deficiency of nervous power." Again, "Delirium, preceded generally by vertigo, is known as an effect of extreme starvation, without other obvious disease, as frequently recorded in the narrative of shipwrecks." Dr. Holland, in the admirable chapter from which I have quoted the preceding remarks, pictures eloquently the irreparable consequences too often attendant on an indiscriminate employment of depletion for symptoms of this nature, arising from antilephoric causes. We want a constant repetition of such appeals to keep this subject alive in the minds of medical men. Much has already been written on the subject. To Marshall Hall the profession owes a deep debt of gratitude for his book on "the morbid effects of loss of blood." In letters of gold every page of that work should be inscribed. Still how much is left to be done! How the profession still swarms with Sangrados! Let a poor wretch happen to sink on the pavement of a populous street, whose day has been spent in anxiety and fatigue of body and mind, and who has fasted for many hours: he presents more or less of the symptoms of apoplexy, is taken into the nearest doctor's shop, is bled to deliquium, sent to his house with a pocketful of drastic pills; is then, perhaps, bled again, and dies to a certainty—not of his disease, but manslaughtered (to be mild in expression) by his doctor. Yet the doctor is not wise or no wiser than ever, and will practise the same feat on the following day. Another is overtaken in the streets by a fit. He also is robbed of a pound or two of blood, because it is a fit, while food and stimulus might have restored him to health. It cannot, indeed, I think, be denied that an immense amount of incurable mischief is annually done by this rage for blood-letting, whilst comparatively little would result from a prejudice against the remedy; there being a tendency in most diseases, as Dr. Clutterbuck observes, to subside

spontaneously, if not interfered with; whilst purgation often renders the adoption of the other unnecessary.

I cannot agree with this eminent physician in thinking it preferable to draw blood in general, where other substitutes might be found for it; or "that it is milder in its operation or safer in its effects than other remedies that are resorted to in its stead." Neither do I think that "convalescence, or the restoration of strength after the termination of disease, is sooner accomplished where the cure has been effected chiefly by bleeding than where it has been brought about by those mis-called milder means." "Again," says the same authority, "the opposition to the practice has been chiefly founded, I believe, in an affectation of singularity, for the sake of vulgar notoriety; it is certainly not sanctioned by experience." I think, on the contrary, we should husband blood in every affection to which our "flesh is heir," where we can safely do so, where we can find a more innocent substitute, and where active inflammation is not positively going on. The mischief created by Dr. Clutterbuck's "herculean remedy," when employed in the spirit of that phrase, is generally injurious—is often irreparable. I have been led insensibly into this long digression, by the nature of my subject, to which explanation I must also refer the overgrown length of this article. I cannot, however, in conclusion, resist extracting one passage more from Dr. Gooch's article on this interesting affection:—

"In observing disease, two sets of symptoms may be noticed, which are mixed together in the case, but which require to be discriminated to form a correct opinion of it: the one consists of the striking symptoms which form what may be called the physiognomy of the disease; the other consists of those symptoms which indicate the morbid state of organization, on which the disease depends; the former only are noticed by the common observer, but the latter are the most important, and the skilful physician takes them for his guides in the treatment. 'He notices not only where the hour-hand of nature's clock points, but also the run of its hour and minute-hands.'

"Two patients complain occasionally of dimness of sight, swimming of the head, singing in the ears, and observe

that if they turn the head on one side to look at an object, they feel as if they should fall; but the one is plump, florid, and has a full pulse; the other is pale and thin, has cold hands and feet, and a pulse small and feeble. One practitioner bleeds them both; the other bleeds the one, but does all he can to give blood to the other. The latter cures both his patients; the former cures the one, but ruins the health of the other; but such is the nature of the human mind that the cases for a pre-conceived opinion are retained easier than those against it. He remembers his good deed, forgets the other, or calls the case anomalous, and marches on, without the slightest doubt that bleeding is the universal and sovereign remedy, for dimness of sight, swimming of the head, and singing in the ears, save and except only in anomalous cases."

What eloquent, what beautiful, what masterly reasoning! I can do no homage to that critic who will not allow that I have quoted one of the most striking master-pieces of medical composition in our language—one of the most beautiful appeals to the understanding—and one of the most faithful pictures of daily occurrence that has ever adorned the literature of our profession.

Let me urge those members of the profession (and few, I trust, they are) who have not read this great physician's work on "Some of the most Important Diseases of Women," (which contains the article that I have quoted so largely in this paper), not to delay longer an opportunity of increasing their store of practical information. Every word in that rich production tells; in every line is a homily.

The work of Dr. Marshall Hall, in which is contained his history and first notice of this pseudo-hydrocephaloid disease, must be well known to every practitioner. Few there must be who are not familiar with his explanation of the "Morbid Effects of Loss of Blood." Truly may these master workmen in our art—these authors of two such books—be styled "giants" amongst "the small fry" of their calling.

[To be continued.]

OBSERVATIONS

IN REPLY TO

T. WHARTON JONES' STRICTURES.

BY DR. MARTIN BARRY.

[For the London Medical Gazette.]

My claims to originality in my "First Series" of Researches in Embryology* are before the scientific public, and by their deliberate opinion will be ultimately decided. It is not out of any anxiety to vindicate these claims that I offer the present communication; it is to repel certain charges made by T. Wharton Jones, in the MEDICAL GAZETTE, July 20, 1839, having a personal bearing, and calculated to induce an impression of unfairness and want of candour on my part, in alluding to the works of other physiologists in general, and his own in particular. My "pretensions to novelty, originality, and correctness" are before a tribunal on whose intelligence and impartiality I can rely, and from whose decision I will not shrink.

The first accusatory remark of T. Wharton Jones is an allusion to the following passage, which he quotes from my "First Series":—

"It may not be improper, in the first place, to furnish an idea of what has been already published on some branches of the subject; for it is one to which the attention of physiologists in this country has scarcely begun to be directed."

To this quotation T. Wharton Jones appends the following note:—

"Had there been no other, the labours of Dr. Allen Thomson in this field ought to have been sufficient to have obviated the reproach so sweepingly implied, in Dr. Barry's allegation, against the physiologists of this country."—*Loc. cit.* § 1.

I think it is obvious from the context of the passage cited, when taken in conjunction with what had preceded it—and which T. Wharton Jones has not quoted—that I meant to make no invidious allusion whatever to the labours of English physiologists on the subject of embryology in general, but that the remark objected to in that passage has a reference only to that portion of the

science of embryology which regards the existence of the microscopic ovum in the ovary of mammals, as discovered by Baer, and upon which so little had been observed or written in this country as compared with German research, that I thought—and still think—myself perfectly justified in stating, that the attention of physiologists in England had scarcely begun to be directed to it*.

One of the objects of T. Wharton Jones, in his communication above referred to, was to apprise me that a paper of his—read before the Royal Society in 1835, but not printed in the Philosophical Transactions—was published in the MEDICAL GAZETTE for Session 1837-38, pp. 680-88; London, 1838†. I was not previously aware that the paper in question, by T. Wharton Jones, had been published, or that it was any where accessible, otherwise I should have deemed it right to include some statements made by that author along with similar ones previously made by others, which I noticed in my "First Series," for the purpose of showing that they differed from my own observations. I have now seen, in the MEDICAL GAZETTE, No. 18, 1838, the paper to which T. Wharton Jones has directed my attention; and I refer him to my "First Series" for the points of difference just alluded to.

I will here observe, that there is the less necessity for going into the scientific part of the question at any length with T. Wharton Jones, inasmuch as I find in his paper no new fact whatever, with the single exception that he has stated the Graafian vesicle of mammals to be analogous to the capsule of birds‡. With that one exception there is, indeed, nothing that appears to me

* It affords me particular pleasure to quote the following from an eminent German author:—"The best and most condensed survey of the whole doctrine of generation—based on his own observations—has been given by Allen Thomson, in the article 'Generation,' in Todd's Cyclopædia of Anatomy and Physiology, vol. ii. p. 424."—(Rudolph Wagner, Lehrbuch der Physiologie, Erste Abtheilung, Physiologie der Zeugung und Entwicklung, p. 6. Leipzig, 1839.) I may add my belief, that no one is more competent to offer an opinion on this subject than Professor Rudolph Wagner.

† A considerable portion of it was republished by him in the MEDICAL GAZETTE, July 20, 1839.

‡ I was not aware that T. Wharton Jones had asserted the analogy above-mentioned at the time when my "First Series" was written, for the reason before given. But it will presently be seen how much he knew of the real nature of either of the structures in question. As to the

to have been new at the time when he presented his paper to the Royal Society, in 1835; and to tread over beaten ground for the mere sake of personal controversy, is neither pleasant nor profitable. But there is one point upon which T. Wharton Jones seems to set up "pretensions to novelty, originality, and correctness," on which I must be permitted to say a few words.

In 1835 this author presented to the Royal Society an account of the germinal vesicle discovered by him in the *Lam-miferous ovum*; adding, in a postscript in reference to this discovery, "it would appear that M. Coste has anticipated me." The Memoir of T. Wharton Jones not having been printed in the *Philosophical Transactions*, the author published it at full length in the *MEDICAL GAZETTE*, in 1838 (No. 18, p. 680), with the same postscript in which he had yielded the priority of discovery to Coste. It is remarkable, however, that T. Wharton Jones had not in the meantime heard that in 1834 a thesis was published at Breslau, in which ten quarto pages were devoted to a description of the germinal vesicle as existing in the ovum of all orders of the class mammalia, and remarks connected with it. This thesis was by Bernhardt*, but the drawings are by Valentin, who seems to have been the discoverer of the vesicle in Germany. This thesis was particularly referred to in a translation I gave from the German of Valentin, in the *Edinburgh Medical and Surgical Journal*, No. 127, 1836. But farther, in the year 1834 R. Wagner sent to Müller's "*Archiv*" a particular description of the germinal Spot, discovered by him within the germinal vesicle, a structure which he considered constant in the class mammalia—so extended had been his observations. This discovery by Wagner was mentioned in the *Edinburgh Medical and Surgical Journal*, No. 126, 1836, above alluded to, and it was at the same time stated in that journal, on the authority of Professor Johann Müller, that the account had been sent by Wagner to the "*Archiv*" in 1834. Upon these points T. Wharton Jones is silent.

T. Wharton Jones quotes two pas-

sages from pages 312 and 314 of my "First Series," in which I showed that a vesicle, called by me the "ovisac," in mammals, corresponded to one which had been denominated the "chorion" in other vertebrata; and also, that it was by those vesicles acquiring a covering susceptible of becoming highly vascular, that the structure is produced, usually termed a "Graafian vesicle" in mammalia, and a "capsule" in other vertebrata. T. Wharton Jones adds, "All this is true; but I dissent from the allegation that it was not clearly stated before. I can answer for myself, that I am not one of the authors who have mistaken the ovisac of birds for the analogue of the chorion of mammals." (*Loc. cit.* § 6.) I did not say that T. Wharton Jones was one of the authors who had mistaken the ovisac of birds for the analogue of the chorion of mammals. On the contrary, it does not appear from his papers that he ever saw the vesicle which I denominated the "ovisac" of birds, in its originally independent state; and as to the corresponding vesicle, called by me the "ovisac" in mammals, I am not aware that any observer had described it before myself. With what degree of justice, therefore, T. Wharton Jones made the above assertion, will now be obvious.

T. Wharton Jones says (*MED. GAZ.* 1838, No. 18, p. 682), "I shall mention the points most worthy of notice in the structure of the hen's egg, in the *first stage* of its formation," and he then describes the capsules, as "varying in magnitude, from that of a *millet-seed* to a full-sized yolk." In my "First Series," (plate v. fig. 22), the ovisac—*i. e.* the subsequent inner layer of the capsule—of the bird was figured (having the incipient ovum within it) of a size so minute that some thousands of such ovisacs might be contained within a "*millet-seed*." Yet, according to T. Wharton Jones, he described the hen's egg in the "*first stage*" of its formation.

T. Wharton Jones says (*MED. GAZ.* 1838, No. 18, p. 686), "I might also add, that the granular membrane, proligerous *disc*, and granular fluid of the Graafian vesicle, are probably superadded parts, of which there is no trace within the capsule of the bird's ovary." In my "First Series," it was shown that a fluid containing "granules

analogy between the ovum of the bird and the Graafian vesicle of the mammal, this was pointed out by several authors in 1834.

* Symbolæ ad Ovi Mammalium historiam ante prægnationem.

essentially the same [as the very remarkable ones in the ovisac of mammalia] exist at an early period in the ovisac of birds."—(*l. c.* p. 329, pl. v. fig. 23; pl. viii. fig. 76). It was also shown (pp. 329, 330), that the situation of the ovum in the Graafian vesicle had not been understood by those who stated it to be contained in a "*disc.*" T. Wharton Jones took some pains to point out the resemblance between the Graafian vesicle of the mammal and the capsule of the bird. Yet now, when made aware how much he knew of the real nature of either of these objects, he considers them "structures of secondary importance in the economy of the ovum—structures which, on that account, had been less carefully studied" (*MED. GAZ.* July 20, 1839, § 9).

To vindicate my own motives and conduct against charges of misrepresenting or undervaluing the labours of others, or claiming undue credit for my own, being my chief object, I have no wish to recriminate on T. Wharton Jones; but when he chooses to quote a passage from the abstract of a paper by me, as an illustration of my opinion upon an important subject of physiological investigation, I cannot help observing that it was not quite fair to have garbled it in the manner in which the following passage has been garbled:—"He (Dr. B.) has traced the chorion from stage to stage, up to the period when it becomes villous, and shows that it is not, as he formerly supposed, the thick transparent membrane itself of the ovarian ovum, but a thin envelope closely investing that membrane, and not appreciable as a distinct structure until the ovum has been crushed. * * * The chorion subsequently thickens, and imbibes a quantity of fluid, presenting a gelatinous appearance."—(*Loc. cit.* § 7.) The asterisks certainly indicate that something has been omitted, but the reader would understand thereby that what was omitted was not necessary to the proper understanding of the question in dispute between us. By the omission, however, which T. Wharton Jones thought proper to make, he has got rid of the difficulty of noticing certain anatomical facts, the "pretensions" of which "to novelty, originality, and correctness," it was, perhaps, easier to omit than answer*.

Another paragraph of T. Wharton Jones (*l. c.* § 10) contains the following passages, quoted from the abstract of my "Second Series" of "Researches on Embryology"*:—

"The knowledge at present supposed to be possessed of the early stages in the development of that ovum (the mammiferous ovum) consists chiefly of inferences from observations on the ovum of the bird.

"But there exists a period in the history of the ovum of the mammal regarding which we have hitherto scarcely any direct or positive knowledge."

T. Wharton Jones then remarks—"For a perfect and unqualified contradiction of this very bold assertion, I would refer to my memoir, contained in the *Philosophical Transactions*, Part II. for 1837, page 339, already alluded to."

Now what is the "perfect and unqualified contradiction" of this "very bold assertion" for which T. Wharton Jones refers to his memoir? The contradiction thus alluded to appears to be certain inferences from observations on the ova of the frog and newt; consequently, more conjectural than demonstrative.

As to the "mode of origin of the chorion," another point on which T. Wharton Jones dwells at some length, my "Second Series," to appear in the forthcoming volume of the *Philosophical Transactions*, will show what are really the differences between the results of his observations and my own, on the relative value of which I leave physiologists to determine. I shall only further remark, that T. Wharton Jones's opportunities of observation, as compared with my own, may be stated as *one to twenty-five*—that gentleman, on his own admission, having examined *four* rabbits, whereas the number devoted to anatomical inspection by myself exceeds *a hundred*; and also, that the paper in question will show that T. Wharton Jones has only renounced one erroneous "notion"—as to "the mode of origin of the chorion"—to fall into another.

admits of demonstration as a distinct structure, the ovum consists of *three* membranes; a state which the author *has seen* in an ovum no farther advanced than about an inch into the Fallopian tube."—(*Proceedings of the Royal Society*, No. 38, 1839.)

* *Proceedings of the Royal Society*, No. 38, 1839.

* The words omitted to be quoted by T. Wharton Jones were these:—"When the chorion first

CICERO.

THE NEW EDINBURGH PHAR-
MACOPŒIA.

WE remarked in our late article on this subject, that the Edinburgh College have ventured upon an alteration in the language of their Pharmacopœia, which will gratify the majority of those who use it; and though *laudatur ab his, culpatur ab illis*, may be applied to every change, more will be found to praise than to blame Dr. Christison and his able colleagues for using English instead of Latin. They have been so bold and so fortunate as to effect another change, which, we think, will meet with even more applause, as it is a still greater step to intelligibility, and therefore to public advantage. The Edinburgh College, far from attempting to follow the last changes of chemical nomenclature, and catch the "Cynthia of a minute," have very sensibly adopted, in many instances, the well-known names formerly used in pharmacy and medical practice. Thus they call calomel, *calomelas*; and corrosive sublimate, *sublimatus corrosivus* *. These names have the immense advantages of being perfectly distinct from each other, and universally understood—advantages which can certainly not be predicated of *hydrargyri chloridum*, and *hydrargyri bichloridum*. "The result," they say, "has necessarily been a patchwork, of which we cannot boast, but which the public will probably receive in consideration of its convenience."

This motley state has arisen from the partial retention of the modern names,

* Perhaps *sublimatum corrosivum* would be better.

which has been done, probably, on the supposition that many of them were pretty well naturalized in pharmacy. This is true in certain cases; in others, the chemical names scarcely serve the purpose of names at all, as they are not commonly understood without a definition appended to them. Thus, in popular nomenclature, the carbonate of soda is called the subcarbonate; and to shew that even chemists may disagree, the same alkali, saturated with carbonic acid, is called by the London College the sesquicarbonate of soda; and by the Edinburgh, the bicarbonate. If we were inclined to lament the schisms of botanists, and the everlasting splitting of genera which allows no name to be safe, we might find sufficient examples in the Pharmacopœia of this island. Thus, in London it is asserted that gamboge is produced by the *Stalagmitis cambogioides*; in Edinburgh, they say that the Siamese variety comes from an unascertained plant inhabiting Siam, probably a species of *Hebradendron*; the Ceylon gamboge from the *Hebradendron cambogioides*. Camphor is obtained from the *Laurus Camphora*, according to the London College; but Nees von Esenbeck and the Edinburgh College call the plant *Camphora officinarum*. The plant producing cardamoms was once named *Amomum Cardamomum*, and, for a short time, *Matonia Cardamomum*; but now the northern college call it *Reuealmia Cardamomum*, and the southern one, *Alpinia Cardamomum*. Here, rhubarb is afforded by the *Rheum palmatum*, and cascarilla by the *Croton Cascarilla*; while there, the former is the root of an undetermined species of rheum, and the latter is the bark, probably of *Croton Eleuteria*, and possibly of other species of the same genus.

But enough of this; we will now proceed from words to things. On comparing the *Materia Medica* of the

Edinburgh with that of the London Pharmacopœia, the chief articles in the former, which are not to be found in the latter, are the sulphate of barytes, the nitrate of lead, and chiretta—a name given to the herb and root of *Agathotes Chirayta*. This is probably the same plant which has been called *Chirayit*, *Creata*, and *Gentiana Chirayita*. It is one of the *Gentianæ*, and is said by Gray to be highly esteemed in India*. The Edinburgh College direct an infusion to be prepared with four drachms of chiretta to a pint of water.

Bucku does not belong to the list of additions, but to the catalogue of varying names given above; it means Buchu leaves, which are said by the Edinburgh College to be the produce of various species of *Barosma*; but are identical with the leaves of the *Diosma crenata* of the London Pharmacopœia. Some other substances, such as *ferri iodidum*, we pass over, for though not in the London *materia medica*, they are in the body of the work.

On examining the preparations and compounds, the following are some of the more striking points. Among the alkaloids and their salts we find a very useful solution of muriate of morphia, containing four grains and a half in the ounce; it is equal in strength to laudanum.

It is to be regretted that the London College, in the last edition of the Pharmacopœia, omitted the table giving the proportion of opium and other powerful remedies contained in their compounds; nor is there any assistance of the kind in the work before us.

Among the decoctions there is one of logwood; and the decoctum *scoparii* differs from the London preparation by containing cream of tartar instead of taraxacum; the quantity of the salt

ordered is three drachms to a pint, which is far more than it will dissolve.

Among the distilled waters we find an *aqua laurocerasi*, a convenient form of Prussic acid. In the French Codex, the *eau de laurier-cérise* is marked with the star, which indicates that it is to be kept by every druggist.

There are no cataplasms in the Edinburgh Pharmacopœia. The enemata, five in number, are all useful; and perhaps the enema catharticum, consisting of olive oil, Epsom salts, sugar, and senna, with sixteen ounces of water, might be advantageously admitted into the London Pharmacopœia. Two of the enemata, however, are open to objection in their present state, for they contain an ingredient in a variable dose: the enema *opii* is to be made with half a fluidrachm to a drachm of laudanum, and the enema *tabaci* with fifteen grains to half a drachm. Now this offered choice frustrates one great object of a Pharmacopœia—that of relieving the memory of practitioners, who need recollect only the name and the dose of a preparation, but not the exact proportion of its ingredients. In both these instances it would have been sufficient to give the weaker compound only; or else there should be a clear understanding that when the physician prescribes enema *opii*, or enema *tabaci*, without fixing the strength, the smallest quantity of the potent drug is to be used.

The extractum *Kramerie* (*rhatany* root) is peculiar to the Edinburgh Pharmacopœia*, and so is the extract of *nux vomica*. The latter is highly extolled by Magendie.

Among the infusions we find an inconvenient clashing of the two Pharmacopœiæ in one of our commonest preparations. The *infusum sennæ* of the

* Supplement to the Pharmacopœia, 4th edit. p. 56.

* Whenever we use this phrase in our present analysis, we do so in a limited sense, and mean *peculiar* to signify that which is not common to it and the London Pharmacopœia. Both the extracts above mentioned are in the French Codex.

Edinburgh work is nearly the same thing as the inf. sennæ comp. of the London one, being only a fifth weaker; but the infusum sennæ comp. of the Edinburgh Pharmacopœia, independently of its containing tamarinds, coriander seeds, and brown sugar, is made with only a drachm of senna leaves to eight ounces of water. This must lead to misapprehension and mistake; but let us hope that better days are approaching. The extreme similarity of the two Pharmacopœiæ must strike every reader; and it would require but a few mutual concessions to convert this likeness into identity.

We will continue this subject on an early occasion.

ENGLISH PRACTITIONERS AT WIESBADEN.

No one can practise physic in any part of Europe unless he has been licensed by some medical college of the country. Such, we believe, is the universal theory; but the practice is as various as the climates. In England, for instance, the unlicensed practise physic and surgery with impunity, while it is most dangerous to be a contraband apothecary. In France the theory is more strictly observed; yet, even there, every town patronized by the English has its complement of British practitioners, who but rarely, we apprehend, have the license of any French college.

It is not very long ago, however, since the attempt was made to expel the English physicians from Boulogne; but, ultimately, they were allowed to remain, on condition of prescribing for their countrymen alone.

In Germany, again, the authorities must often find it for the interest of a town to wink at the practice of English physicians; and we never heard, till last week, of their forcible expulsion.

The gouty layman, indeed, whose lively pamphlet we introduced to our readers on a former occasion*, laments the want of a sufficient number of good physicians at Wiesbaden; and says, "The permission to English physicians to write prescriptions without risking arrest by the police, it is to be hoped, will either be granted, or competent persons, with a knowledge of their own profession and of our language, be appointed to attend the place; otherwise the English, to whom Wiesbaden is most indebted, will be in a somewhat destitute condition: for their own knowledge of French being much upon a par with that of the local physicians, the dialogue cannot always have a very satisfactory, or, indeed, be otherwise than of doubtful result."

In fact, if patients most deeply skilled in their native language can scarcely find words to express the endless shades of morbid sensation, how vain must be the attempt when the language spoken is foreign both to the physician and the sufferer, and each idea is expressed, or rather veiled, by the dim medium of a double translation! But in spite of the apprehensions of the pamphleteer, the English at Wiesbaden have hitherto enjoyed the advantage of English advice, and have not been molested until this season. Their medical attendants this year were Dr. Downie, who is physician to the Landgravine of Hesse-Homburg, and lives at Frankfort; and our correspondent, Mr. Edwin Lee, the author of a work on the mineral waters of the continent. It appears, from a letter in a late number of *Galvani's Messenger*, that, as early as the month of April in this year, the native physicians complained to the municipal authorities, that Dr. Downie and Mr. Lee practised at Wiesbaden; and as the letter of the law was against

* Wiesbaden recommended to the Gouty, &c.
MEDICAL GAZETTE, vol. xxii. p. 810.

our countrymen, the apothecaries of the place were forbidden to make up their prescriptions. They still continued, however, to practise, the medicine-chests of their friends supplying drugs for their patients; but as this was equally fatal to the interests of the Wiesbaden doctors, they were lately summoned before the head of the police, "who obligingly informed them that they must quit the town in forty-eight hours." We anticipated the possibility of such an occurrence in the article above referred to, observing, that an unlicensed practitioner "must not expect to be favoured with a letter from an attorney giving him notice of an action to be tried next Trinity Term—the Duke of Nassau v. Dr. X.—but just be satisfied with a simple order enforced by the police, that within twenty-four hours he must quit the dominions of his Highness*."

We are sorry that our forebodings have been so soon realized; but if the English at Wiesbaden will but manifest their natural predilection for British practitioners with sufficient firmness, this foolish preference of the letter to the spirit of the law must be renounced by the rulers of Nassau. The sudden departure of a dozen English carriages from the *Hôtel des Quatre Saisons* would throw infinite light upon the fact, that the legal exclusion of foreign physicians was framed not for the benefit of Nassau leechcraft, but for the protection of the natives from quacks. Now, not to mention that, in the present case, there is not even the pretence of charlatanism, the sixpenny or ninepenny fees given by the natives are of themselves a sufficient guarantee against the attacks of British practitioners; besides which, they might be confined, as at Boulogne, to their own countrymen. This emigration of English visitors

would, perhaps, be rendered unnecessary by a well-drawn petition, in which it might be pointed out that nearly all the most enlightened nations of Europe severally prefer their own physicians; and that while the English, the French, the Germans, and the Italians, extol with plausible arguments the respective merits of their practitioners, it would be unjust to deny the patients of each country the pleasure of profiting by them. If the influx of foreign doctors became too great, it might be necessary to institute some examination as a test of fitness; but then it should be a purely practical one, as it is hardly fair to harass middle-aged practitioners with questions about the Coniferæ, or the sub-salts of silver, or the last experiments of Tiedemann and Magendie.

In some future age of good sense, it will be thought even more strange that shackles should ever have been imposed on the commerce of talents, than that France should have refused the cotton of England, and England the wine of France.

We hope that this foolish attempt of the Wiesbaden doctors may come to nought, like a true "bubble from the Brunns of Nassau."

THE PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

THE Seventh Anniversary Meeting of this society was held at Liverpool, as we mentioned in our last number, on the 24th and 25th of July.

The following is the Report of the Council:—

REPORT OF THE COUNCIL OF THE PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION, FOR 1838-39.

The law of this association, which makes it imperative on the Council to render an account, at each returning anniversary, of the condition and prospects of the institution, is very salutary in its tendency; for not only are those in whom this trust is reposed thereby reminded that they have an important duty to perform, but those occurrences to which it is of consequence

* MED. GAZ., vol. xxii. p. 811.

that the attention of the members at large should be directed, are thus brought conspicuously forward, and every one may readily become acquainted with the aims and views of those who take an active part in the proceeding of the Association. On this account it is desirable that the report should touch upon all the prominent circumstances which have occurred; though, in order that time may not be spent in details which might be otherwise more beneficially employed, it is necessary to condense this notice as much as it is practicable.

Happily the members have in the history of this recently formed association no ordinary degree of encouragement: without the slightest approach to exaggeration, it may be confidently affirmed that no institution has ever before been formed for the cultivation of medical science which has in the first seven years of its establishment succeeded in combining together, for the promotion of important objects, so large a number of the members of the several branches of the profession. Previously to the formation of this association, the medical profession resident in the English provinces were dissevered, and had scarcely any common bond of union.

Transactions.

Distinguished as many of the profession have ever been by their medical writings, there was no common provincial repertory through which these writings might come before the public. It was to supply this deficiency that the *Transactions* were originally proposed, and that they are in no small degree calculated to answer the purpose designed, may be inferred from the fact, that contributions have not been wanting to supply interesting and valuable papers, so that every year has produced a volume abounding in useful information. The seventh volume, which has been published since the anniversary meeting at Bath, is peculiarly rich in medical topography; and the Council are assured that the members in general participate with them the gratification they feel in observing that our foreign members take an interest in our proceedings, and enhance the value of our *Transactions* by their excellent contributions to its pages. The Council have frequently pointed out the paucity of reports of provincial sanatory institutions supplied to the Association: of the value of the information to be derived from such sources there can be but one opinion, and a comparatively small portion of industry and perseverance on the part of those who are connected with these establishments would afford most useful and interesting facts, from which conclusions highly instrumental in ad-

vancing the healing art might ultimately flow. Already the number of facts of this nature which have been collected in one town alone (Birmingham) is considerable, and your Council cannot but entertain the hope that future volumes of the *Transactions* may have more numerous contributions of this nature. Your Council also here take leave to allude to the recommendation in the Report of the last year, that the members should forward the history of such cases as are of an interesting nature, but not of sufficient importance to be published separately, to the Secretaries, with the view of their being classified upon some future occasion, when they shall be in sufficient number or of sufficient importance to render it desirable to publish them.

Members.

Within the last year the Association has received a considerable accession to the list of members, and they amount in number to 1180.

District Branches.

Your Council have every reason to believe that the system adopted of dividing the Association into District Branches is operating favourably. In no other manner would the business be so easily arranged; and the respective Annual Meetings of the District Branches are admirably calculated to keep alive an interest in the proceedings of the General Association, at the same time that they afford opportunities of social and professional intercourse to many who are prevented by a variety of causes from being present at the General Meetings.

Finances.

It must be remembered, that the annual supply of a volume of *Transactions* to every member, free of any charge, is a very considerable drain upon the funds; and the liberality of our laws in this respect is worthy of notice, as such a custom is followed by scarcely any other society. It makes it, however, the more incumbent upon members to pay their subscriptions punctually, since every one to whom a volume is sent has so much value received, for which his subscription is very little more than an equivalent. Your Council, however, notwithstanding the heavy disbursements for printing, and for the engravings and colouring the plates, and also the existence of arrears in subscriptions to a considerable amount, have to announce the gratifying fact, that the actual receipts for the year exceed the disbursements. Your Council also assure the members, that on all occasions a due exercise of economy is studied; and, at the same time, care is taken so to expend the funds

as to make the *Transactions* creditable to the Association.

The income for the last year is £1324 1 4
The expenditure of the last year is 722 6 9

The balance is.....£601 14 7

Parochial Medical Relief.

Your Council have still to regret that they are not enabled to report any very satisfactory progress in the settlement of this unhappy question. They regret to say that, notwithstanding the decided recommendation by the Parliamentary Committee to the contrary, the system of "Tender" is still persevered in by several of the Boards of Guardians, under the sanction of the Commissioners. The Poor-Law Committee have not been inattentive to their duties since they last reported to the members; and, in particular, they have been in frequent intercourse with Mr. Serjeant Talfourd, who is warmly interested in procuring justice for those of our professional brethren who are oppressed by the provisions of the New Poor Law. It is the advice of this gentleman, on whose judgment and acquaintance with parliamentary business the Council have the fullest reliance, that no further step shall be taken until the next session of parliament, when government must again bring forward a bill, either to continue the powers of the Poor-Law Commissioners, or to substitute another scheme in lieu of the present: the learned Serjeant will then undertake to do all in his power to introduce clauses into the new bill to remedy those defects which the Parliamentary Committee have, in their own Report, stated to exist. Your Council therefore recommend that the Committee, which was appointed last year to watch the further progress of the subject in parliament, and to suggest to the Council from time to time such measures as appear to them necessary to meet circumstances as they arise, be requested to continue their services.

Vaccination Section.

The section appointed to consider the present state of vaccination have assiduously endeavoured to collect accurate information on that subject. The report is prepared, and will be submitted to the Association at this meeting.

Benevolent Committee.

The committee for managing the benevolent fund have continued their efforts to promote the prosperity of this interesting proportion of our undertaking, and will likewise present a report detailing their proceedings for the last year.

Medical Reform.

Your Council beg to assure the Association that, in their multifarious labours, they never lose sight of the general interests of the profession, nor of the necessity of procuring for it a better legal constitution. To this object the energies of the Association may be worthily and beneficially directed. Circumstances, however, have hitherto repressed any direct endeavour on the part of the Association to call the attention of the legislature to the subject. These circumstances will be explained in the report of the committee deputed in 1837 "to watch over the interests of the profession," which will be presented to the present meeting. For this report, and for the recommendation with which it will conclude, the Council earnestly solicit the favourable consideration of all who wish to see the profession rescued from a state of unseemly anarchy and confusion, and placed under the rational government and legal protection to which, as an important branch of civil polity, it is so justly entitled.

Empiricism.

Intimately connected with the question of medical reform is that of quackery, the evils of which were deemed of sufficient importance at the last anniversary meeting to induce the Association to empower their council to form a section for the consideration of the nature, extent, and evils of quackery, and to report on the same at the next anniversary meeting. The Council considered that the wishes of the general body could not be more efficiently carried into effect than by appointing Dr. Cowan, of Reading, who has so meritoriously given much time and attention to this important subject, to be chairman of the section, from which, at the present meeting, a short report will be presented. Its members, however, seem inclined to the opinion, that all active measures, in relation to the suppression of quackery, had better be delayed, in the hope that a better organization of the profession may render the suppression of quackery a more practicable undertaking than it appears at present to be. In the meantime, to use the words of a former report, the Association may be employed in the inquiry into the nature of the evils, their extent, and remedies, by which means they may be enabled, at the proper season, to render valuable aid in legislating upon this question. The Council, therefore, advise, that the section they have appointed be requested by this meeting to continue their investigations on this subject.

Sections.

In the last report your Council adverted

to the propriety and expediency of appointing from the Association sections for the investigation of particular departments of medicine. The meeting at Bath coincided in that recommendation, and appointed a section, to whom the replies to the queries on vaccination were referred. The result of this measure will be found to have been already highly beneficial, and your Council request this present meeting to empower them, during the ensuing year, to propose subjects for investigation by sections of the Association, if circumstances should arise to render it probable that such a proceeding would be attended with satisfactory results.

Report upon Surgery.

At the anniversary at Bath, and subsequently to it, some influential members regretted that no special report had yet issued from the Association on the progress of surgery, and a wish was expressed that this subject should be taken into consideration by the Council. After due deliberation, your Council fully concurred in the propriety of a report being presented to this anniversary on the progress of surgery, and they happily prevailed upon Mr. James, of Exeter, to devote his time and energies to the performance of this duty, for which his acknowledged zeal in the prosecution of the literature of his profession so eminently qualifies him.

Notices of Motions.

Your Council beg to inform the members, that a notice has been given to the secretaries by Dr. Symonds, of Bristol, that a resolution touching the late regulations of the College of Surgeons, which are considered injuriously to affect Provincial Medical Schools, will be submitted to this Meeting.

A notice also of a motion by Dr. James Johnstone stands for consideration at this meeting, to this effect:—"That any member of the Association wishing to compound for his annual subscription may do so by paying ten guineas, which amount shall in all cases be invested in public securities, and the interest arising therefrom be appropriated to the general purposes of the Association."

Conclusion.

Having touched upon so many topics, and indicated the general bearings of the proceedings in which the Association is so meritoriously and so appropriately engaged, your Council feel it altogether unnecessary to prolong this report by any general remarks on the auspicious prospect of the affairs of the Association. To carry on with any degree of success, commensurate with their obvious importance,

the several undertakings in which the members are engaged, will require judgment, discretion, zeal, perseverance, and union. Your Council would earnestly entreat every member seriously to consider the magnitude of the objects which are at stake, and then determine whether he can be justified in withholding his exertions from a cause in which the best feelings of humanity prompt him to engage,—as it is intimately connected with the progressive advancement of medical knowledge, and directly tends to the augmentation of human happiness.

CHARLES HASTINGS.
JAMES P. SHEPPARD.

The Association now consists of 1180 members, and the meeting was probably attended by at least a quarter of that number, as about 250 dined together on the second day. Sir James Murray, Mr. Carmichael, Dr. Jacob, Dr. O'Beirne, Dr. McDonnell, and Dr. Maunsell, came from the Medical Association of Ireland; Dr. Webster and Dr. M. Hall represented what is called the British Medical Association. The following are the principal points in the proceedings:—A petition to parliament for Medical Reform, and another in favour of Vaccination, were adopted. Mr. Turner moved, that a memorial be presented to the College of Surgeons against those regulations which are unfavourable to provincial schools. His resolution was carried by a large majority, yet we apprehend that the heads of the profession will ever be of opinion that a residence in the metropolis is essential to a complete medical or surgical education. A Report on the Progress of Surgery since 1836, was read by Mr. James, of Exeter; the Report of the Benevolent Fund Committee, by Dr. Conolly, of Cheltenham; and a Report on Quackery, by Dr. Cowan.

A joint committee was formed of members of the Provincial Medical Association, the Medical Association of Ireland, and the British Medical Association; and it was

"Resolved—That Drs. Barlow, Webster, and Maunsell, be respectively the organs of communication of the different bodies which they represent, and that a free communication be forthwith commenced between those bodies, for the purpose of drawing up a plan of general medical reform, in the shape of heads of a bill to be considered by the

several committees, and subsequently proposed to the Association.

"Resolved—That a communication with the medical profession in Scotland, and with local Associations in England and Ireland, be opened as soon as possible, and that the members of the committee shall exert their influence to the same effect.

"(Signed) E. BARLOW, M.D."

The first of the Associations just mentioned may be a good representative of the feelings of Provincial practitioners; and the second a tolerable one of Irish opinions; but assuredly the British Medical Association does not fairly represent the practitioners of London and its vicinity. Men of note either fight shy of it, from not liking the queer hands by which it is guided; or, which is even still less flattering, seem quite unconscious of its existence.

Professor Gibson, of Pennsylvania, and Dr. Smith, of South Carolina, were among the visitors.

The next meeting of the Association is to be held at Southampton; Dr. Steed is the President elect, and Dr. Forbes will deliver the Retrospective Address.

We are indebted for these particulars to Berrow's Worcester Journal of August 1, which has a Supplement entirely devoted to the proceedings of the society.

DISCOVERY OF VARICOSE CAPILLARIES.

LETTERS FROM DR. HAKE AND MR. KIERNAN.

FROM DR. HAKE.

To the Editor of the Medical Gazette.

SIR,

I TAKE the liberty of transmitting you the accompanying correspondence for publication. I avail myself of this opportunity of stating, that, in my work, which will shortly appear, I have not appropriated any of Mr. Kiernan's views to my own use, but, on the contrary, have only related facts, which, if known to Mr. Kiernan, he first became acquainted with by an inspection of my drawings.

I have the honour to be, sir,

Your very obedient servant,

F. G. HAKE.

42, Gordon Square, Tuesday.

Mr. Kiernan has this moment received the inclosed, which appeared in the MEDICAL GAZETTE of Saturday last, and loses not a moment in sending it to Dr. Hake. Mr. Kiernan informs Dr. Hake that he considers plagiarism, even in the title of a work, a personal insult, and will resent it accordingly. Mr. Kiernan will be at home all this evening, and to-morrow until two o'clock.

8 o'clock P.M., Aug. 12, 1839,
33, Beaumont Street, Devonshire Place.

Gordon Square, Aug. 13, 1839.

Dr. Hake writes to Mr. North, after calm consideration of Mr. Kiernan's very extraordinary note, and the propositions* of which Mr. North was the bearer.

It is impossible for Dr. Hake to avoid seeing that the present wish of Mr. Kiernan is to submit the matter in dispute to the issue of a duel. Had Mr. Kiernan chosen this mode at first, the proposal he has now made might have had some claim for consideration, though even then Dr. Hake would have thought it an extraordinary way of determining the priority of right to a scientific discovery. But Dr. Hake feels, that after Mr. Kiernan has made choice of an appeal to the scientific world, through the usual scientific channels, he has forfeited all right of settling this dispute in the manner now sought by him, even if such right had ever existed.

Dr. Hake does not think it necessary to trouble any of his friends on this matter, as called for by Mr. North; and requests that any future communications may be made in writing, which he deems it right to say may be made public.

John North, Esq.

FROM MR. KIERNAN.

To the Editor of the Medical Gazette.

SIR,

It is with much reluctance that I request the favour of your insertion of the following letters in the next number of your journal.—I am, sir,

Your most obedient servant,

F. KIERNAN.

33, Beaumont Street,
Aug. 14, 1839.

* The propositions of Mr. Kiernan, made through Mr. North, were as follows:—

That Dr. Hake should promise in writing, for the purpose of publication—

1. Never to repeat his advertisement.
2. Never to appropriate to himself any of Mr. Kiernan's views.

Charterhouse Square,
Aug. 12, 1839.

My dear Kiernan,—If you desire any testimony to the entire originality of your discoveries on the subject of morbid growths, you may at any time call on me to declare that I witnessed the “*looped and varicose capillaries*,” at your house, in sundry preparations, as far back as the year 1836; and that I have on sundry occasions examined them since that period. I perfectly well remember the interest with which you pointed out, and I examined, at that date, the beautiful series of preparations illustrative of disease in its various stages, from its first appearance up to its full development, which formed the crowning effort of years of previous exertion. Allow me to add, that I also have repeatedly and urgently requested you to make your discoveries known, in the full expectation that the product of your labours would, in some form or other, be anticipated by others.

Believe me, dear Kiernan,

Most truly yours,

FREDERIC C. SKEY.

Francis Kiernan, Esq.

My dear Kiernan,—As I perceive, from the journals of the last week, that a question has arisen between yourself and Dr. Hake, as to the discovery of a varicose state of the capillary vessels, I feel it but an act of justice to you to declare, that, in frequent conversations with you upon the subject of your researches during the last two years or more, you have often stated to me that you were prepared to prove, by preparations, that the essence of cancer, and other morbid growths, consisted in a dilated and varicose state of the capillary vessels.—I am, my dear Kiernan,

Yours very truly,

J. NORTH.

Gloucester Place, Portman Square,
August 12th, 1839.

F. Kiernan, Esq.

[Mr. Kiernan has also transmitted to us copies of letters from Messrs. John Tomes, Campbell De Morgan, and W. R. Gerrard, all bearing testimony to the same point, though their acquaintance with the morbid appearances in question does not date from so long a period; but for these we cannot afford room. Mr. Gerrard, in addition, says, he has learned from Mr. Kiernan that

the development of new vessels occurs in two ways; one is by a looping or doubling of capillaries in a varicose manner, while the other may be compared to an aneurismal state of the capillaries, as in the annexed wood-cuts.

With the greatest respect for Mr. Kiernan's talents as an anatomist, and success as a discoverer, we have doubts whether he has adopted the tone best suited to a scientific controversy. —
ED. MED. GAZ.]

PARTICULARS
OF THE
DISEASE AND POST-MORTEM EXAMINATION
OF A
LITHOPHAGUS.

By Dr. NERET,

Physician to the Hospital St. Charles, at Nancy.

DOMINIQUE Henrion was born at Metz, in 1761. Being but little pleased with the occupations to which he was put when young, he began, at the age of 22, to swallow pebbles. Sometimes he took them whole, and without any preparation; sometimes he broke them between his teeth, after having reddened them in the fire, and then suddenly plunged them in cold water. By this means he passed himself off as a savage from America.

Several years since, he had fixed his abode at Nancy, and there continued the same kind of life, swallowing every day a greater or less number of stones, which on some occasions amounted to 30 or 40. The largest were of the size of a large nut, but they were commonly smaller, and Henrion used to demonstrate their presence in his stomach by the noise they made when he struck his epigastric region. He passed them by stool in 24 hours after taking them, and often made use of

them again next day. He swallowed also live mice, but only one a day, as well as moderate-sized crabs, after having cut off their claws. As to the mice, when they were put into his mouth, they at once rushed into the pharynx, when they were soon suffocated, and the deglutition of them was then facilitated by that of a stone. The next day they passed from the rectum, with their skins destroyed, and covered with mucus.

This man continued the same kind of life up to the 1st of April, 1820. At that time, after having filled his stomach with a considerable number of stones, he swallowed, for a small sum, a tinued iron spoon, five inches and a half long, and an inch broad. Some hours after, he was seized with vomiting, which continued to the time of his death. He first vomited bilious substances, and then fluid tinged with blood, and of a very fetid smell.

In this state he was brought to the hospital on the 6th of April. The vomiting continued; the thirst was excessive; the pulse small and irregular; the abdomen hard, distended, and painful, especially beneath the umbilicus. Next day, after an enema, the patient passed five stones by stool, but he grew worse, and died on the following day, aged 59.

At the autopsy, the medullary substance of the brain was very firm; there was some serum in the ventricles, and some hydatiform vesicles on the choroid plexuses. The lungs were firmly adherent to the walls of the chest, but healthy. The heart was in no respect remarkable. On opening the abdomen, the stomach was found distended with gas; the great omentum was inflamed, and there were points of suppuration on its anterior surface, as well as on the transverse arch of the colon. The whole internal surface of the digestive tube and the parietal peritoneum participated in the inflammation. On raising the great omentum, an aqueous fluid flowed out, in which there floated globules of oil, which appeared to be the medicine that the patient had taken, and which indicated a perforation of the intestinal canal. In fact, the spoon could be felt in the transverse part of the duodenum, and it was seen that the handle, after having pierced this intestine where it curves to take the name of jejunum, was sticking out two inches beyond it. Internally, the duodenum was covered by a thick layer of greyish mucus.

The internal surface of the stomach was red and inflamed; here and there were points of ulceration; the pyloric orifice was more than usually dilated; but the degree of dilatation of the pharynx, œsophagus, cardia, and the stomach itself, was by no means remarkable. There were 32 pebbles in the great cul-de-sac of the sto-

mach, with liquid and oily fluids; some stones were also found in the duodenum, and in some other parts of the intestinal canal; the cœcum contained five; so that the whole number found in the course of the digestive tube was 53, and they weighed altogether one pound and three ounces: the largest weighed five drachms. In form they differed considerably: there were some long and sharp, and others which approached the cubic form; but in general they did not appear to have been chosen to prevent the wounding of the digestive canal.

The liver was large and hard, and the gall-bladder contained a small quantity of fluid.

This case was published soon after its occurrence by Dr. Neret's predecessor; but as the details then given were insufficient, and Dr. N. has himself had the opportunity of examining the case, he thought it but right again to print it, and to add that which was wanting in the previous account.—*Archives Générales de Médecine*, Juillet 1839.

MEDICAL STUDENTS IN AMERICA.

University of Pennsylvania.—Four hundred and two medical students matriculated in this school the past session. The number of graduates was 158.

Transylvania University.—The number of students in the medical department of Transylvania University during the session 1838-39 was 211; and at a commencement held on the 11th March, 1839, fifty-one received the degree of doctor of medicine.

Dartmouth College.—From the catalogue of the officers and students of this college, issued in September last, it appears that the number of medical students at that time was 78.

Medical College of Georgia.—The class the past session numbered 60; and at the commencement held 2d March, 1839, twelve were graduated doctors in medicine.

Geneva College.—The number of graduates in medicine in this college was, in 1835, six; in 1836, eight; in 1837, five; in 1838, seventeen.

Louisville Medical Institute.—The catalogue of the class during the session of 1838-39 shows the number of students to have been 120.—*American Journal*.

CITRATE OF QUINA IN INTERMITTENTS.

THIS is recommended by Professor Beraudi, because it is equal in effect to the sulphate, in doses one-third smaller; and because it is more easily borne by the stomach, and causes less congestion in the brain.—*Bulletin de Thér.* and *Schmidt's Jahrb.*

LITERARY ANNOUNCEMENT.

WE are authorized to announce that a Treatise on General Anatomy is being prepared for immediate publication by Mr. Paget, Demonstrator of Pathology, and Curator of the Museum, at St. Bartholomew's Hospital.

This treatise will be composed with a view to direct practical application in Physiology and Pathology; and in addition to the subjects usually included in works on General Anatomy, it will contain the Elements of Animal Chemistry, and the results of the extended microscopic observations in which anatomists, especially those of the German schools, have been lately engaged. It will be carefully adapted to the use of Students and Graduates in Medicine.

BOOKS RECEIVED FOR REVIEW.

The Plague and Quarantine. Remarks on some Epidemic and Endemic Diseases, &c. By John Murray, F.S.A. F.L.S. &c. 2d Edition. London, 1839. 8vo. pp. 54.

A Series of Anatomical Plates. Edited by Jones Quain, M.D. and W. J. Erasmus Wilson. Fasciculi 72 and 73, containing Division 4—Viscera, 3; and Division 4—Viscera, 4. London, 1839.

An Address to Medical and Surgical Pupils on the Studies and Duties of their Profession; to which is appended, a Case of Cæsarean Operation. By James Barlow, Surgeon, Blackburn. Blackburn, 1839. 8vo. pp. 119.

Nineteenth Annual Report of the Directors of the Dundee Royal Lunatic Asylum. Dundee, 1839. 8vo. pp. 42.

Medical Report to the Managers of the Lunatic Asylum of Aberdeen, for the year ending 30th April, 1839. Aberdeen, 1839. 8vo. pp. 16.

Observations on the Disorder of the General Health of Females called Chlorosis. By Samuel Fox, Surgeon. London, 1839. 8vo. pp. 132.

Prevailing wind, S.W.

Except the afternoons of the 13th and 14th, generally clear; a little rain fell during the evening of the 11th.

PERIODIC METEORS.—From nine in the evening till nearly one hour after midnight of the 10th, the meteors were very numerous, though generally very small; eight of these were of more than ordinary brilliancy, and all followed by trains varying from 10 deg. to 20 deg. in length. The most remarkable fact was, that nearly all appeared to proceed in one direction—viz. from N. N.E. to S. S.W.

Rain fallen, .075 of an inch.

CHARLES HENRY ADAMS.

NOTICES.

WE have received a letter from Mr. H. W. Dewhurst, addressed "to the members of the medical profession, and the friends of literature and science in general;" and we regret to learn from it that a man who has had a complete medical education, and has united great zeal in the diffusion of knowledge to untiring industry in the pursuit of it, should be reduced to a state of destitution. Mr. Dewhurst hopes to be relieved from his present embarrassments by small donations from his professional and scientific friends, and would also wish to be employed as a literary or scientific lecturer. His address is 25, Marlborough Square, Chelsea.

We are much obliged to Mr. Henry Smith for his communication.

The letter signed "M.D. Erlangæ" will probably be made use of on some future occasion.

M. D. L.'s letter from Berlin; and

Mr. T. S. Wells's reply to Dr. Allnatt, in our next.

Mr. Fergusson's Observations on Yellow Fever, shall appear as soon as we can make room for them.

Dr. Wightman's packet has just been received.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.
By DR. VENABLES.

Ulceration sometimes occurs in both the bladder and prostate gland; but affections of this sort generally belong to the province of the surgeon; nor, indeed, are there any specific symptoms by which ulceration can be recognised. When, however, a sort of bloody pus is voided with the urine, we may suspect ulceration. With respect to the treatment, it must be conducted upon general principles; and if there be any means peculiar in the treatment of ulceration of the bladder, I believe it consists in injecting the bladder with a solution of chlorine, from which, in two instances, I witnessed the very best effects.

When the prostate suppurates, the pus is discharged by the urethra, and the disease for the most part terminates favourably. In some cases, however, a sort of scrofulous ulceration attacks this gland. In old people, also, the ulceration becomes extensive, with frequent abscesses, ultimately terminating in complete disorganization of the gland; but such complaints so completely fall within the province of the surgeon, that it is unnecessary to consider them at greater length.

Irritable bladder.—Irritability of the bladder sometimes exists to so great an extent as to prove extremely distressing to the patient. One consequence is a frequent desire to pass urine; but, contrary to what happens in cystitis, the quantity of urine

passed at each micturition is either of the natural quantity or may exceed this. Sometimes there is a real diuresis, and the quantity greatly exceeds that of health. Such cases are frequently confounded with diabetes, but are, indeed, of a very different nature. The bladder, though in an irritable state, is not so impatient of urine as to be excited till a certain distension has taken place; but as soon as the quantity of urine attains to a certain amount, the bladder becomes impatient of further distension; there is an irresistible impulse to its evacuation.

In many instances of this sort, several articles in common use, and under ordinary circumstances producing no inconvenience, become highly stimulating to the urinary organs, and excite to an increased flow of urine. Thus tea, and especially green tea, I have known produce, in certain individuals, so immediate and so irresistible a desire of emptying the bladder, that the individual could hardly resist it for a moment. In many, too, the urine seems to acquire, under such circumstances, a peculiar acrimony, as the retention of the urine in the bladder is attended with a sort of smarting or burning pain; yet, if examined, the urine does not appear to have undergone any remarkable change of properties. I have seen, however, several instances in which persons affected with irritable bladder, and so situated as to have been forced to resist the call, have been seized with a complete retention of urine. This appears to arise from some spasmodic action of the sphincter; and the attempt to relieve the patient by the introduction of the catheter only increases the mischief.

Diagnosis.—An irritable state of bladder is a concomitant of urinary diseases, such as peculiar acrimony of the urine, mechanical irritants, as calculi, or inflammatory diseases of the bladder itself. But the affection under consideration is not referri-

ble to any one of these. In them we shall be able to discover some peculiarities of the urine to account for the phenomena, or there will be some symptoms to indicate some specific disease. In the affection to which I allude the urine is natural, and the bladder does not appear to suffer till a certain accumulation and distension have taken place. This, in fact, appears to me to be one of the principal diagnostics.

Causes.—I had an opportunity of examining the bladder in one instance of this affection. The patient had been subject to irritable bladder for some time; but, being suddenly attacked with very severe pneumonia, died; and a dissection being allowed, the bladder was examined. It presented no diseased appearance; the mucous coat, if any thing, was a little redder than natural. The immediate cause, therefore, would appear to be some peculiar irritability of the mucous lining, which, extending to the muscular coat, excites it to contraction.

The remote or exciting causes are probably of a varied character. Particular irritations seem often to induce this state. Of these, I may mention the inflammation of the mucous lining of the urethra, known as *gonorrhœa*. When *gonorrhœa* has been very severe, and the urethral inflammation has run very high, the bladder often remains in an irritable state for a long time after. A first or second attack, perhaps, may have only a temporary effect; but if they have been numerous, a permanently irritable bladder, if nothing worse, will certainly be the consequence.

The improper introduction of bougies for the cure of supposed *gonorrhœa* is another fruitful source of irritable bladder. Irritation of contiguous parts, as, for instance, hæmorrhoids, and in females uterine affections, frequently produce irritability of bladder to such an extent as to cause great inconvenience, by the frequent calls to empty the bladder.

Among the causes, also, may be mentioned, a thickening of the coats of the bladder. This condition is frequently attended with a sort of chronic enlargement of the prostate gland. In some cases of this sort, the coats of the bladder often acquire a thickness exceeding three or four times their natural substance. The thickening is probably induced by the exertion which the bladder has to make to expel the urine, which enlargement of the prostate, or some such other obstruction, may impede. In many, however, it seems to arise from diseased action in the bladder itself, as, with the thickening, the substance becomes hard and rigid; in many of which cases the disease may spread to

the ureters, or even to the kidneys themselves.

When the bladder has been much thickened it may often be felt above the pubes, when there is a sense of weight in the hypogastrium, with which there is often an incontinence of urine. In such also the bladder, in its hard and thickened state, may compress the nerves and vessels in the neighbourhood to a greater or less extent, producing some very unpleasant sensations in the lower limbs, attended with great restlessness, so that the patient cannot keep quiet a single moment. In other cases there is total paralysis of the lower extremities. Generally, too, there is more or less of difficulty in passing the feces, owing to the pressure of the bladder upon the rectum.

In some instances an irritable state of bladder is brought on by disease of the inner lining. Thus, in one case which I met with, there was a complete fold of the inner membrane, so as to form a complete pouch, and, at the same time, a fungous excrescence was growing out from another portion*. This patient was seized with frequent desire to void the urine; but at last he became incapable of voiding any. It was supposed that he was labouring under stone in the bladder, under which circumstances I was called to visit him. On examining the urine, however, I found no reason to believe in the existence of a calculus, and this opinion was further confirmed by sounding, when no calculus could be discovered. Upon this occasion, though between sixty and seventy years of age, he recovered so far as to be able to go about as usual, and he lived one or two years, when, being again attacked, he died rather suddenly and apoplectic; but as I did not see him upon this occasion I cannot state the particulars. I was present, however, at the dissection, and witnessed the appearances above stated.

Enlargement of the prostate gland is often attended with an irritable state of bladder. In many, the gland becomes very much enlarged. A hardened or knotted state of the same organ often induces a desire of frequent micturition. In such cases the condition of the gland may be discovered by an examination through the rectum.

Diagnosis.—With respect to the diagnosis, it is evident that it is to be distinguished in different cases by different methods, or rather signs. Where the affection is purely an irritable condition of the bladder, without concomitant dis-

* The bladder, I believe, is in the Museum of the Royal College of Physicians.

ease of any of the neighbouring organs, we shall have no great derangement of the urine, and the signs of the diseases of the neighbouring or contiguous parts will be absent. But if the irritability of bladder be associated with disease of the neighbouring parts, then we shall have the signs by which these are indicated—many of which have been already treated of at sufficient length.

Treatment.—It is evident, from the history which has just been given, that this affection is sometimes purely one of the bladder alone. In such cases, we must endeavour to ascertain the state of the general health, and correct any deviations that may have arisen there. These are so various, and have been already so sufficiently dwelt on, that it is unnecessary to recapitulate them. The means immediately applicable is what we are now to consider: and, first of all, we must attend to the state of the bowels, for if they be confined, it invariably aggravates the complaint. Next we have to consider the choice of means. There is mostly associated with the complaint an irritable, or, at least, a strong tendency to an irritable state of rectum, and, therefore, the bowels must be solicietd by mild rather than by powerful remedies. There is nothing answers the purpose so well as castor oil, and where this can be taken, as is mostly the case, it is the best and safest remedy. If, however, it cannot be taken, then we must have recourse to some of the aperient infusions, as rhubarb or senna, with some of the purgative tinctures, and the occasional use of enemata.

For the purpose of relieving the urgency of the complaint, we must give narcotics. The extract of colchicum with morphia I have found most effectual; and at the same time a draught, composed of the *mistura amygdalæ* and a few drops of the compound tincture of camphor, may be directed to be taken at proper intervals two or three times a day. We should at the same time examine the state of the urine, and correct any deviations from the natural condition. Thus, if there be any alkalescence, or, indeed, any tendency to it, such as being neutral, we should give a little of the phosphoric or the hydrochloric acid, in doses proportioned to the state of the urine, and continued until the necessary change has been effected. In the slighter cases, this, with avoiding all exciting causes, such as stimulating drinks, as tea, soda water, saline effervescing draughts, &c. is all that will be necessary. But when the disease is complicated with other affections, then we must have recourse to the means specially adapted to the parti-

cular condition. In hæmorrhoids, for instance, if much inflamed, we must apply leeches to the anus, and, in addition to the urinary treatment, we must adopt such means as are specially suited to the hæmorrhoidal affection. In the case of the uterus being affected, we must endeavour to restore it to its healthy condition. Where the prostate seems engaged, leeches frequently applied to the perineum seem to hold out the fairest prospect.

It has been already stated that in such cases there is often an inability to pass the urine in consequence of spasm, excited by the irritation of the bladder: hence, the urine is retained, and the bladder becomes most painfully distended. It is too often the practice to endeavour to relieve this state of things by the introduction of catheters: the attempt almost always proves abortive, and only increases the mischief by increasing the irritation. I remember the case of a baker, who was subject to attacks of this sort, and attempts were usually made to evacuate the bladder by means of the catheter, which generally failed. To render the introduction more easy, the patient was bled, and then put into a warm bath, when the urine would flow, and the bladder be gradually emptied. I was called to him upon one of these occasions. The urine had been retained for several hours; the bladder was distended, presenting a tumor the size of a large orange in the abdomen above the pubes. Several attempts had been made to introduce a catheter, but without success. The pain and straining were very urgent, and the distress of the patient was very great. In this emergency I directed leeches to the perineum, and a draught, containing one grain of hydrochlorate of morphia, with thirty minims of the wine of colchicum, and a drachm of the tincture of hyoscyamus, to be given every ten minutes, till relief was obtained; the abdomen at the same time was fomented with hot flannels. As the bowels had been rather confined, they were emptied by a laxative enema. In about five minutes after taking the third draught, the patient suddenly exclaimed that he felt something give way, and, on examination, the urine was found flowing in a full free stream, and continued till the bladder was completely emptied, when the morphia began to take effect, and he fell into a sound sleep, in which he remained for several hours, and on waking said he felt tolerably well. This person, by attending to the directions given to him, continued, while I had an opportunity of seeing him, tolerably well. Whenever he felt any tendency to his complaint, a dose of opium and colchicum relieved him

completely; and he took the sesquichloride of iron with good effect.

Spasm.—Spasm of the bladder may arise from various causes, especially the presence of a stone in the organ. Frequently, too, it arises from diseases of the kidney, uterus, or rectum; and in such cases it often appears to recur periodically. According to some, there is an idiopathic spasm of the bladder, to which old people are sometimes particularly predisposed, while others believe it wholly the result of sympathy with neighbouring parts.

Spasm, in many of its symptoms, resembles inflammation, with which it may be readily confounded. But one particular point of difference is the sympathetic fever which accompanies inflammation, but does not attend spasm. The pain, too, serves to assist in the diagnosis. In inflammation the pain is incessant, while in spasm it comes on in paroxysms: in cystitis, it is throbbing, lancinating, and with a sense of burning, but in spasm it is dragging, oppressive, or twisting, and somewhat resembling labour-pains. We may also derive some assistance from the circumstances of the patient: in the young, robust, and sanguine temperaments, inflammation is the more probable disease; in the weak, nervous, and irritable habits of body, spasm. The urine, also, in inflammation, is red and high coloured, and comes away in very small quantity; but in spasm, unless when the paroxysm is on, it is pale, abundant, watery, and of low specific gravity. It may, however, arise from acrid urine, abscesses of the kidney, organic disease of the bladder itself, retention of urine from gout and various other affections, and it often terminates in the affection we shall consider next.

Paralysis.—This is a state in which the bladder is incapable of expelling the urine, in consequence of the want of excitability in the muscular coat, whence it will not contract. It generally occurs in old age. It is indicated by a sense of uneasiness, sometimes of pain, about the neck of the bladder. There is also a sense of tension and oppression, nor is there a feeling of relief from passing off the urine. The bladder too often acquires an enormous size, from the habitual distension to which it is subjected. The urine dribbles away from the patient involuntarily, and, if not relieved, the patient dies, with all the symptoms of suppression of urine. In some, even a rupture of the bladder has taken place, and the patient has died suddenly. The disease, though it may be complicated with some others, cannot readily be mistaken. It arises from the causes previously stated—over-distension

of the bladder, paralyzing its muscular coat—and in old persons, from the partial evacuation of the bladder, by which a considerable portion is left behind, which, undergoing decomposition, becomes acrid, exciting other affections, ultimately terminating in paralysis.

Treatment.—In spasm arising from, or accompanied with, inflammatory symptoms, the antiphlogistic treatment should be adopted; the warm bath afterwards, with opiates, antispasmodics, and anodyne enemata, are effectual measures. In gouty habits, especially if it appear connected with a suppression of the fit, we should apply sinapisms to the gouty joints, so as to produce some inflammation; and we may at the same time exhibit colchicum internally. When there appears to be spasm of the neck of the bladder, giving rise to a species of retention, the tinctura ferri sesquichloridi, in doses of from ten to thirty minims, every ten or fifteen minutes, will very frequently give relief. Indeed, I have often seen this remedy produce surprising effects.

Paralysis.—In paralysis, the first thing to be done is to empty the bladder by the catheter, lest too great an accumulation take place, because, so long as unusual distension is kept up, the muscular coat will not resume its proper tone. If it be connected with an exhausted state of system, as occurs in young and middle-aged subjects after fevers and other debilitating causes, tonics, with the use of the cold bath, will prove serviceable.

Paralysis, however, may depend upon some affection of the spine, or disease of the spinal marrow. In such cases issues or setons in the back, blisters to the sacrum, and the internal use of stimulants, as tincture of catharides, galvanism, electricity, &c. are the most effectual remedies. In one or two instances I have exhibited strychnia to one or two aged persons affected with paralysis of the bladder and a dribbling away of the urine. The affection seemed connected with some disease of the spinal marrow. Strychnia was given in the dose of one-eighth of a grain, gradually increased to one-half of a grain, three times a day. In two it proved successful; but in one, a very old subject, though it appeared to have some effect at first, it produced no permanent benefit. In all cases accumulation of urine in the bladder should be prevented by frequent resort to the use of the catheter.

VELPEAU'S
CLINICAL LECTURES
ON
OPHTHALMIA.

By J. HENRY BENNET, B.L. & B.S.
Sorbou.

INFLAMMATORY AFFECTIONS OF THE
CORNEA.

*Keratitis.—Vascularity of the Sclerotica ;
non-existence of Sclerotitis.*

WE are now about to examine a peculiarly interesting class of diseases, which had never been properly studied or described until within the last few years. Until the commencement of the present century, surgical writers, confounding all the inflammatory affections of the eye and its appendages under the name of ophthalmia, made no attempt to ascertain the precise seat of the disease. Far from throwing any light on the nature of the inflammation, they rendered it still more obscure, by adding to the general term ophthalmia the name of various specific diseases, although the inflammatory affections of the eye are not in reality of a specific nature, as I hope satisfactorily to prove to you in the course of these lectures. It is to the prevalence of these doctrines—to the confusion which they engendered—that we may attribute the slight progress which ophthalmology has hitherto made. Pinel and Bichat were among the first to perceive that they have no real foundation. By their labours they proved, in the most satisfactory manner, that in the eye, as in all other regions of the body, the influence which each tissue exercises on the morbid affections of which it is the seat, is such as to render it imperative that they should be studied separately. It is because surgeons were formerly either ignorant of this fundamental principle of pathology, or otherwise neglected to apply it, that we look in vain in their writings for a description of the inflammatory affections of the cornea, considered apart from those of the other membranes of the eyes.

Diseases of the cornea are of extremely frequent occurrence, as will be seen by the perusal of the various statistical accounts which have been published since the attention of practitioners has been directed to the subject. No membrane of the eye, indeed, appears so frequently to be the seat of morbid action. Thus Saunders says, that out of 1942 cases admitted into his infirmary, there were 659 affections of the cornea; more than a third. Out of

250 cases of eye disease which I treated during the two years I was at the hospital of La Pitié, there were 125 cases of disease of the cornea; exactly one-half. Nor can we be surprised at the frequency of these affections, when we reflect on the superficial situation of the cornea, and on the important functions it has to fulfil—functions which are of such a nature that the slightest alteration in its physical properties constitute at once a serious malady. Is it not, therefore, a singular feature in the history of medical science, that keratitis has only been specially studied since the commencement of the present century, and that even since that epoch many ophthalmologists of talent have not examined the disease with the attention which it deserves?

I shall not, in these lectures, treat of all the morbid alterations which may take place in the cornea, but merely study the inflammatory affections of that membrane. Setting aside, therefore, wounds, contusions, tumors, hernia, &c., I shall forthwith commence the description of keratitis, acute and chronic; and subsequently, as consequences of that affection, I shall describe softening of the cornea, its gangrene, as also the vegetations, abscesses, ulcerations, perforations, and specks, which it so often presents.

Keratitis.

Keratitis is the name under which inflammation of the cornea is generally designated. If we peruse attentively the works of those who have written on ophthalmology, we shall find that several surgeons, in the last century, had a faint view, as it were, of the true nature of the disease, but none described it. Thus Maitre Jan, Boerhaave, Deshayes, Gendron, Janin, and several others, merely mentioned the existence of such a malady. It is to Vetch that we owe, in 1807, the first description of keratitis; but he was much surpassed, shortly after, by Mr. Wardrop, whose attention had been for some time directed to this affection. Mr. Wardrop rendered a real service to ophthalmological science by his account of inflammation of the cornea, which I shall take as the basis of what I am about to say; and since that time, keratitis has been admitted into all nosological classifications. Since then, also, other ophthalmologists have written on the subject, but in a much more general manner, and their description of the disease is much inferior to that of Mr. Wardrop. This being the case, it is singular that M. Hauffbauer (De Cornea, ejusque Morbis, &c. Berlin, 1820) should have been looked upon as the first observer of keratitis. M. Mirault,

who called the attention of the French medical public to this disease in 1823, although he mentions Saunders and Mr. Travers, does not even allude to Mr. Wardrop. Indeed, many symptoms described by Mr. Wardrop, have been repeatedly brought forward as new.

Keratitis may be either acute or chronic, diffuse or circumscribed, general or partial. It may also be external, interstitial, or deep seated, according as the inflammation attacks the superficial layers of the cornea, the tissue of the cornea itself, or its internal surface. This division, introduced by Mr. Wardrop, has been criticized by some as too minute, and more theoretical than practical. The objection, however, is groundless, for the three forms I have just named may really be met with separately; indeed many of you have repeatedly seen them in my wards. The former and the latter are, it is true, generally combined, the one with conjunctivitis, the other with iritis; but this complication does not do away with the utility of a division which bears directly on the prognosis and on the treatment of the disease. I intend to examine separately each of these forms of keratitis; but before I enter upon such an examination, I must enumerate the causes capable of producing the disease, and also describe the symptoms considered in a general point of view, with which I think it necessary that you should become acquainted as soon as possible. You will, no doubt, soon perceive that many of these symptoms are generally attributed to rheumatic or to serofulous ophthalmia, to iritis, to choroiditis, &c.

Causes.—Keratitis is, as you have already seen, a very common disease, accompanying nearly all the other inflammatory affections of the eye. The causes which may give rise to it are exceedingly numerous, and may be divided into immediate or local and predisposing.

Under the head of immediate causes we may class wounds, blows, burns, foreign bodies brought into contact with the cornea; indeed, every species of external violence, as also various operations practised on the eye. It is thus we see the point of the needle, used in the operation for cataract by conching, wounding the posterior surface of that membrane, occasion inflammation of the membrane. To these causes we may add the existence of any disease of the eyelids or of any other part of the eye; the reflection of the sun in warm countries; the introduction of pus, of virulent matter, or of any other impure fluid between the eyelids.

Exposure of the head or of the body to rain or to damp air, and a sudden change

from a warm to a cold atmosphere, have been placed among the causes which are more especially considered to produce what has been called rheumatic keratitis. But this is a form of ophthalmia which, in my opinion, does not exist; and I hope, in a subsequent lecture, to prove fully that my ideas on this subject are correct. These causes may, undoubtedly, give rise to keratitis, but they may also give rise to nearly every other form of malady. We can only look upon them as general causes of disease.

The predisposing causes of keratitis are not well known. In some instances there appears to exist a peculiar predisposition to the affection, independent of hygienic circumstances and constitutional peculiarities, which are, however, generally considered to exercise great influence over the production of the disease. Although, therefore, it is frequently met with in the poorer classes of society—among those who are exposed to the vicissitudes of the atmosphere, whose food is unwholesome and insufficient—you must not suppose that it is only under these circumstances that keratitis makes its appearance. You will see it attack those who live wholesomely, and who are in perfect health: you will meet with it in every age, temperament, and constitution; in the young and in the old—in the lymphatic, the nervous, the sanguineous—in the weak and the robust. It has been said that children are most frequently affected with this malady. Inflammatory affections of the eye are certainly more frequent among them, generally speaking, than among adults, but I cannot say whether the remark applies to keratitis.

Some professions may be considered as predisposing causes. Thus, the reflection of light to which blacksmiths, locksmiths, &c. are exposed, the dust, the corpuscles which float in the air in places where cotton or wool are worked, must often give rise to inflammatory affections of the external tunics of the eye. Watchmakers and jewellers, who make use of magnifying glasses, are also often attacked by this disease.

Many authors assert that climate and season exercise great influence over the frequency of keratitis, and that, consequently, it is much more prevalent in some countries than in others. With respect to seasons, their assertion appears in some degree correct, for although we meet with it in every period of the year, it is certainly more frequent in summer and in winter than in spring and in autumn. I also believe that climate has more or less influence over the disease; but it is extremely difficult to

ascertain how far this is the case, as keratitis is not described in other countries under the name by which it is known here. Dr. Mackenzie, in his work on the Pathology of the Eye, does not describe simple keratitis—a fact which rather surprises me. He speaks of rheumatic corneitis, and of serofulous ophthalmia, but it is difficult to say whether, by these terms, he really means the disease I am now describing. I have, however, heard practitioners say, that they have seen keratitis on the other side of the Channel, and that it was there called rheumatic or serofulous ophthalmia. I am therefore warranted in concluding that keratitis is as common a disease in London as in Paris.

Symptoms.—When the cornea is inflamed the symptoms are either anatomical or physiological. The anatomical symptoms are those which are supplied by the vascularity of the sclerótica, and by the coloration of the cornea. We will examine them with care, as they will enable you, if properly understood, to recognise keratitis whenever it presents itself to your observation.

Vascularity of the Sclerótica.—Non-existence of Sclerotitis.

The vascular appearance which the sclerótica presents in keratitis is one of the most important features of the disease, and differs in many respects from that of the conjunctiva. When the latter membrane is inflamed it offers numerous vessels of a bluish kind, approaching nearer to the colour of venous than to that of arterial blood, which anastomose freely with one another, and thus constitute a moveable vascular network. The vascularity of the sclerótica, on the contrary, is constituted by exceedingly minute capillary vessels, which persons, unaccustomed to the observation of eye-diseases, would at first with difficulty distinguish. Their colour is not always the same: with some persons they are of a vivid red; with others, especially in the first stage of the disease, they are of a pale carmine colour. These vessels advance in a parallel manner without visibly anastomosing with one another, and form a kind of radiated vascular zone round the cornea. They seem deeply imbedded in the tissue of the sclerótica, and on arriving at a short distance from the cornea cease to be visible. They do not all disappear in the same manner; some, leaving the sclerótica, seem to continue their course in the conjunctiva; others appear to re-enter the eye; whilst others remain in the sclerótica. You will easily understand this distribution of the vessels which constitute the vascular zone

I am describing, if you remember what has been already said regarding the distribution of the arteries of the eye. Near the cornea, the vascularity assumes the appearance of a narrow band or ring, which may be complete or incomplete, regular or irregular. This circular band advances about half a line on the cornea, in the same manner as the rim of a watch advances over a watch glass. I cannot say whether it adheres or not to the cornea, as I have never had the courage to ascertain the fact by attempting to introduce a foreign body between them. I am inclined to think it is a fold formed by the injected vessels of the sclerótica. However we may account for its formation, it cannot be confounded with chemosis, which we have seen accompanying inflammation of the conjunctiva. It is merely a thin, narrow, membranous band, neither red nor tumefied, presenting, indeed, none of the characters peculiar to chemosis. In some cases, the membranous band does not exist; the vessels which constitute the vascularity pass on to the cornea, and may be traced, when it retains its transparency, under the form of exceedingly minute filaments, until they terminate about a quarter of a line, or half a line, from its circumference. Sometimes we find neither vascular band nor minute vessels extending into the tissue of the cornea, but a grey circle, about a quarter of a line in width, which either entirely surrounds the cornea, or merely borders it opposite the inner and outer angle of the eye. This is what some authors have improperly called the arthritic circle; it may be assimilated to the senile circle in the healthy eye.

The vascularity of the sclerótica does not only differ from that of the conjunctiva by the distribution of its vessels, but there are also other characters which may serve to distinguish them. Thus the injection of the sclerótica diminishes as we recede from the cornea, that of the conjunctiva on the contrary increases. The width of the vascular zone of the sclerótica, although it varies according to the acuity of the inflammation, rarely exceeds two or three lines; whereas the redness of the conjunctiva is, generally speaking, universal. On pressing the inflamed conjunctiva, and drawing it slightly aside, through the medium of the eyelids, you will find that it is extremely moveable, and that the pressure, expelling the blood from the vessels, renders it much paler. This is not the case with the vessels of the sclerótica: they remain immoveable; no change takes place in their relation to one another, or to the cornea; nor does their colour undergo the least alteration.

Such are the characters by which the

vascularity of the sclerotica may be recognized. The interpretation which I give to this phenomenon is very different to that which is generally adopted by ophthalmologists. I consider it as indicating the presence of keratitis or iritis, whilst they look upon it as symptomatic either of a specific inflammation or of scleritis. Thus in the work of Dr. Mackenzie—one of the most able writers on ophthalmology of the present day—the vascular zone of the sclerotica is described as the characteristic indication of scleritis, a disease the very existence of which I consider improbable. As I wish to prove to you that the opinions I profess are correct, I shall take this opportunity to lay before you the reasons which have induced me to question the existence of a disease so universally recognized and described.

Real scleritis is, in my opinion, an extremely rare disease, if even it has ever been really observed. I do not mean to deny the possibility of the sclerotica becoming inflamed; I am far from pretending to assign a limit to inflammation; but I am firmly convinced that the vascular zone, as also the other symptoms which are described by authors as indicating the presence of scleritis, are merely the result of an inflammatory affection of the cornea or of the iris. This opinion may at first appear paradoxical; I hope, however, soon to place it in a more favourable light. Let us analyse with care the symptoms which authors attribute to this malady; we shall then see whether the lesion of some other membrane of the eye might not equally well account for their presence—whether, indeed, some of these symptoms are not altogether inapplicable to the affection to which they are referred. We must also, in pursuing this investigation, take into consideration the anatomical texture of the sclerotica, and the nature of the inflammatory affections which attack similar tissues in other parts of the body. We shall thus be able to judge how far the German ophthalmologists are right in giving to this supposed affection the name of rheumatic ophthalmia: this they have done from preconceived theoretical notions. Rheumatism attacks fibrous tissues; and the sclerotica being fibrous, they have concluded that the inflammation of its tissue, which they suppose to be indicated by the vascular zone it so often presents, is of an arthritic nature. Even Dr. Mackenzie, however, although under the influence of the school of Beer, is obliged to admit that he has often met with this symptom in patients who had never been affected with rheumatism in any shape; but we will, for the

moment, lay aside all theoretical ideas, in order to submit the facts on which the existence of scleritis is founded to an accurate analysis.

The first question which presents itself to us is, whether vascularity of the sclerotica may be attributed to any other cause than to inflammation of that membrane? To this I shall answer decidedly that it may; that it is quite as rational to attribute this vascularity to keratitis or iritis, as to inflammation of the sclerotica; and in this I am sure you will agree with me, if you remember what I have said respecting the distribution of the vessels of the eye. When the cornea or the iris are inflamed, their vessels become injected; and owing to the numerous anastomoses which exist between the vascular system of these organs and that of the sclerotica, the vessels of the latter membrane also become turgid. The redness of the sclerotica is not, therefore, to be attributed to inflammation, but to the injection of the vessels which exist in its tissue. If, indeed, you examine the eye very attentively, you will find that the sclerotica remains perfectly white between the vessels. An experiment which I have often made satisfactorily proves that vascularity of the sclerotica is not dependent on inflammation of that organ. I have repeatedly endeavoured, by wounding the sclerotica, to give rise to the vascular zone, which is generally looked upon as the symptom of its inflammation, but always without success. A speck, an ecchymosis, or a slight purulent affection, were the only consequences of the lesion. When, on the contrary, I have wounded the cornea, I have generally produced the vascularity of the sclerotica. I do not, however, consider these arguments alone of sufficient weight to warrant our denying the existence of scleritis, as we must also allow that if the tunica albuginea were to become inflamed, that inflammation would be as likely to give rise to vascularity as either keratitis or iritis. We will therefore rest satisfied for the present with the knowledge that this phenomenon may be explained in a satisfactory manner, without our being obliged to suppose an inflammatory affection of the sclerotica.

But if we continue our analysis of the symptoms, we shall find that there are two which cannot be allowed to depend on an affection of this membrane—I allude to intolerance of light, and to effusion of tears. These symptoms are very generally ascribed to the imaginary disease we are now examining, although a few moments' reflection must convince you that they

could not possibly be occasioned by such an affection. The sclerotica is merely an organ of protection, and has nothing to do with the visual functions, nor has it any connexion with the secretion of tears. I shall not, however, enter at present into any details on the subject, as I shall have to treat of these phenomena in a future lecture; I will then prove clearly to you that they are characteristics of keratitis, retinitis, or iritis.

The examination of the symptoms which scleratitis is said to present is evidently far from conclusive with regard to its existence. Let us now see if theory will be more favourable to the general opinion.

If the symptoms which authors ascribe to scleratitis really belong to an inflammatory affection of that membrane, it must be considered one of the most common of the various forms of ophthalmia; indeed, those of you who follow my practice attentively, will remember having seen these symptoms in at least half the patients we have received in the wards for diseases of the eye this year. Now when we reflect on the anatomical structure of the sclerotica—when we consider that it is a tissue which, in other parts of the body, is so rarely inflamed, that some pathologists entertain doubts as to its ever being the seat of inflammatory action—how can we possibly reconcile our minds to the extreme frequency of scleratitis? Again, the inflammation of a fibro-cellular membrane no more remains confined to one spot, limited to a circular portion of the organ, than that of a mucous or a serous membrane, but spreads in every direction. The vascular zone of the sclerotica, on the contrary, never extends to the posterior portion of the membrane; it merely encircles the cornea, gradually disappearing as it recedes from it. You are also, no doubt, well aware that when tissues analogous to the sclerotica have been inflamed, there generally remains some trace of the inflammation, such as thickening, &c. Has any similar lesion ever been seen on the sclerotica when once the ocular inflammation is entirely subdued?

You see, then, that both observation and reasoning are equally contrary to the existence of scleratitis; I therefore feel myself perfectly justified in excluding it from the list of ophthalmiæ, until, at least, its existence shall have been demonstrated in a much more satisfactory manner than has hitherto been done.

CLINICAL OBSERVATIONS ON THE USE OF THE AIR-DOUCHE IN THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE EAR.

By T. WHARTON JONES, Esq.

[For the London Medical Gazette.]

No. IV.

In the preceding cases, the air-douche served both as a means of diagnosis and as a means of treatment. In the three cases next to be related it served only to inform me somewhat of the state of the middle ear, more especially of the perviousness or imperviousness of the Eustachian tubes, and in the case of imperviousness to remove the obstruction. It did not produce any improvement in the hearing such as to warrant a perseverance in its use.

CASE V.—Exploration of the Ears by the Air-douche, showing Obstruction of the Eustachian Tubes—complete on one side, incomplete on the other. Hearing not improved by the removal of the obstruction.

Mr. J. J., aged about 82, grandfather of the subject of Case II.

Right ear.—Dull of hearing for a long time, though pretty useful till within a few years. Has had in the ear a succession of small gatherings or abscesses. The auditory passage is dry, and is occasionally affected with a troublesome heat, followed by the exfoliation of a thin waxy scale. A week ago, on awaking in the morning, could not hear any thing. This extreme degree of deafness is abated now, he being able to hear the human voice, if clear.

Left ear.—Has been useless for thirty years at least. In driving over some newly-gravelled road in a phaeton, lately, thought he heard the noise of the wheels with the left ear, and found that it was undoubtedly so; and on getting home, heard the clock, though in a very low soft tone, as if the bell-hammer were muffled. The left ear is now, however, as insensible as before.

1st August, 1838.—Auditory passages wide; the right presents a sufficiently healthy appearance; the left, dry and scaly.

Does not hear the watch with the right ear, even on close application.

Applied the air-douche on the right side, and found the Eustachian tube quite impervious. On sending in a stream again, thought once or twice I heard the entrance of a bubble or two of air. After the air-douche, heard the watch when applied so as merely to touch the ear.

2d.—Hears the watch in the same way as yesterday.

Applied the air-douche again to the right ear. The air now entered at first with a gurgling, then with a howling or whistling sound, as if it penetrated only in a small stream.

After the air-douche, the watch was heard when applied to the ear, but the patient thought, not so distinctly as before.

Friday, 3d.—Introduced the catheter into the left Eustachian tube; and, on blowing with the mouth, found the air enter with a gurgling sound. A stream of air from the air-press was then sent in, which I heard enter with considerable gurgling.

No improvement in hearing followed this application of the air-douche to the left ear.

Saturday, 4th.—Does not hear the watch to-day with the right ear. Applied the air-douche to the right ear, which entered as before.

After the air-douche, heard the watch in the same way as on the 2d.

CASE VI.—*Exploratory Treatment, by which obstruction of both Eustachian tubes was ascertained, but the removal of which effected no change in the hearing.*

Saturday, 13th Oct. 1838.—Miss K. L. Has been very dull of hearing for about twenty years, and supposes the cause to have been cold caught in crossing from Liverpool to Cheshire.

Has suffered many things of many physicians without benefit. At present hears the watch with the right ear at the distance of five inches, with the left only on application. Has noises in the ears. Hears better in a cold dry air than in warm weather. Hears the chirping of the cricket, even to a painful degree, when a sound ear cannot perceive it.

External auditory passages and membræ tympani quite natural, only that on the left side there is not a due secretion of cerumen.

Applied the air-douche, and found both Eustachian tubes quite impervious.

Monday, 15th.—Applied the air-douche to the right ear, and heard at last some bubbles making their way into the tympanum with a gurgling sound.

Tuesday, 16th.—Hearing distance of right ear six inches.

Applied the air-douche to the left ear. The air did not at first penetrate, but by and by I heard a few bubbles working their way through the obstruction; and at last the air entered in a small jet, with a sound partly whistling, partly gurgling, compared by Mr. Owen, who was present, to the sound produced by blowing one's nose.

Wednesday, 17th.—No improvement in the hearing of the left ear, and with the right scarcely hears at such a distance as yesterday.

Applied the air-douche to the right ear. The air did not at first penetrate, but after a slight gurgling it entered at last in a small, shrill, whistling stream.

Thursday, 18th.—No improvement in hearing.

Applied the air-douche to the left ear. The air now enters freely, and with a rushing sound.

Friday, 19th.—No improvement.

Applied the air-douche to the right ear. The air entered in the same way as on Wednesday.

CASE VII.—*Exploration by the Air-douche, showing perviousness of the Eustachian tube in the ear examined.*

October 1838.—Dr. M. N., a retired physician, hears a loud-ticking wooden clock at the distance of four yards with the right ear; a watch he hears only at the distance of two or three inches. Hears the watch with the left ear only on application.

Applied the air-douche to the left ear. The air entered the cavity of the tympanum with a rushing sound. No improvement in hearing was observed to take place.

Friday, 7th December.—In consultation with Dr. Bennett, at Dr. M. N.'s request.

Applied the air-douche to the left ear again to-day. The air entered as before, and the Doctor could afterwards hear his watch at the distance of about an inch and a half.

A contraction in the right nostril

prevented the introduction of a catheter into the right Eustachian tube.

REMARKS. — Case I. showed that simple obstruction of the Eustachian tube is not of itself sufficient to cause a very great degree of deafness. In Case V., just related, the duller ear was that in which the Eustachian tube was pervious; in the other ear the tube was obstructed, but the removal of the obstruction produced little or no change. In Case VI. both Eustachian tubes were quite impervious; but the restoration of the access of air to the tympanic cavities was not followed by any amelioration of the deafness. In Case VII. the Eustachian tube of the ear examined was quite free. These facts are sufficient to expose the incorrectness of the principle alleged in favour of the operations of perforating the mastoid process and membrana tympani, even supposing the condition said to require one or other of those operations, viz. closure of the Eustachian tube, had been always unequivocally ascertained to exist.

The pathology of the ear not being sufficiently known, a direct diagnosis cannot be drawn from the exploratory treatment above detailed. It can only be said, *per exclusionem*, that the proximate cause of the deafness did not lie in the external parts of the ear, nor in the Eustachian tubes, nor in any accumulation of mucus in the tympanic cavities. Was it owing to thickening or other change in the texture of the membrane lining the tympanic cavities, and, consequently, of the membranes closing the fenestræ? or was it owing to some change in the labyrinth in general? or to affection of the auditory nerves in particular?

It would be of the greatest importance if these questions could be satisfactorily answered, because the state of the ears under consideration appears to be, more or less, that of a large proportion of habitually deaf persons, and because we should then be more likely to ascertain the signs diagnostic of its commencement, and thus be able to adopt early and efficient treatment on general principles. An inflammatory origin is scarcely to be doubted. This subject will be further considered in another communication.

As to the prognosis in the cases under consideration, the absence of any benefit from the air-douche did not encourage

to its further use; and this, combined with the long standing of the cases, equally forbade the hope of obtaining advantage from any application made directly to the membrane lining the tympanic cavities. General treatment was out of the question: in Case VI., indeed, it had been already tried in vain, and even to the extent of implicating the health.

The following case, one not of such long standing as the above, presented, during the exploratory treatment, the same signs to the listening ear, but the improvement which supervened was such as to encourage further attempts, either by the air-douche, or by the injection of ethereal vapours, according as events in the course of treatment might have indicated.

The patient, however, finding his hearing improved as much as his business required, had no inclination to undergo further treatment.

CASE VIII.—*Exploratory Treatment followed by some improvement of hearing.*

Thursday, 21st February, 1839.—O. P., a house-porter, aged 46. Was affected with a severe cold a fortnight ago. Within this last week deafness came on. Has been subject to attacks of deafness when affected with cold.

Hearing distance of the right ear, five inches; of the left ear, one inch.

Nothing in the external auditory passages to account for the deafness.

Applied the air-douche to the right ear. The air entered in a small whistling stream.

No improvement immediately after the air-douche.

Friday, 22d.—Right ear, seven inches.

Applied the air-douche to the left ear. The air entered in a small irregular stream, with a whistling, screaming sound.

No improvement observable immediately after.

Monday, 25th.—Right ear, two feet and a half; left ear, eight inches.

Left ear treated. Air entered readily and freely, with a whistling and rushing sound.

No further treatment submitted to.

REMARKS.—This patient must have been affected with more or less deafness for a long time. As, comparatively, a very small degree of hearing is sufficient

for all ordinary purposes of life, and as the affection of the structures of the ear giving rise to deafness is in many cases unattended by pain, it is allowed to go on for a long time without the patient's notice being particularly attracted to it: hence one cause of the great intractability of diseases of the ear.

Having discussed those cases in which the exploration points only to an unfavourable prognosis, I now come to consider those in which, from the circumstances of the youth of the patient, the short standing of the complaint, or, it may be, some small improvement effected by the air-douche, as in Case VIII., just related, the expression of a less unfavourable prognosis is justifiable. In such cases, what experience of any value we possess indicates, in addition to appropriate general treatment, a direct medication of the middle ear. If the principle on which I have in the previous communications endeavoured to explain the sometimes beneficial action of the vapours of acetic ether injected into the tympanum be not freely admitted, then I hold the use of the remedy to be as yet entirely empirical. In addition to its effects in Case III., the pathology of which was pretty evident, and those to be related in the continuation of Case II., the nature of which we can also in some degree trace, I may here mention, that in cases in which, without there being actual obstruction of the Eustachian tubes, the air, nevertheless, does not enter freely, the application of the ethereal vapours is followed by a greater freedom to the entrance of the air. This, I think, is similar to the relief obtained, as first pointed out by Dr. Boottcher, of Copenhagen, and more recently, though in an exaggerated manner, perhaps, by M. Raspail—a relief I have myself experienced from the action of the vapour of camphor applied to the nostrils when obstructed from catarrh. I do not mean to say that nervous deafness does not occur, but if by nervous deafness is meant some disease of the auditory nerve at its terminating expansion in the labyrinth, at its origin from the brain or in its course, in short, an affection analogous to what we call amaurosis in the eye, then it may reasonably be doubted if the injection of the vapours of acetic ether into the tympanum ever benefited a case of nervous deafness. Exposing the eyes to ethereal

or other stimulating vapours is not unfrequently prescribed along with other remedies in cases of amaurosis, but with how much advantage?

CASES OF ASTHENIA.

BY MELBOURNE B. GALLWEY, Esq.

Assistant Surgeon, Royal Artillery.

[Concluded from p. 770.]

THE case, of which I am now about to give a brief detail, occurred in the Royal Ordnance Hospital at Woolwich, in October last; and although some considerable time has now elapsed since the period of its occurrence, in consequence of my absence from the country on foreign service; yet so strongly impressed on my mind is every circumstance connected with its history, that what the notes I have preserved of the case do not supply, my memory, I doubt not, will fill up.

Thomas Bullock, æt. 20, a gunner in the Royal Artillery, and a delicate-looking man, of a leuco-lymphatic habit, was admitted into the hospital on the 9th of October, 1838, with some tenderness about the false ribs on the right side, unattended by fever, but characterized by a general air of languor and debility; pulse soft, weak, and frequent; tongue clean but exsanguineous; skin cool and somewhat rough.

For these symptoms he was ordered by the surgeon under whose care he was placed—

Haust. Emetic. statim. Pulv. Ipecac. comp. gr. x. vespere.

10th.—Emetic operated well, but brought off nothing unusual in appearance from the stomach. The pain and tenderness continuing unabated—

Cueurbitulæ eruentæ parti affectæ applicentur. Habeat æger Mist.* Diaphor. Aperient. 3iss. ter in dies.

11th.—Much relieved by the cupping; passed a tolerable night.

Continuentur Mistura ut heri.

12th.—Pain in the side returned and aggravated; pulse 80 and feeble; no febrile movement; passed a restless night.

* This medicine is composed of Magnes. Sulph. oz. j.; Antim. Potass. Tart. gr. j.; Aquæ, oz. viij.

Empl. Iyctæ lateri dolenti applicetur.
Continuentur Mist. ut antea. Habeat
Pulv. Ipecac. comp. gr. x. vespere.

14th.—The pain was relieved by the blister, and has continued so since the last report. Bowels kept open by the aperient medicine.

Continuentur Mist. et Pulv. Ipecac. comp.

15th.—Passed a good night. Pain has not increased; some dryness and heat of skin to-day; great prostration of strength and dejection of mind.

Continuentur Mistura. Hirudines vj. lateri dextro. To have beef-tea.

18th.—No material change in the symptoms since the report of the 15th. The pain, however, has returned with its original force, accompanied by some febrile movement, but the debility and dejection are excessive. Ordered by the surgeon—

Venæsectio. Omittantur Mist. Diaphor. Aper.

R Hyd. Chloridi, gr. j.; Pulv. Opii, gr. ʒ. Ft. pil. j. Habeat uiam bis in dies. Beef-tea to be continued.

19th.—The patient bore the blood-letting so ill, that I had scarcely taken four ounces when he fainted; blood, however, slightly buffed, exceedingly pale, and impoverished in quality; red particles scarcely perceptible; expresses relief from the bleeding; pulse 80, feeble, and small; skin moist.

Continuentur Pilulæ ut heri.

21st.—Pain much diminished; extreme weakness continued.

Continuentur Pilulæ Hydr. Chloridi.

24th.—Has continued in the same state since the last report; very slight tenderness now remains in the site of the original affection of the side; lies flat on his back, complains of no pain, and the only prominent symptoms which now attract attention are those of extreme exhaustion. Gums slightly affected by the mercury.

Omittantur Pilulæ. Ordered sago and wine instead of beef-tea.

Sept. 6th.—No species of improvement or alteration in the patient's symptoms since the 24th ult. Says he feels no pain or uneasiness, and is rather comfortable than otherwise; sighs at every twelfth or fifteenth inspiration

and says he is sensible of his heart beating now, which he had not observed before. Some infusion of quassia was ordered him on the 1st, and a mutton chop a day or two before, which, however, though continued daily, he has scarcely been able to touch. Face presents a deadly pallor, with a peculiar leaden hue; features shrunk; eye dull, and surrounded by a dark areola. On the whole, if one might suspect organic mischief to be going on in this case, his appearance rather indicates abdominal disease than aught else; but, on the most careful examination of the abdomen, no fulness, no tenderness, is detected. The stools are pale, but otherwise natural, and require to be solicited by medicine.

Omittantur Infus. Quassiae.

R Quinae Disulphatis, gr. vj.; Infus. Rosæ comp. ʒiv. Misce. Habeat tertiam partem ter in dies.

9th.—Complains of severe diaphoresis in the morning; bowels confined; feels no pain.

The gentleman who had hitherto superintended the treatment of this case being himself taken ill, the patient was placed under another surgeon, who desired the quinine to be omitted, and ordered the following:—

R Creosoti, ℥v.; Mist. Acaciae, ʒiij.; Aquæ Cinnamomi, ʒiiss. Misce. Sumat æger tertiam partem ter in dies. Olei Ricini, ʒiij. statim.

13th.—Patient says the creosote does not disagree with him. No change, however, for the better. Continues to perspire profusely towards the morning; rests badly at night; complains for the first time of pain in the right iliac region; no perceptible fulness there; appetite stagnant.

Habeat Olei Ricini, ʒss. statim. Continuentur Creosoton ut antea.

20th.—Still no change for the better; face and surface of whole body exsanguineous to an extreme degree; tongue of a chlorotic appearance both in colour and density; pulse exceedingly feeble; bowels confined; appetite beginning to improve; enjoys more rest at night; no return of pain in the right hypochondriac region; the uneasiness in the right iliac has also left him.

Continuentur Creosoton.

R Pil. Hydr. gr. v.; Pulv. Rhei, ʒj. ft. pil. ij. Habeat j. mane nocteque.

On the following day creosote was exchanged for—

R Quinæ Disulphatis, gr. v.; Ferri Sulphatis, gr. iv.; Infus. Quassiae, ℥iij. ss.; Syrupi Aurantii, ℥iij.; Acidi Sulph. Dil. ℥xxv.

Misce. Habeat æger tertiam partem ter indies.

The diaphoresis continuing, sponging the surface with warm water has been employed with some benefit.

27th.—On the 24th this patient was manifestly improving under the use of iron and quinine; and the amendment now is remarkable, considering the short time they have as yet been made trial of. His face is less bloodless, and his general aspect approaches more to a state of health.

Oct. 2d.—Steady and progressive improvement; is entirely free from pain or uneasiness; all the functions are in healthy action; appetite becoming voracious. Says he gains strength perceptibly every day.

Continuentur Mist.

14th.—Since the last report of this case, the patient has so far recovered as to be enabled to walk about the ward. The chlorotic aspect of his face has given way to a light rosy tint, and the roundness and fullness of health have taken the place of the former falling-in of the features. Is now placed on full diet, with a pint of porter daily, which seem perceptibly to invigorate his health.

27th.—This patient has continued to convalesce since the 14th inst. and, at his own urgent solicitations, has returned to day to his duty.

There are some points of considerable practical interest in the history of the preceding case. The subject of it, constitutionally a delicate man, had been but a short time in the regiment, and, like many young recruits, who enter the service in a moment of temporary distress or of unnatural excitement, had pined for some time to return to his home, and been further depressed, physically as well as morally, by the severity with which the drill falls at first on the recruit. Hence we see a sufficient explanation of the causes which may first have undermined his health. Depression of mind and body reacting on one another—"the sword wearing out the scabbard," and the rust of the scab-

bard feeding again on the sword. Hence arose a general debility, depression of spirits, and decline of the appetite—symptoms he acknowledged to have been under the influence of for a considerable period antecedent to his admission into hospital. Here we probably have an explanation of the predisposing cause of the subsequent state of suffering. With the languor of the appetite (arising, we may suppose, from a state of exhaustion of the nervous and muscular powers of the stomach,) we should probably find co-existent an accumulation of the intestinal secretions, from a similar condition of the exhausted energy of that canal, and a depraved state or deficient quantity of the bile, as another consequence of the depression of the sanguineous system. Imperfect or impoverished chyle would be elaborated, and, finally, from the latter so depraved and lifeless a kind of blood, as sufficient in itself to account for the symptoms of anæmia which arose subsequently. Here, then, we behold a state of the system in every respect the opposite to that in which we might look for excessive action; although in such a condition I am aware we occasionally meet with local determinations of blood, especially in the brain or its membranes. All the symptoms in this case, from the first, strongly betokened, in my mind, a state of great depression and exhaustion of the nervous and arterial systems. I should have attached no more importance to the pain and tenderness in the right side than to a similar symptom we meet with in chlorotic girls, which Dr. Marshall Hall believes to be dependent on a loaded or abnormal condition of the colon in its transit by the seat of pain. Again, there was no increased action of the pulse—no febrile movement accompanying it. But what more than all should have induced us to look further for an explanation of this symptom than to a state of inflammation, is, that the expected relief did not follow upon the administration of the remedy calculated to subdue such a condition of the part; nay, that when repeated, the same result not only followed again, but the symptoms for which it was prescribed became aggravated under the treatment.

"This is a circumstance," says Dr. Marshall Hall, in alluding to topical pains in the course of diseases of debi-

lity, "which ought always to excite the attention, if not the alarm, of the physician." "It is certainly," says the same physician, "the passion of the present day to consider all painful affections to be inflammatory. But I am persuaded there is great danger in this opinion, and that it has frequently led to the adoption of measures which have issued in the sinking of the patient." Again, in another place, "I have seen many, very many, cases of protracted indisposition, which have entirely ensued from the misapplied and unnecessary use of the lancet; and I would insist upon this point the more earnestly, because I believe it will generally be found, in such cases, not only that the disease was mistaken, but that other remedies, which ought to have been administered with or without the blood-letting, had been omitted; and it is incumbent on me to observe, that protracted indisposition is not the only bad effect of misapplied blood-letting, but that that remedy has, as well as the neglect of it when necessary, been attended with fatal consequences*." The topical means employed in the present case, for the relief of the pain and tenderness, having failed of success, the patient was subjected to general bleeding. The fate of this experiment I have already mentioned. Scarcely had I opened a vein when the patient fell back and fainted; a circumstance which every sound and practical man of the present day regards as an eloquent argument in favour of the necessity of an opposite mode of treatment, or, at least, of there being a contra-indication for the use of the former. It is true that the pain and tenderness, for which blood-letting was here prescribed, were to a degree overcome by the remedy; and this must really be considered a very unfortunate arrangement in the economy of our system, for it entices men to renew the same treatment; so, also, in cases of excessive pain, throbbing of the vessels of the head, delirium, &c., when the offspring of an exhausted state of the brain, we find these symptoms give way to and are greatly relieved by blood-letting; but they are aggravated soon after in a tenfold degree, and the patient hurried on, peradventure, to the fatal goal, to which before he had been quietly and leisurely travelling.

I look, indeed, upon the employment of general bleeding, in the case under our notice, to have been a mistake of the most serious nature, and one which, if repeated, might probably have disabled nature effectually from making further head against the struggle.

The next point of interest in this case which occurs to my mind, is the immediate and remarkable improvement effected by the introduction of iron into the system. We have seen how ineffectual was the adoption of every preceding plan of treatment. The creosote might have been calculated to urge on the feeble circulation, but it could have no power in enriching the vital fluid, by which alone the system could have been recruited and supported, and restored to its natural condition. Iron, indeed, I look upon to have been the indication in the treatment of this case, from the very outset of the affection. Iron and porter would have cured the disease at once, and removed every local symptom that in such cases is wont to stalk forth as a fresh disease; whilst, I believe, it would as certainly have continued to resist every other remedy in the Pharmacopœia.

On the whole, I look upon this affection to have been a genuine case of chlorosis in the male—a disease which every now and then presents itself in practice, to remind us of the possibility of its occurrence in our own as well as the opposite sex, although we must admit that such cases are sufficiently rare. I was at first disposed to consider it an example of that affection designated and described by Dr. Marshall Hall as "disorder of the general health," acute at first, then lapsing into the chronic state, which he so forcibly pictures of that disorder. But on a careful review of every symptom and every circumstance attending its history and progress, and more particularly from the absence of that peculiar condition of the tongue and fauces, which he deems almost indispensable to characterise the above disease, I have no doubt of the case being one of genuine chlorosis, as described in books to be met with occasionally in the male, although it is the only instance I have met with myself.

LANGENBECK'S
SURGICAL PRACTICE
AT
GÖTTINGEN.

To the Editor of the Medical Gazette.

SIR,

HAVING had occasion to spend three or four weeks at Göttingen, I made a few observations there, amounting, perhaps, to little more than gossip, but which are at the service of your readers. Most of them will have heard of Langenbeck. On June 26th last, I paid a visit to his clinical hospital, and saw him for the first time. He is somewhat above the middle height, and has a fine muscular development, especially of the arm and leg, to which he probably owes much of his dexterity. His crown is bald, hair inclining to grey, nose Roman, and whiskers worn across the cheek. He came into the theatre to perform two operations, dressed in a short linen jacket, reaching not quite to the hips, and with sleeves terminating above the elbow; the forearm was bare, and he had an oil-cloth apron tied round him. The first case was an *amputation above the knee*. The patient was a youth, with serofulous disease of the knee-joint. The preparations for the operation were exceedingly simple. Two basins with water and sponges on the floor; a few ligatures in the hand of one assistant, a saw, and three or four pairs of Amussat's and the common forceps, in the hands of others; a case of scalpels, and a case containing two amputating knives, on a little side-table. The simplicity of the apparatus contrasted strongly with the pails and saw-dust, and glittering array of knives and scissars, and scalpels in extended file, flanked by tourniquets, bandages, strips of plaster, piles of rag, &c. witnessed in some English hospitals. The knife which Langenbeck uses is supposed to be peculiar to him, and in consequence has received his name; but its prototype may be seen in the hands of any butcher in England, being a short knife, rounded at the point. The blade and handle are each about four inches long; the former about 5.8ths in breadth. The artery being compressed by an assistant, Langenbeck took the knife just described in his hand, stepped back two steps—stood in a theatrical attitude, with the knife ele-

vated above his head; then darted upon his patient, and made a deep gash on the outer part of the lower third of the thigh, cutting half away through to the bone; the knife describing a slight curve downwards and backwards; another application of the knife, slanting upwards, reached the bone. The same method was followed on the opposite side. The knife was then made to describe one or two turns round the bone; was changed for the saw; the muscles were retracted by the hand, and in about one minute from the commencement of the operation the limb was severed. The artery was sufficiently compressed to prevent a jet, but not enough to secure the patient from the loss of more blood than he ought to have suffered, considering his age and great debility. After tying the arteries, the thigh was rolled, and the face of the stump slightly covered with a piece of rag. The patient was then taken to his bed, and rag, wet with cold water, applied. In an hour or two, the lips of the flap were united by four or five sutures. Next day I found the roller removed, and nothing upon the stump except a strip of wet paper along the line of union. This mode of water-dressing has been practised by Professor Langenbeck for about thirty years. It is not so good as Liston's, because there is nothing to prevent the paper drying. To remedy this, a painter's brush and a basin of water stand close to the patient's bed, that the paper may be moistened from time to time.

Extirpation of part of the tongue.—Next came a female, aged about 40, with scirrhus disease of the right side of the tongue. Two stout ligatures were first passed through the tongue, by which the assistant was enabled to retain it firmly out of the mouth, and the diseased part was then cut away by means of a common scalpel. Two or three arteries were twisted and tied. This was an out-patient, and when I left was well.

Chronic abscess treated by a seton.—Next came a boy with a tumor in the upper part of the thigh. It was a doubtful case, and there was a long inquisition upon it. It is well known, that in the German clinics there is a student in charge of each patient, who is examined by the professor, respecting the case, in the presence of the class. The questions put are those suggested by the

anatomical and physiological relations of the part affected; and the professor rectifies, explains, or illustrates, the answers: in doing which, Langenbeck mingles a little wit, a good deal of theatrical gesticulation, and a good deal of extraneous matter, with much useful information. The wit, gesticulation, and foreign matter, are far from being useless, as they serve to impress the case upon the memory of the students, by exciting and keeping up their attention. Indeed, nothing is more dull and soporiferous than one of these cliniques conducted with legitimate professional gravity. Langenbeck is generally censured for his declamatory and showy manner, in which he strongly resembles Lisfranc; but he is in the right.

There were some symptoms which indicated a foregone conclusion in this case, although so much was said and done before the treatment was entered upon. The assistant-surgeon at last brought into view a formidable looking instrument, which I had observed lurking in his hand at the time the case came into the theatre. This was a long needle, not unlike a packing needle with an eye at the sharp end, but twice as thick, and three times as long, measuring, I think, not less than fifteen inches. This unwieldy instrument baffled even Langenbeck's dexterity, as, after he had thrust it into the lower end of the abscess, it was only after repeated mishaps that he was enabled to guide it aright, and bring out the point at the place where he wished. A seton thread was then put through the eye, and the needle drawn back. In a week or two the thread had cut through nearly the whole of the intervening skin, leaving two large ulcers.

Fungus hæmatodes of the os humeri: amputation at the shoulder-joint.—This patient came into the hospital on July 1st, and the limb was amputated the next day. A large irregular tumor extended from the elbow to nearly the shoulder, marked with large blue veins, and having bosses upon it of various degrees of hardness. The man was about 30 years old, with a sallow complexion, and uneasy anxious expression of countenance; the disease had commenced three years before. The preparations for the operation were exactly the same as for amputation of the leg. The patient was seated on a low chair,

with his side to the operator. So soon as all was ready, Langenbeck stepped into the area, took his knife, and approached the patient. An assistant covered his eyes. The operator made a deep gash in the outer part of the shoulder to the head of the bone; then withdrawing the knife, it was curved round the shoulder, so that its point rested in the lower end of the incision. From this point the second incision proceeded upwards, to terminate in the upper end of the first. There was another turn or two of the knife in the joint, and in about half a minute Langenbeck threw the amputated limb on the floor. In the case of amputation of the thigh, there was a combination of the flap and circular method; but in this case there was no flap, and consequently we had a round surface, with the glenoid cavity not far from the centre. The subclavian artery was effectually compressed, and the arteries rapidly tied, those which had retracted being dissected out by a small scalpel. The patient was treated like the boy. Next morning I found the lips of the wound united by numerous sutures. The thread of the sutures in common use is three-thread sewing cotton. On the eighth day the patient had pain in the head, fever, &c. and was bled. The professor remarked, that sometimes after excision of the humerus the patient becomes insensible, the breathing stertorous, and there are all the symptoms of apoplexy. These were relieved by bleeding; and although a few days after, slight secondary hæmorrhage recurred, in three weeks from the operation I found the ligature was removed from the axillary artery, and the wound in a fair way for healing.

Extirpation of the uterus.—After the preceding amputation was finished, a preparation of the female organs of generation, without a uterus, was exhibited, the vagina terminating in a *cul de sac*. This preparation had been taken from the body of a female, who consulted Langenbeck twenty-four years ago for complete prolapsus of the uterus, when he extirpated it. As accoucheurs and others had expressed their doubts that the operation had been really performed, because they fancied it impossible, the display of the preparation was a genuine triumph, and was exhibited in the manner peculiar to the professor. Dr. Langenbeck, the nephew—a most indefatigable pathologist,

but those by which the poor might be seduced into selling their fairest birth-right—liberty—for food and raiment. In every European country so many wretched beings are constantly living on the brink of famine, that unless the law interposed its humane prohibition, there would be great danger of the revival of serfage, if the indigent were allowed to sell their very life for drachmas.

We do not know what the English law says to these bargains, but we should hope that it repudiates them: yet the candid must allow that some approximations to slavery take place even in England. The friendless children, for instance, who are drafted from our workhouses into the service of needy householders, are in a state which has not many of the attributes of freedom. The contracts made for them by the parish authorities are seldom advantageous, and the threefold choice of toiling for a painfully inadequate reward, of returning to the workhouse, (and that perhaps a union bastille!) or of starving, might seem to leave the serf but little to envy. After all, however, the state of the parish child, though a reproach to civilization, is better than that of the serf chained to the soil; for while the *adscriptus glebae* is exposed to still harder usage unrebuked by law or custom, and has scarcely a hope of advancement, the alumnus of Marylebone or St. Pancras may appeal to boards and magistrates, and may rise to anything that he is fit for. Now, it appears from the decision of the Court of Cassation, that the French law, though jealous of the liberty of every citizen, and utterly disallowing serfage under any disguise, has no apprehensions for the freedom of family physicians, and looks without alarm on the life-long services of Dr. Mojon, and the perpetual annuity which rewards them. Although a physician may become the slave of fashion, or

the slave of theory, the French law does not fear that he will be made the slave of his patient. Yet among the ancients this was so common, that a scholar of the last century wrote an essay, *De servili medicorum apud antiquos conditione*. In stating the fact so broadly he fell into an exaggeration, with the intention, we believe, of vexing Dr. Somebody, his acquaintance.

Every human being must be satisfied with the defeat of Madame de Fenchères, and yet every one must see the imprudence of a bargain of this sort, by which the patient may be compelled to see a physician for half a century, who has outlived her liking in a month. The *Gazette Médicale* has just been informed, that on the 24th of August the Baroness sent a tipstaff to summon M. Mojon to attend her professionally!

If forensic medicine is the science where law and medicine touch, this encounter of doctor and patient, after three law-suits, may be truly called a medico-forensic meeting. The handsomest and most sensible thing the lady could do on such a visit, would be to pay the Professor the large fee of 200,000 francs imagined in the contract, and restore him to the freedom concerning which she was so anxious.

STATE OF THE POOR OF GLASGOW.

It is now about six months since we reviewed Dr. Cowan's Essay on the Vital Statistics of Glasgow, and gave an abstract showing the increase of disease and mortality in that great city*. After mentioning some of the methods by which the state of Glasgow might be improved—such as building hospitals, forming drains, and teaching the poor to clean and whitewash their houses—we added, "the evils are so enormous that one might imagine there

* MEDICAL GAZETTE, March 2, 1839.

must be a slowness to subscribe in the good town of Glasgow."

This conjecture is unfortunately confirmed by the "Fourth Annual Report of the Glasgow University Lying-in Hospital and Dispensary," which has just reached us. In a town where fever and small-pox multiply their ravages, until the number attacked by the former disease in 1837 is estimated by Dr. Cowan at 21,800; where the constant influx of Irish indigence adds to the number of those whom disease finds helpless and destitute; in a town, finally, where commerce enriches not few and far between, but hundreds and thousands; we should have imagined that an institution like that whose Report is before us would have been fostered by the warmest patronage, and that merchant and manufacturer would have hastened to alleviate those ills of which they were in some measure the cause. Instead of this, the subscriptions and donations for the year 1838 amounted to £86. 15s. 3d.; and even this ridiculously minute sum was greater than the preceding year. Adding fifteen guineas from the College of Glasgow, ten pounds from the City, the fees of students, amounting to £44. 8s., and two other small items, the whole income was £165. 14s. 3d. One might be inclined at first to suppose that this lamentable deficiency of subscriptions arose from the institution being destitute of distinguished patrons, and that it had usurped the title of "University," though in reality only the obscure Charity of a few second-rate traders. The fact is, nevertheless, that among the office-bearers we find the Lord Provost, the Sheriff of the County, the Principal of the University, the Rev. Dr. Brown from the Clergy, and the Dean of Guild. How with this scanty sum the Directors contrived to treat 125 cases in the hospital, and 297 at home, besides 1837 Dispensary patients, is really a difficult problem;

but we fear that the line which separates economy from parsimony must often have been overpassed.

The Report gives a melancholy picture of the state of the poor of Glasgow. The streets in which they live are ill paved and badly lighted; many, indeed, being wholly without lamps. These dwellings are often "quite ruinous, unfit for lodging human beings, and such as would be condemned by any board of inspectors." The authors of the Report suggest the establishment of a board of this kind, and also of a building society, to supply the poor with better rooms at more moderate rents. Both these suggestions are worthy of attention; but while the former could not be carried into effect without an Act of Parliament, the latter might be realized by any association of philanthropists, or, indeed, by a single one. Spirit drinking is making frightful advances among the lower classes of both sexes. The Reporters advise that Temperance Societies should open small shops where the poor might obtain hot broth, tea, coffee, chocolate, &c. for a trifle; they also wish for an increase of the duty on malt* and spirits, and the punishment of drunkenness; and they justly suppose that the want of amusements is an exciting cause of intemperance. Unfortunately, the passion of the day is too exclusively a dry utilitarianism, and innocent entertainments for the common people are neglected, or scouted. The Reporters do not mention the establishment of public baths at a low rate, though this is one of the most crying wants in every part of these islands. The Report is sensible as well as benevolent; but we acknowledge that the amazing tenuity of the hospital and dispensary income disheartens us, and makes us apprehend that if Glasgow is to be much improved, it must be by assessment rather than subscription.

* We do not agree with them on this point, as we have no wish to add to the price of beer.

proving "that when the arteries and veins of a part are tied, the nerves being left entire, and the acid introduced into a wound, it does not act, but takes effect the instant the ligatures are removed from the blood-vessels." He adds, that either on the hypothesis of Brodie or Krimer the cause of the retardation of death in my experiment is obscure. Certainly it is. But just admit that the sympathetic nerves have an important influence over the action of poisons, and it is plain enough. We can then also readily explain Krimer's results, for by tying *all* the vessels, the communication between the ramifications on their surface and the ganglionic centres would be cut off almost as completely as by dividing the nerves.

No one can be less desirous than myself to jump to any conclusion before my experiments have been repeated by other and abler hands. This I thought sufficiently evident from my letter; and will only add, that after carefully considering the *reply* of Dr. Allnatt, I am unable to discover any point in it at all opposed to my statements or opinions, and remain, sir,

Your obliged and constant reader,
THOMAS S. WELLS.

Barnsley, Aug. 14, 1839.

NOTE ON DR. MARTIN BARRY'S REPLY TO MR. WHARTON JONES.

By T. WHARTON JONES, Esq.

[For the *London Medical Gazette*.]

THE following passage occurs in Dr. Barry's "Observations in reply to T. Wharton Jones's *Strictures*," contained in last week's number of the *MEDICAL GAZETTE*:—

"But there is one point upon which T. Wharton Jones seems to set up 'pretensions to novelty, originality, and correctness,' on which I must be permitted to say a few words.

"In 1835 this author presented to the Royal Society an account of the germinal vesicle discovered by him in the mammiferous ovum; adding, in a postscript in reference to this discovery, 'it would appear that M. Coste has anticipated me.' The Memoir of T. Wharton Jones not having been printed in the *Philosophical Transactions*, the author

published it at full length in the *MEDICAL GAZETTE*, in 1838 (No. 18, p. 680), with the same postscript in which he had yielded the priority of discovery to Coste. It is remarkable, however, that T. Wharton Jones had not in the meantime heard that in 1834 a thesis was published at Breslau, in which ten quarto pages were devoted to a description of the germinal vesicle as existing in the ovum of all orders of the class mammalia, and remarks connected with it. This thesis was by Bernhardt*, but the drawings are by Valentin, who seems to have been the discoverer of the vesicle in Germany. This thesis was particularly referred to in a translation I gave from the German of Valentin, in the *Edinburgh Medical and Surgical Journal*, No. 127, 1836. But farther, in the year 1834 R. Wagner sent to Müller's '*Archiv*' a particular description of the germinal spot, discovered by him, within the germinal vesicle, a structure which he considered constant in the class mammalia—so extended had been his observations. This discovery by Wagner was mentioned in the *Edinburgh Medical and Surgical Journal*, No. 126, 1836, above alluded to, and it was at the same time stated in that journal, on the authority of Professor Johann Müller, that the account had been sent by Wagner to the '*Archiv*' in 1834. Upon these points T. Wharton Jones is silent."

If Dr. Barry will refer again to Mr. Wharton Jones's memoir on the Ova of the Mammifera before Impregnation, as it is printed in the *MEDICAL GAZETTE* (No. 18, p. 680), he will see by several foot notes, signed "Ed. Gaz.," that it purports to be inserted there on the authority of the Editor, and not on that of Mr. Wharton Jones. Moreover, if Dr. B. will turn to page 692 of the *same number*, he will read, under the head of "Analyses and Notices of Books," the following remarks:—

"On the first Changes in the Ova of the Mammifera, in consequence of Impregnation, and on the Mode of

* Symbolæ ad Ovi Mammalium historiam ante prægnationem.

† Mr. W. J. mentioned in his communication of the 20th July, p. 594, that a figure of Bernhardt copied by Dr. Barry (plate viii. fig. 72) represents the spot on the side of the germinal vesicle, whilst the body of the vesicle is concealed by the yolk grains. It is remarkable that Valentin should have passed over in his description what in fact he represents in his delineation.—T. W. J.

Origin of the Chorion. By THOMAS WHARTON JONES, Esq.

"Such is the title of a paper in the Philosophical Transactions for 1837, Part II. The subject is one of so much interest, that we shall copy the paper into our journal; but as about two years and a half ago another paper, by the same gentleman, was communicated to the Royal Society, on the Ova of the *Mammifera before impregnation*, we have given it first, for the better understanding of the other (see present No. page 680). This we the more readily do, as in the paper communicated two years and a half ago, which was only read, not published, is detailed a discovery of great importance in reference to the physiology of generation. We mean the discovery which Mr. Wharton Jones made in the human unimpregnated ovum, as well as in that of other mammifera, of a vesicle analogous to that first described by Professor Purkinje, of Breslau, in the immature eggs of birds and other ovipera. It appears that some time before Mr. W. J. made his discovery, the existence of such a vesicle was asserted in France by M. Coste, of Paris, from some observations he had made on the ova of the rabbit; but an examination of his work will show that he rather vaguely indicated than unequivocally demonstrated the existence of the vesicle. This indication of it, however, by M. Coste, was an inducement to Professors Purkinje and Valentin to recommence their investigations on the subject. The result was a very elaborate description of the vesicle by Valentin, though still incomplete, for he had overlooked one important point, the spot on the side of the vesicle. This deficiency in Valentin's description was afterwards supplied by Wagner.

"Hence, it appears that, like many other discoveries in science, the germinal vesicle of the mammiferous ovum was discovered about the same time in this country and on the continent. But it will be seen from Mr. Jones's Memoir, that he had investigated the subject so fully and successfully as to be able to give such a description of it as is only to be drawn from the united labours of Coste, Valentin, and Wagner.

"A comparison of dates will determine the mere matter of priority. Mr. Wharton Jones's observations were made in the beginning of September 1834,

and his memoir read before the Royal Society, 18th June, 1835.

"We may mention that MM. Coste and Valentin received the great prizes of the French Institute for their communications on the subject."

Mr. Wharton Jones having merely communicated to the editor of the MEDICAL GAZETTE a copy of his paper as it was read to the Royal Society, the editor alone was responsible for the manner in which it was printed; therefore Dr. Barry's insinuations as to want of candour towards Valentin and Wagner, contained in the passage above quoted from his last week's communication, had they been justified by facts, must have become applicable to the editor; but the passage now reprinted from the number of the MEDICAL GAZETTE in which Mr. W. J.'s first memoir appeared, is a complete refutation of the charge.

Addendum to Mr. Wharton Jones's "Observations on the Ova of the Mammifera," &c. in No. 43, p. 592.

In his recent communication on the Ova of the Mammifera, Mr. Wh. Jones mentioned (p. 596-7) that the authority of Professor Rudolph Wagner was quoted by Dr. Barry, in support of the existence of a vitellary membrane in the mammiferous ovum, different from the thick transparent envelope which Mr. W. J. contends is the part analogous to the vitellary membrane of the bird's egg. Mr. W. J. could not then give any quotation bearing on the point from Professor Wagner's Memoir, but having since seen the Professor's more recently published work on Physiology (*Erste Abtheilung, Spezielle Geschichte der Lebensprozesse, Leipzig 1838*), Mr. W. J. finds the following (p. 36, § 20): "In general the yelk-ball lies in close contact with the chorion*, but in very mature ova there may be perceived, though it must be admitted rarely, a distinct space between the inner wall of the chorion and the yelk-ball, which is somewhat farther enlarged by the imbibition of water. We then see that the yelk-ball is bounded by an envelope, which appears a membranous external granular layer (proligerous stratum? † perhaps vitellary membrane?)"

The remarks Mr. W. J. has already made on Professor Baer's mode of

* Vitellary membrane.—T. W. J.

† Keimschicht, stratum proligerum.*

accounting for a vitellary membrane, he considers applicable to the above, and is not without astonishment that Professor Wagner should be undecided whether the external layer of granules of the yolk constitutes the proligerous stratum or vitellary membrane.

August 20, 1859.

VARICOSE CAPILLARIES.

DR. HAKE'S STATEMENT.

To the Editor of the Medical Gazette.

SIR,

IN the pursuit of knowledge there are two great principles to be observed: the first and most important being the dignity which invests the subject; the second, the personal interests of parties occupied in the pursuit. It is of the nature of the latter to affect us too closely; but in the controversy on which I am now entered, I trust I may ever be mindful of the former, whatever may be the character of the language used towards me by an opponent.

For my own part I place but little value on any discovery beyond its usefulness to the public, and am by no means ambitious of being called a discoverer for the mere sake of the title. It would even give me greater satisfaction to resign any fact that I might have arrived at, than be suspected of so low a vice as plagiarism. But when I put you in possession of the principal circumstances which have transpired in the matter at issue between a distinguished anatomist and myself, I am convinced you will agree with me that I could not have selected a more candid line of conduct than that which I have chosen.

About six weeks ago, I passed the latter part of an evening at the house of Mr. Kiernan, Mr. Powell being present. At a very late hour, and after we had examined a variety of objects, Mr. Kiernan, without comment, placed under the microscope a preparation of intestine, and invited Mr. Powell and myself to inspect it. I looked at it for some minutes, and during that time made various remarks, and, among others, one was to the effect that it contained what I had reason to think was varicose capillaries, which was certainly not met in the affirmative by Mr. Kiernan, but by the

remark that one day I should know "all about it," and a repetition of the usual expression that he possessed "some extremely curious things," which he had never shown to any one. My curiosity being excited, I asked him to produce some of these curiosities, not at all expecting him to comply, and added, that he need not be afraid of my betraying him. He answered that he might, perhaps, one day. From that time to the present I have never seen one of his preparations.

Before stating to you the history of my humble researches, and the manner in which they were treated by Mr. Kiernan, to whom they were unreservedly submitted, I shall allude to the statements made by that gentleman in your journal, and examine the nature of his assertions.

As respects my having "repeatedly seen the greater number of his preparations illustrative of the anatomy of cancer," I can only say that I was once at that gentleman's house by invitation, when about half a dozen bottles were handed from his shelves for my inspection; that I have been present once or twice when the same scene has been repeated for the gratification of others; but that instead of these preparations, beautiful as they are, being illustrative of the anatomy of cancer, they contain nothing that may not be seen daily in the anatomical museums of the metropolis.

Mr. Kiernan asserts that "he had told me that he had other preparations illustrative of the mode of development of every description of growth;" that I "had repeatedly asked him to show me those preparations, and to communicate his views to me, promising him that I would not divulge any thing he might communicate to me."

Each of these sentences by itself is in a great degree true: Mr. Kiernan had told me that he possessed such preparations; I did ask him, but not repeatedly, to show me those preparations, and did say that I would not take any unfair advantage; but in the sentence which follows, viz., "that having no reason to doubt my honour, he complied with my request," the truth is entirely distorted; he asserts that in consequence of such request he produced his preparation, whereas the request was made by me subsequently to my seeing that preparation, as stated in my narrative. That Mr. Kiernan "fully explained" to me

that preparation of "varicose capillaries" or even used, or assented to that term when employed by me, I unhesitatingly deny. The real fact is, that he was obstinately taciturn, and that whatever remarks were made came from me, with the exception of such as alluded to the beauty of the object, or the success of the injection.

The assertions which follow in Mr. Kiernan's letter relate to the subject of my researches; I will therefore pass over them for the present, and examine his letter to Mr. Powell, as well as the reply.

The only important part of that letter is contained in this sentence—"Dr. Hake now claims what I then showed him as a discovery of his own, and is about to make it public." In reply to this accusation, I beg distinctly to affirm that I never made such claim, or had such intention; but, on the contrary, at my last meeting with Mr. Kiernan, and before he wrote to Mr. Powell, I told him that I would publicly admit having seen his "preparation of intestine" before having entered on my present investigation.

Since then I have seen this disease in the intestine, but I fairly admit having first seen it in Mr. Kiernan's preparation: not that it was new to me, for I had previously seen aneurismal* capillaries in the spleen.

Mr. Powell, in his reply to Mr. Kiernan's letter, says, "during the time (which was about an hour and a half) that Dr. Hake was examining it (the preparation) with the microscope, you pointed out several different parts to him, one of which you said was disease in its most incipient state. Dr. Hake said he could sit and look at it all night, and wondered you had not published it. He thought if you did not do so, it was likely some one would do it before you; and he added, he would be as silent as the grave."

I have already stated how long I looked at this preparation, which, although it showed no principle, but only a disease of capillaries in a particular structure, I admired as a microscopic object, but expressed no more admiration than I had done on examining the circulation in an aquatic plant, which I had looked at for a much longer time

that evening, and which Mr. Powell was absorbed in while Mr. Kiernan and myself were viewing the intestine. But Mr. Kiernan did not point out "different parts," one of which was illustrative of disease in its "incipient state," as Mr. Powell intends to imply: he only moved the preparation to show the parts which were injected. He said that he had preparations illustrative of the different stages of disease, which led me to remark that I wondered he did not publish them, for the Germans and French were hard at work, and, if there was any thing to be found out, they would succeed. To this Mr. Kiernan replied, that no one living could find out what he had done—it was utterly impossible: to which I rejoined, that the human mind was sufficiently alike in all men, and that one could observe as well as another, if he had but the industry to work; and these were the sentiments which I repeated to Mr. Powell while walking homewards in company with that optician.

Some weeks after this the diseased liver of a rabbit was sent to me by my poulterer, who had been in the habit of supplying me with various things for dissection. This liver was covered with what appeared abscesses. I examined the purulent matter which the cavities contained, and found that it consisted principally of ovate bodies—a form of pus which I had never before seen. Being satisfied, from this examination, that the disease was of more than usual interest, I took the liver to Mr. Kiernan, and stated to him that a disease had fallen under my observation, which probably would especially interest him, the liver being his subject, and requested him to accept it as an addition to his collection. He replied, that he was acquainted with the nature of the disease—he had seen it in the mouse and other animals—that, in fact, it consisted of abscesses. I continued, that I should like to show him the pus of these abscesses, as it presented remarkable characters. After a time we placed a small quantity of the fluid under the microscope. The first glance at it arrested his entire attention. "This," he said, "is wonderful; this is a discovery. I advise you by all means to work it out. I dare say, he said, I have some of it in my collection, but when I was collecting these fluids, I had not a microscope. You should call on the person who sent you the disease, and find out

* It may be suggested that I am indebted to Mr. Gerrard's letter for this expression; I therefore state that my work, in which this term occurs, was printed, and in the hands of Mr. Liston, before that letter appeared.

whether he has any more of the rabbits." I then proposed examining the fluid of the gall-bladder, which was done, and the same corpuscles were found in it, which led me to remark, that the disease must be in the ducts. To this he replied, that if I advanced that opinion, he should say that the abscesses had ulcerated into the ducts, and so effected a passage for the matter into the gall-bladder. On my leaving his house, Mr. Kiernan said that he thought the discovery a very fortunate one for me, and that he should call in the course of a few days, and see how I was getting on. He said the sub-editor of the *Lancet* was his friend, and he could insure me the means of publication in that journal.

On reaching my own house, I dissected the liver, and found that the disease was in the ducts. Two days afterwards I called on Mr. Kiernan, and, not finding him at home, wrote that I had some diseased ducts to shew him, which I was sure would interest him. He was prevented, however, from calling on me for several days, and when, at length, he paid me a visit, his first question was how I had got on with the disease. I informed him that what we had thought abscesses had proved to be enlarged ducts, and I shewed him my drawings, which represented their structure, while I explained to him that it consisted entirely of varicose capillaries, (the very expression I had formerly used at his house,) which were derived from the portal vein and hepatic artery. Upon this he exclaimed, that he knew "all about it"—that, in fact, he "had done it all himself." I was surprised at such an assertion after he had declared on the occasion mentioned above that the disease was abscess. I reasoned with him to that effect, but he evaded my arguments, and said that I could not have understood the disease without having first seen his preparation of intestine. In this I differed with him, but assured him, that when I published the paper on which I was then engaged, I intended to state distinctly that he had shown me his preparation of intestine previous to my researches on the ducts. He replied, that "the less I said about him the better." I said that I did not choose to publish without mentioning that preparation; to which he replied, "If you do, I shall contradict you." He then said that he thought that in describing the structure of the

ducts I might very well confine myself to stating that I found them "highly vascular," as he had actually used the term "varicose capillaries" in his paper. Unwilling to deceive the public in so palpable a manner, in a matter of science, I declined acting on his suggestion.

I must not omit to allude to a statement which at this time Mr. Kiernan made respecting a gentleman who he said had seen all his preparations, and had threatened to divulge his secret. "I have shewn them," he said "to no one but him, and I do not believe that he could have understood them, not being a medical man."

The preceding is a faithful account of what has passed. With respect to the sentences which Mr. Kiernan has dexterously applied to his own purposes, viz.—"He has now the audacity to claim what I then communicated to him as a discovery of his own, founding his claim on the fact of his having 'worked during several hours for several days, and rediscovered' what he calls my 'secret'; admitting, however, that he first saw 'varicose capillaries' at my house, and in my preparation; but stating that had I not shown them to him, he should have discovered them himself." Convinced, no doubt, by his laborious investigations, continued perseveringly "during several hours for several days," Dr. Hake assured me, my opinions were quite correct." The truth is as follows. When Mr. Kiernan suggested to me the use of the expression, "highly vascular," instead of a "plexus of varicose capillaries derived from the portal vein and hepatic artery," I said, "You should have accepted the disease when I offered it to you, but now I am interested in it, for I have worked incessantly at it for ten days." He then said he had used the words "varicose capillaries" in his paper, and that now my work would appear before his, as it was in so advanced a state, adding, that I had certainly "hit on the truth." To which I replied, that if varicose capillaries constituted the secret, of which he had so often spoken, his views were quite correct.

What Mr. Kiernan's secret really is, I do not know at this hour. If it consists in what he has published through Mr. Gerrard, the dispute at once ceases, for I confess I have never seen similar "looped and varicose capillaries." Mr. Kiernan, by "varicose,"

seems to imply "tied into knots:" my views are widely different. As respects the manner in which new vessels are formed, and the mode in which the blood enters them, these things have long ago been decided, and I believe published, by Dr. Todd, of Brighton.

Mr. Kiernan's last assertion, that "all Dr. Hake knows of varicose capillaries he has learned of me," I leave for others to decide on by an examination of my publication, wherein it will be seen how much my views differ from his on the subject of varix.

The gist of this controversy is briefly thus:—

1. Mr. Kiernan asserts that I desired him to exhibit to me his series of preparations, and that in consequence he showed and explained to me a preparation of varicose capillaries; whereas the truth is, I made that request after he had submitted to my inspection, without explanation, a preparation of intestine, and that that request was never complied with.

2. Mr. Kiernan asserts, in a letter to Mr. Powell, that I had claimed what he had shown me as a discovery of my own, and was about to make it public; whereas I had told Mr. Kiernan, previous to his letter to Mr. Powell, that I intended to give him publicly the full advantage of his preparation.

3. Mr. Kiernan asserts, that all I know of varicose capillaries I had learned of him; whereas the truth is, that I first saw varicose capillaries at Paris*. I beheld them subsequently in Mr. Kiernan's preparation, and worked them fully out in carcinoma of the hepatic ducts in the rabbit; and moreover, that my views of varix and Mr. Kiernan's are totally at variance.

I have the honour to be, sir, with deep respect,

Your very obedient servant,

T. G. HAKE.

42, Gordon Square,
August 21, 1839.

Extract of a letter from Henry Lindo, Esq. of Paris, to Dr. Hake.

"I immediately wrote to M. Monneret stating exactly the contents of your letter. This morning I have received his letter for you. I think you will find M. Monneret's letter suffi-

cient testimony that you had seen the dilatations. And, moreover, I wrote to M. Billot, who, if you remember, was present with me when you showed us some of your preparations; he does not remember your having shown us,—but that you mentioned the circumstance of having observed, the dilatations of the arteries: and that is exactly the impression left on my mind.

"I should think that M. Monneret's letter is sufficiently clear to prove that you had observed the varicose state of the capillaries, and I have no doubt that you will find it so."

(COPY.)

19 Août 1839.

Mon cher confrère,—Je me rappelle fort bien qu'il y a quatre ou cinq mois, lors de votre séjour à Paris, vous avez bien voulu me rendre témoin de vos recherches microscopiques sur la structure de la rate; vous avez même dans ce but apporté chez Monsieur Andral et montré à ce professeur les diverses préparations anatomiques destinées à rendre évidentes la disposition des vaisseaux (artères et veines), leur mode de communication et la structure de ce que vous considériez comme les granules spléniques; vous m'avez parlé également à cette époque, de la dilatation des artères dans une rate tuberculée. Voilà ce que je puis affirmer, mais je ne puis dire si j'ai aperçu bien manifestement cette dilatation; mes souvenirs ne me servent pas en ce moment assez pour cela.

Je vous avais proposé à ce sujet de mettre dans les journaux de médecine français une note, dans laquelle vous auriez exposé succinctement les idées nouvelles que vous vous proposiez de développer plus tard; vous aviez même rédigé quelques lignes que vous m'avez montrées dans ce but. Il paraît, monsieur, que vous avez eu grand tort de ne pas suivre mon conseil, puisque l'on vous a contesté la priorité de quelques-unes de vos découvertes. Je le regrette vivement, d'autant plus que vous ne mettiez aucun mystère à publier le résultat de vos recherches.

Si mon témoignage peut vous être de quelque prix, je vous le donne avec le plus grand plaisir, et je profite de cette occasion pour vous renouveler mes souvenirs d'amitié.

DR. MONNERET,

Agrégé à la Faculté de Médecine de Paris.

Rue St. Opportune, No. 7.

* I possess four preparations of aneurism of the capillaries in tubercle of the spleen. These were made by me in Paris nearly a year ago, as MM. Andral, Monneret, D'Arcet, Dujardin, Lindo, and others, can bear testimony.

MEDICAL GAZETTE.

Saturday, August 24, 1839.

"Licet omnibus, licet etiam mihi, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

THE NEW EDINBURGH PHAR-
MACOPŒIA.

WE make no apology for again, and so soon, directing our readers to the new Pharmacopœia of the Edinburgh College: for, among the multiplied objects which engage the attention of medical practitioners, the knowledge of officinal formulæ, if not one of the most shining accomplishments, is assuredly one of the most useful; yet it is one which, at the present day, is most strangely neglected. Instances of deficiency in this point are painfully numerous. If we look over a file of prescriptions, or read those which are printed in the medical journals, we see countless examples where the prescriber has been awkwardly straining at a combination, which occurs as an elegant formula in some well-known Pharmacopœia. Nay, in too many cases, the practitioner is actually unacquainted with the most essential formulæ in the Pharmacopœia of his own country! Perhaps it would be too much to expect from ordinary diligence an acquaintance with all the minutiae of the work; but it certainly is not too much to ask that, when the physician prescribes *digitalis* or *prussic acid*, he should know how his orders will necessarily be interpreted. Yet, if we may believe the critics, and we fear that we must add our evidence to theirs, it is quite common for the physician and the druggist to use a different language. Dr. Collier, in his translation of the London Pharmacopœia, after observing that the present infusion of *digitalis* is only one-half the strength of the former one, asks what

the druggist is to do if he finds this infusion in a prescription; is he to send the old or the new one?—as if there could possibly be any doubt about the meaning of the term *Inf. Digit.*; the Pharmacopœia being expressly published for the purpose of "preventing all deceits, differences, and uncertainties, in making or compounding of medicines, if, for the future, the manner and form prescribed therein should be practised by apothecaries and others, in their compositions of medicines."

The painful fact, of course, which suggests the doubt is, that the prescriber too often continues to use old formulæ in cases where it is essential that he should adopt the new. But if it should be objected that Dr. Collier is too acrid in his commentary, and as he sometimes imagines faults that have no existence, may also fear a misapprehension that can scarcely arise, we will back his authority by a gentler witness. In the *Lancet* of last Saturday, Mr. Bell, the druggist, of Oxford Street, complains of the changes of nomenclature in the London Pharmacopœia, and says, that although the last edition has been published about two years, physicians in great practice are heard to assert that they never prescribe from the new work, but adhere to the former names and formulæ. He illustrates the inconvenience of this by the instance of hydrocyanic acid. Suppose the physician to proportion the dose to Scheele's strength, while the prescription is made up according to the new form, the patient takes only about one-third of the quantity intended, and the druggist is blamed for the badness of the acid. We do not think, however, that in the instances brought forward by Dr. Collier and Mr. Bell, the compilers of the Pharmacopœia are to blame. Mr. Bell justly regards such a work as "a simplified medium of communication between the prescriber and compounder of medicine."

But how can it become so, if the prescriber sturdily refuses to make himself acquainted with its contents? The Italian language is an excellent medium of communication between the English traveller and the inhabitants of the Levant, but only on the condition—that he has learned it. Now, though we exceedingly regret those constant changes in nomenclature, which have arisen from the attempt to keep up with the chemical theories of the day, and the fond persuasion that those theories were immutable truth, we cannot lament every alteration, or wish that the Pharmacopœia was a mere reprint of its predecessor.

It was obviously desirable that the infusion of foxglove should be diminished in strength; and still more urgent, that prussic acid, the most formidable of all preparations, should be in a very diluted form. All practical physicians must acknowledge this, and the sooner every one makes himself acquainted with the exact arithmetical meaning of the *dilutum* in *Acid. Hydrocyan. dil.* the better.

Mr. Bell talks of its “being commonly supposed by those whose occupation does not lead them to study the intricacies of pharmaceutical chemistry, that unless they wish to prescribe any new remedies, they are not obliged to depart from the forms to which they are accustomed.” But surely it requires no acquaintance with the subtleties of pharmacy to know that a given infusion has been ordered weaker or stronger than in the previous edition—to look at the book is sufficient. Mr. Bell also objects to the change in the measures; and we agree with him as to the inconvenience of the alteration, but believe that the College had no choice. The Act of Parliament was stringent, and it would have ill beseeemed a body like the College of Physicians to attempt to infringe it. We confess we

see no valid reason for the parliamentary substitution of the imperial for the wine gallon. Mr. Bell's letter, however, taken aright, is an excellent hint to prescribers to make themselves masters of the Pharmacopœia; for, undoubtedly, nothing can be more discreditable than to be unversed in the necessary medium of communication between themselves and those who are to execute their ordinances. If the physician adds a knowledge of other Pharmacopœiæ to this indispensable acquaintance with his own, it will often enable him to give more vigour to the substance of his prescriptions, and more elegance to their form.

Among the preparations of metals in the Edinburgh Pharmacopœia, we find the *Ferri Carbonas saccharatum*, which will probably be a useful medicine for children; a solution of iodide of iron; a black oxide of iron; *ferrugo*, which appears to be the hydrated tritoxide of iron; and sulphuret of iron.

There is no solution of corrosive sublimate: so convenient a preparation ought not to have been wanting.

Under the head of mixtures and emulsions, there is one of *Althæa* (marsh-mallow); another of creasote, with acetic acid, compound spirit of juniper, and water; and one made with seven grains of scammony and three ounces of milk. The *Mist. Camph.* contains almonds and sugar, but no spirit; and the *Mist. Camph. c. Magnesîa* is made with ten grains of camphor, twenty-five grains of carbonate of magnesia, and six ounces of water.

Of the ointments, liniments, and cerates, we will mention only the *Lin. Ammoniæ Comp.*, which, we believe, is the same thing as Dr. Granville's counter-irritant. It is composed of five ounces of aqua ammoniæ of the density of 880, two of tincture of camphor, and one of spirit of rosemary.

It may be worth observing, as it shows

a leaning to different modes of prescription in France and this island, that the Parisian Codex, though so exceedingly copious, contains only eleven formulæ for pills, while the London Pharmacopœia has fifteen, and the Edinburgh twenty-three.

Under this head, the Edinburgh College have given four different kinds of aloetic pills; others made with the colocynth pill mass and extract of hyoseyamus; pills of ammoniated copper; of Dover's powder; of sugar of lead and opium; rhubarb pills containing acetate of potash; and pills made with extract of rhubarb and dried sulphate of iron.

Among the powders, the Pulv. Effervescentes, the Pulv. Rhei Comp., and the Pulv. Salinus Comp., are peculiar to the Edinburgh Pharmacopœia; and among the syrups, those of vinegar and ipecacuanha.

Under the head of tinctures, the College, after mentioning the usual method of preparing them, adds, "a much superior method, however, has been lately introduced, which answers well for most tinctures, namely, the method of displacement by percolation." They give the details of the method, and afterwards, when giving the directions for each separate tincture, generally mention whether or not it can be conveniently prepared by percolation. The tinctures of buchu, lactucarium, lobelia, tolu, quassia, saffron, veratrum, the compound tincture of quassia, the ammoniated tincture of castor, the ammoniated tincture of opium, and the ethereal tincture of lobelia, are not in the London work. The Edinburgh Pharmacopœia has three tinctures containing rhubarb, the London but one. The Edinburgh College order only a simple tincture of iodine, and the London College only a compound one. On the other hand, the tinctura colchici comp. and the tinctura cubebæ, of the southern Pharmacopœia have no equivalents in the northern one.

Dr. A. T. Thomson affirms that "the lozenges of the confectioner are superior in elegance to those of the apothecary, thence the London and Dublin Colleges have properly omitted them." (Dispensatory, 9th edition, page 1151). Nevertheless, the Edinburgh College have increased the number of troches from six in the former edition to ten in the present one; and if an additional argument were wanting in favour of these pleasant remedies, it might be found in the fact that our brethren across the Channel have no less than twenty-eight sorts of lozenges in their Codex. Those of the Edinburgh College are made with gum arabic, tartaric acid, chalk, liquorice, lactucarium, magnesia, morphia, morphia and ipecacuanha, opium, and bicarbonate of soda. It is clear that several of these contain drugs too powerful to be entrusted to the confectioner; but even if, in spite of this objection, the wholesale manufacturers of lozenges supply them to the druggist, it is well that the Pharmacopœia should contain directions for their benefit.

We will conclude this subject on a future occasion.

REGULATIONS FOR MEDICAL GRADUATION IN THE UNIVERSITY OF DUBLIN.

THE times of graduation are Shrove Tuesday and the first Tuesday in July. The medical examinations terminate the Tuesday of the preceding week. Candidates must previously have completed their medical education, and produced a chart testifying to the details of the same, and subscribed by the Registrar to the Professors in the School of Physic, as well as by the persons signing the certificates.

Medical students may obtain the degree of Bachelor of Medicine in two modes:—

1st. Candidates who have graduated in *Arts* may obtain the degree of Bachelor of Medicine at any of the ensuing half-yearly periods of graduation, provided the requisite medical education and examinations shall have been accomplished. The pay-

ment at entrance is 15*l.* The fees for study in Arts, during four years, are 7*l.* 10*s.* each half year; and the fees for graduation in Arts, 8*l.* 17*s.* 6*d.*

2*d.* Candidates are admissible to the degree of Bachelor of Medicine, *without previous graduation in Arts*, at the end of five years from the July* following the Hilary Examination of the first undergraduate year, provided the usual education and examinations in Arts of the first two years of the undergraduate course shall have been completed, as also the medical education and examinations, as in the case of other candidates. The fees for two years' study in Arts (besides the usual entrance payment of 15*l.*) are 7*l.* 10*s.* each half year.

The graduation fees for the degree of Bachelor of Medicine are 11*l.* 15*s.* The Testimonium of the M.B. degree will contain the following certificate:—"Testamur sedulam operam medicinæ navasse et examinationes coram professoribus feliciter sustinuisse."

The medical education of a Bachelor of Medicine comprises attendance on the following courses of lectures (of which three, at the discretion of the candidate, may be attended at the University of Edinburgh), in the School of Physic established by Act of Parliament, provided that one and not more than three of the courses which begin in November be attended during each of four sessions. The courses are on—Anatomy and Surgery—Chemistry—Botany—Materia Medica and Pharmacy—Institutes of Medicine—Practice of Medicine—Midwifery (by the Professor to the College of Physicians)—Clinical Lectures at Sir Patrick Dun's Hospital during at least one session of six months, as delivered by the Professors in the School of Physic—the attendance on such Clinical Lectures by the Professors to be extended to three additional months of another session, unless the practice of the hospital be certified by the ordinary physicians of the institution to have been attended from the 1st of May till the 1st of November following the session.

The fees for attendance on the Clinical Lectures are regulated by Act of Parliament: they amount to 3*l.* 3*s.* to the Professors for each three months' attendance, and (provided the student be of two years' standing in the University) 3*l.* 3*s.* to the Treasurer of the Hospital for the first year, with a proportionate sum for any

longer period. The fees for each of the other courses are 4*l.* 4*s.*

The examinations for the degree of Bachelor of Medicine are conducted by the Regius Professor of the University, the six Professors of the School of Physic, and the Professor of Midwifery to the College of Physicians.

No further examination is requisite for the degree of Doctor of Medicine, which may be taken at the expiration of three years from taking the degree of M.B., *provided the candidate shall have graduated in Arts*. The fees for the degree of Doctor of Medicine, which entitles the possessor to the same elective privileges as the degree of Master of Arts, are 22*l.*

Deputy Registrar.

July 1839.

ON CUTICLE, PUS, AND MUCUS.

By DR. HENLE, of Berlin.

No complete account of the remarkable discoveries of Dr. Henle on those subjects having yet been published in English, we have made the following succinct abstract of the most important results to which he has arrived, from his two chief papers* :—

The most general and essential character of the structure of cuticle is, that it is composed of one or more layers of cells, which cover all the free surfaces of the body—all the internal surfaces of its canals and tubes—and all the walls of its cavities. It is found, therefore, on the external skin, and on all mucous membranes, to the very terminations of the gland ducts that open upon them; on the surfaces of serous membranes; and on the inner surface of the heart; and of all the vessels of the whole vascular system, to their finest net-works. The cells themselves always contain one small, more or less flattened, roundish, or oval kernel, which again contains one or two punctiform granules.

The chief forms of the cuticle-cells are the plaster epithelium, which (like the epidermis) consists of flattened, roundish, or polygonal cells, about 1-160th of a line in diameter, each inclosing a kernel of the same shape with itself, in which one or more granules are contained. When these cells are deposited in several layers, the external are always broader and flatter than the internal, so that they form delicate lamellæ or scales, on whose surface the kernel forms a slight prominence.

* Ueber die Ausbreitung des Epithelium im Menschl. Korp.; Müller's Arch. 1838. Ueber Schleim und Eiterbildung, in Hufeland's Journal der pract. Heilk. 1838.

* The first undergraduate year may be saved by attending the October examination of that year, by a student who has entered not later than the first Monday of the July of the same year, and who has completed the payments previously made by his class.

This is by far the most general form of cuticle; it covers the skin, the beginning of the nasal passages, the cavity of the mouth, the tongue, the conjunctiva, the pharynx, and œsophagus, the labia, vagina, and up to the neck of the uterus, the serous and synovial membranes, the linings of the vessels, &c.

2d. Cylindrical epithelium, which is formed of closely set corpuscles of a conical form, about 1-100th of a line long, whose apices are attached to the mucous membrane on which they are placed, while their bases are free, and which inclose in the middle of their length a flat oval kernel, containing a second more minute nucleus. This form is found in the cardiac region of the stomach, and through the whole intestinal canal, in the urethra and its glands, in the vasa deferentia and tubuli seminiferi.

3d. Ciliary epithelium, in which there are added to the cells of the second form, fine ciliæ attached to their free broad extremities. It is found in the whole respiratory mucous tract, from the chordæ vocales downwards, on the nasal cavities and the upper part of the pharynx, and on the linings of the cerebral ventricles.

Now in all these cases new cuticle is generated from below on the organized surface, in proportion as the superficial layers are constantly thrown off. The latter are separated, in the healthy state, in the form of thin membranes or little scales, or as mucus. This desquamation is chiefly seen in the cuticle covering the skin (the epidermis), whose superficial layers, continually scaling off, have their places constantly supplied by a fresh growth from beneath. In certain parts of the mucous membrane, also, a similar scaling off is constantly and slowly going on in the normal state. The separated particles have not the form of dry scales, like those of the epidermis; but they form a delicate membrane, always permeated by a large quantity of moisture, which constitutes the mucous covering (as it is called) of all mucous membranes. The external surface of the ball of the eye, the meatus of the nose, the cavities of the mouth and fauces, of the œsophagus, and of the vagina, are constantly covered by such a layer of mucus, which may be easily scraped or wiped off, or for the removal of which nature has adapted peculiar processes. The mucous or cuticular covering (for the expressions are synonymous) of the eyeball is constantly carried through the nose by the tears; the mucus of the digestive apparatus is removed with its contents—the food, the chyme, the fæces, and so on.

We have thus a *first* species of mucus, which consists of the normal separated

superficial layer of the epithelium, and whose microscopic elements are distinguished from all others, by the cells being very large in comparison with the nuclei, flat, and but slightly connected together. To examine these one need only scrape the nail gently over the tongue or inside of the cheek, and place the substance thus removed, and diluted with a little water, beneath the microscope. Such cells are found, also, in all the excretions which pass over mucous surfaces with a thickish epithelium, as in the tears, the saliva, &c.

Such a desquamation takes place only where the epithelium exists in rather considerable layers. Many epithelia are probably not thus disposed to regeneration, as, for example, those of serous surfaces which could not be removed. The ciliary and cylindrical epithelia, also, separate only under certain conditions, either pathologically, or at certain periods in the healthy state. Thus the whole intestinal canal of the child is thus *skinned* in the first week after birth, and complete coverings of the villi are found in the fæces; the stomach is *skinned* during digestion; the female sexual organs after parturition, by the lochia, and during menstruation. In menstruation, the vagina also always takes part in the process of *skinning*; and the mucus which is separated by the white secretion which precedes and follows the flow of blood, contains the fragments of the epithelium of the neck of the uterus and of the vagina.

In reference to the morbid conditions of the so-called mucus, the *first* and simplest case is that in which neither the formation nor the structure of the epithelium is altered, but the healthy epithelium is separated by some morbid process, as the epidermis often is from the cutis, by abnormal conditions of the latter, by burns, &c. This case occurs—

1st. From mechanical force.

2d. From serous effusion beneath the epithelium, consequent on irritation of the mucous membrane. Bullæ thus formed are often seen on the tongue and the ball of the eye.

3d.—At the termination of many diseases of the mucous membranes, whose similarity to the acute exanthemata of the skin has often been spoken of. Among the most remarkable examples are, the peeling of the tongue, the mouth and lips, and, perhaps, also of the other digestive organs in gastric affections. It is the separated epithelium of the tongue which forms its characteristic coat. The mucus thus separated may contain not merely the elements of the outer layers of epithelium, but also the smaller cells of the inner layers.

In the second class of cases, the forma-

tion of cuticle is, indeed, morbidly increased, but its elements are not at all, or not essentially altered; it is a true hypertrophy of the cuticle. By this process, corns form both on the skin and on mucous membranes, with thick epithelia; or else there is increased desquamation. To this class belong the pityriases, and probably many other cutaneous eruptions among the *squamae*, without any trace of inflammation or general disturbance. Similar local desquamations without pain, or symptoms of disturbed functions, occur from the mucous membrane of the fauces and pharynx. There are many persons who, especially in the morning, spit up thick, yellowish-white, easily dissolving sputa, without being in any respect unwell; such sputa consist of nothing more than lamellæ of epithelium.

The next cases in this class are those in which the cuticle falls off before it has attained its full development. Such are the soft moist scales which so constantly fall off and are reproduced around atonic ulcers, or in moist lichenoid eruptions, &c. The elements of these scales are not so thin or so dry as those of the epidermis generally; they are flat and large, with distinct nuclei, like epithelium cells; and the skin at such parts, with its red colour, glistening and moisture, approximates very closely to the character of a mucous membrane. Lamellæ of epithelium of the same kind occur in sputa, in the mucus of the vagina, &c. but under circumstances with which I am as yet unacquainted.

In the third and most important class of cases, the formation of the cuticle itself is unhealthy. It is the elements of such diseased cuticle which are generally described as mucus-corpuscles, and mucus-globules, and which it has been desired to distinguish from pus-globules. In the fluid and clear mucus of the cavity of the mouth and nose, and in the saliva, of even healthy men, there are scattered roundish globules, slightly granulated, and measuring from 0.003 to 0.007 of a line in diameter. They may be obtained, mixed with a few epithelium scales, by scraping gently over the lining of the cheek, or at the union of the gum and the root of the teeth. In some of these globules there may be seen at once an obscure oval or roundish kernel with a central dark nucleus; in others it becomes visible only after a certain time. Acetic acid dissolves the exterior shell of the globule, but not the kernel. When the acid is very diluted, it sometimes makes the kernel paler, but does not otherwise affect it; in others the kernel becomes indented at its edges in various ways; most commonly there are two opposite indentations, which are continued, more or less,

nearly to the very centre; but not unfrequently there is a third and even a fourth indentation. In some the change does not go beyond indentation; but in most of the globules it is continued till the kernel splits into from two to four portions of smaller size. These smaller corpuscles are roundish or oval, with very sharp dark outlines, and a central depression, so that they sometimes look like rings. When concentrated acetic acid is applied, the process of indentation and splitting, just described, goes on too rapidly to be discerned; and it has therefore been overlooked by Güterbock, Vogel, and other later observers. It need scarcely be remarked, that the same changes which acetic acid produce in the mucus-corpuscles would be produced in the body when the fluid containing them is acid, as the saliva, gastric fluid, &c.

We have thus, in the relation of the mucus-corpuscles to acetic acid, three stages, which may be regarded as so many stages of development traceable into one another. In the first stage the mucus-corpuscles are not distinguished from the epithelium-cells of the mucous or salivary glands, whose exterior in like manner dissolves in acetic acid, and whose kernel remains undissolved, but becomes paler. The other forms are peculiar.

[To be continued.]

ANCIENT & MODERN EMPIRICS.

IN ancient times there was a sect of physicians called empirics. This was not a contemptuous nickname bestowed by their adversaries, but a title of honour taken by themselves, and signifying *those who follow experience*. They maintained that, in medicine, theory is of little avail, and that all future practice, to be successful, must be based upon that which has hitherto been so. The rationalists, on the other hand, asserted that practice must be deduced from theory, and that diseases can be treated by him alone who understands their causes and their seat.

It is probable that in this, as in other controversies, the more reasonable disputants of either party adopted the better points of their opponents' practice; so that the rationalists were in reality guided by the results of experience, as far as those results were available; while the empirics, in cases where they were deserted by experience, had recourse to some rational explanation of the cause and nature of the disease, and by no means treated cases at haphazard. Hence the empiric of two thousand years ago was a physician who was chiefly guided by the registered results of previous practice; while the modern empiric seems destined merely to show how far presumptuous folly can go. Indeed, the very word empiric has

become so degraded by use, that it reminds one immediately of manslaughter, coroners' inquests, and the Old Bailey; and instead of signifying one who learns by the experience of others, too often means a man who is unable to profit by his own.—*The Working Man's Companion*, 1839.

PETECHIAL FEVER AT ST. PETERSBURGH.

A CORRESPONDENT of the *Zeitschrift für die gesammte Medicin*, for August 1839, who dates from Petersburg, says, petechial typhus fever has been really epidemic among us this year. It was not only the hospitals which were full of patients who belonged to the working classes suffering under this malady, but an extraordinary number of cases occurred among opulent families. It was surprising that the patients never seemed to be delirious during the course of the disease, but went on speaking and acting with consistency; yet when the disease was over, towards the end of the third or fourth week, they awoke with astonishment into a consciousness of their condition. The reason probably was, that the typhus action was almost entirely spent upon the lungs and skin, so that the reaction amounted to inflammation in these organs alone, while the brain remained continuously narcotized. With us, as in Germany, the measles have been of an unfavourable character this year, from thorax, and even with irritation of the membranes of the brain; they also attacked many persons for the second and even the third time.

POISONOUS VAPOUR FROM ROTTEN POTATOES.

A POOR family had placed a heap of potatoes under a bed in their only room, where they were frozen during the night, but during the day were partly thawed by the heat of the stove; and they soon rotted from this variation of temperature. One day the children were told to pick the good potatoes, which they did by stirring up the heap with sticks; on which five persons inhabiting the room were immediately seized with giddiness, headache, and vomiting. The accident was ascribed to the fumes arising from the fire glimmering in the stove; and the window being accordingly opened, the patients soon recovered. On the following day the fire was not lighted, but the symptoms returned with equal violence, after the children had again begun to pick out potatoes; and relief was again obtained by opening the window and ventilating the room. These symptoms might be produced from the carbonic acid gas which rose from the fermenting mass of decayed potatoes.—*Med. Zeit. and Schmidt's Jahrb.* May 1839.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.
By DR. VENABLES.

Retention of urine.—This affection consists in the bladder not voiding the urine when the due quantity has been secreted into it. It is generally attended with pain, or a sense of weight and uneasiness, in the region of the bladder. As the urine accumulates, there is an urgent desire to pass it off, while at the same time the distended bladder, rising above the pubes, forms a roundish sort of swelling in the abdomen, which may not only be felt with the hand, but seen with the eye. When the bladder has become so far distended as that it can be seen or felt above the pubes, there can be no great danger of confounding this with any other affection.

Causes.—There is probably no disease which arises from so many and such varied causes, some of which are purely mechanical, others depend upon the morbid condition of the bladder itself. Thus inflammation of the coats of the bladder may ultimately terminate in retention of urine. Spasm at the neck of the bladder will, by closing the entrance to the urethra, produce a retention; and this inability very frequently is the consequence of inflammation. Spasmodic stricture in the urethra, and likewise organic stricture in the same part, are often causes of retention, the latter of which falls completely within the province of the surgeon. Thickening of the coats of the bladder,

and paralysis, are likewise often causes of retention, or an inability to pass off the urine. It also often prevails in the advanced stage of fevers; and it is necessary more particularly to direct your attention to this circumstance, because it is often overlooked by young practitioners, and who may not have seen much of such diseases. When retention has taken place to any extent in fever, there is usually at first some irritation and anxiety, which soon is succeeded by a comatose sort of indifference. The patient at first may be aroused, and may reply to queries, but his answers are mostly irrelevant and unconnected; and this soon ends in complete coma. If the hand be now laid upon the abdomen, a tumor, hard, and feeling somewhat like an orange under the integuments, may be felt; and on inquiry it will be found that the patient has not passed any urine perhaps for the last four-and-twenty, or even eight-and-forty hours. The retention, in such cases, depends upon two different or distinct causes. In one the cause is a decided paralysis of the muscular coat of the bladder, whence it is totally incapable of contracting; and the urine flowing in when the bladder has been fully distended, the urine flows mechanically and slowly through the urethra, producing irritation and ulceration of the external parts, with which it remains in contact. In other cases there is a morbid insensibility—a sort of *anæsthesia*—in which the usual stimuli are insufficient to excite, but if the stimulus be somewhat increased, there is a responsiveness.

Treatment.—The treatment, of course, will, to a great extent, depend upon the nature of the causes which produced the disease. A primary object will be to evacuate the bladder, so as to empty it of its contents. Where the obstruction depends upon spasm, we must employ those means which have proved most powerful or efficacious in relaxing spasm. Thus

narcotics, and especially opium, or some of the salts of morphia, should be given at intervals, and until a relaxing effect has been produced. At the same time anodyne enemata should be thrown into the rectum, and the bowels emptied by castor oil, or mild laxative clysters. The patient also may be immersed in the warm bath, or warm fomentations applied to the perineum. As formerly observed, if this spasm be in the neck of the bladder, the *tinctura ferri sesquichloridi*, given in doses of from ten to fifteen minims every ten or fifteen minutes, has produced the best effects; and if with the chalybeate an opiate be exhibited at the same time, the efficacy of the former will be increased.

When the retention depends upon paralysis, or is an attendant upon fever, the urine should be drawn off by means of the catheter; indeed, in fever more particularly, the urine should be drawn off four or five times in the twenty-four hours, for it is astonishing how rapidly, and in what large quantity, the urine will sometimes accumulate in these fevers; and when the bladder becomes over-distended, the coma and insensibility are invariably greatly increased. I have seen one or two instances in which patients had been tortured in vain by sinapisms for the relief of coma, which the introduction of the catheter completely removed in a few minutes. Therefore, in such cases, always let your first inquiry be, whether the patient has regularly voided the urine, and in sufficient quantity; nor rest satisfied with this, but ascertain the fact by manual examination of the abdomen and hypogastrium.

When the retention depends upon organic stricture in the urethra, the catheter presents the fairest prospect of relief; but it sometimes happens that this instrument cannot be passed; and I must confess, that I cannot approve the violence with which a passage is sometimes forced into the bladder in such cases. If the stricture is impenetrable, it is recommended to puncture the bladder, which may be done either from the rectum, or above the pubes. I have both performed this operation myself, and seen it done by others; but I never saw a case terminate favourably. In my opinion, the preferable mode of proceeding is to introduce a sound, grooved like a director on the back or convex portion, instead of at the side, as in the case for lithotomy, till its point rests upon the stricture. A sharp-pointed double-edged scalpel may now be pushed in from the perineum, till its point is in the groove. If the sound be then pushed, as if to pass through the stricture, the knife will cut through the stricture, and open a passage into the bladder, when a catheter can be

introduced, and the passage preserved open, while the external wound readily heals. I have so far digressed, because I know that many think that, in cases of distended bladder from stricture, what is termed puncturing is the only mode of immediate relief.

Suppression of urine.—This disease, sometimes named *urinary fever*, sometimes *ischuria renalis*, differs from the former ischuria in that, in suppression, the function of the kidney is either partially or wholly suspended, and consequently the urine either altogether ceases to be separated, or is but very scantily secreted. We find this affection attended with acute fever, and a sharp or acrid heat of the surface, with thirst, and frequently a urinous taste in the mouth. The whole body also exhales a urinous odour, perceptible not only to the patient himself, but to the bystanders, a remarkable instance of which I saw in Essex. The patient was suffering from suppression; there prevailed a strong urinous smell throughout the whole room, and the patient was bedewed with a sweat, which, in most of its sensible characters, resembled stale urine so closely, that it could not be distinguished, and no doubt consisted of urine intermixed with the cuticular exhalation.

There is pain in the loins close to the spine, with distension, especially in hypochondres*. There is an urgent desire to pass off a large quantity of urine, but very little is voided, and that by drops, for, as we learn from Aretæus, the urine is not totally suppressed, but there is a feeling of a great redundancy or superabundance of urine†. The distension is said to resemble that arising from the corruption of excess of food in the stomach, and which gives rise to flatulences‡. The pulse is generally small, thready, and irritable. In the beginning, according to Aretæus, the pulse is slow and sluggish or labouring, but as the disease advances it becomes small, frequent, disturbed, and irregular§. The sleep is disturbed, restless, and with pain, and frequent starting, especially upon the slightest disturbance, when the patient again falls off into a sort of comatose slumber, as if worn out by fatigue. The mind is not much disturbed in the begin-

* Ὁδὴν κατ' ὄσφυν ἐπὶ ῥάχι βαρεῖα διατάσις τῶν μερῶν μᾶλλον δὲ τῶν ἀμφὶ τὰ ὑποχονδρία.—Aret. De Caus. et Sig. Acut. Morb. lib. 2, cap. ix.

† Ὅσφρυ ἐπισχεῖσι, ὅκκ ἐς τὸ πάμπαν ἀλλὰ σιάζον μὲν οὐρέουσι, ἐπιθυμῖα δὲ πολλὸν ἐκχέει· πλημμύρης γὰρ ἕισθησις.—Ibid.

‡ Aretæus, *ibid.*

§ Σφουγμοί, τὰ πρῶτα μὲν, ἀραιοί, νωθροί· ἔν δὲ ἐπὶ μᾶλλον τὸ κακὸν πίεση, σμικροί, πυκνοί, παραχῶδες, ἄτακτοι.—Ibid.

ning, but there is sometimes slight delirium, and the face becomes livid. If the suppression continue, hiccup comes on, with nausea and vomiting; and, if relief be not speedily obtained, dyspnœa with coma, or delirium with convulsions, and speedy death. Of those who die, Aretæus tells us, they suffer most in whom nothing is excreted*. When the urine is secreted in very small quantity it is sometimes extremely acrimonious; then coldness, tremors, shiverings, convulsions, and a sense of over-repletion and distension of the præcordia and parts in the neighbourhood supervene; at last a cold, clammy, urinous sweat breaks out all over the surface, and the patient dies in a convulsion.

Causes.—Many of these have been already considered, such as inflammation of the kidneys, stone in the ureter or pelvis preventing the flow of urine into the bladder, although, in such cases, the function of the kidney is not suspended. This affection sometimes prevails in gouty persons, and in hysterical females; and in such it would appear to depend in a great measure upon spasm.

Diagnosis.—This cannot be very difficult, and indeed the only variety of ischuria with which it can be confounded is the ischuria ureterica, in which the urine, though secreted, does not flow into the bladder†. In fact the nonflux of the urine is the common symptom of all, but there can be no danger of confounding suppression with retention. The great object, therefore, will be to determine whether it be a positive suppression, or merely the consequence of stone, or some mechanical obstruction in the ureter. The swelling in the hypogastrium, or the examination of the bladder per rectum, will enable us to determine the question between suppression and retention.

The flow through the ureter is for the most part dependent upon some mechanical obstruction, and this generally arises from the presence of a calculus in the ureter. When the patient has been subject to pass calculi, and is of a gouty habit,

and if any portions of the urine escape, and on examination it indicates the calculous diathesis, we need scarcely hesitate to attribute the suppression to mechanical obstruction from this cause.

As the urine accumulates in the pelvis it will cause a sense of fulness, and painful swelling in the loins; and the urinous odour, depending upon the reabsorption of the urine, will not be exhaled from the surface so early nor so powerfully as in the former case. Lastly, the ease with which the catheter may be introduced into the bladder, and its introduction not being attended with a flow of urine, will farther serve to distinguish suppression from retention.

Treatment.—The treatment in this, as in the case of suppression, will vary, and must be regulated according to the nature of the cause. If there be symptoms of inflammation of the kidney, the antiphlogistic means, already detailed when considering nephritis, must be adopted and persevered in, till the necessary relief has been obtained. When it appears to depend upon spasm, as in hysterical females and persons of similar temperaments, we must have recourse to narcotics and antispasmodics; and of these there are none so effectual as morphia and nitric ether. At the same time, if of a chronic character, becoming as it were habitual, we may exhibit mild and unirritating diuretics and tonics. The sesquichloride of iron and colchicum in such cases has often had a wonderful influence; and when the habit has been as it were broken by these means, we may then endeavour to correct the hysterical tendency by the remedies suited to this object, and especially by the different preparations of valerian. If the spasm prove obstinate, we should conjoin with these means depletives, especially venesection in the erect posture or in the warm bath, so as to induce fainting and its consequent relaxation as speedily as possible, and with as little loss of the vital fluid as is consistent with the in view.

When the suppression is associated with gout or with a suppression of a paroxysm, then, with sinapisms and other stimulants to the affected joints, we may add the use of colchicum; although I have seen two instances of suppression in a gouty habit, induced apparently by too suddenly checking the fit by excessive doses of the wine of colchicum. The suppression gave way to diluents, aromatics or cordial diuretics, the use of the warm bath, and the application of sinapisms to the gouty joints.

When the suppression appears to depend upon some mechanical cause, without any suspension of the function of the kidney,

* Οξύτατα δὲ ἀνίσκουσι τῶνδε, οἷσι οὐδὲν ἐκκρίνει, ὀκῶσαι δὴ ἀνίσκουσι.—Ibid.

† Cullen arranges *Ischuria* in the class *Locales*, order *Epischeses*, and makes four species of the genus ischuria: *renalis* having its cause in the kidney; *ureterica*, in which it is in the ureter; *vesicalis*, in which the urine cannot flow from the bladder in consequence of some affection of that organ; and lastly *urethralis*, in which the flow is prevented by some disease of the urethra. A desire of voiding the urine, with inability to pass it, is common to all four. The two latter are evidently varieties of *retention*, but the term suppression is properly applied only to the ischuria *renalis*, because, although the flux is restrained in all four, its secretion is suspended or suppressed only in one, the ischuria *renalis*.

as for instance a calculus*, we must consider the nature of the case, that we may adapt the means to the particular circumstances. Thus we must endeavour to determine the composition of the calculus, to devise the appropriate remedies. We found that the nuclei of calculi consist almost exclusively of lithic acid, or of oxalate of lime (for we may wholly put the cystic oxide, as so rare, out of the question), and that the phosphates are hardly ever found as forming nuclei. Therefore the great probability will be that the mechanical obstruction must depend most frequently on lithic acid, next after this on the oxalate of lime, and that in the majority of cases we shall be safe in adopting the means detailed when considering those diatheses, and which it is unnecessary here to recapitulate, but care also must be taken to prevent or keep down as much as possible the more acute symptoms of inflammation. If, however, we can obtain a small portion of urine, an examination of its properties will in all probability throw considerable light upon the nature of the case.

But, perhaps, it ought here also to be remarked, that grumous blood has occasionally proved the cause of the suppression, and consequently we should, in the absence of any indication of the operation of calculi, consider the possibility of the ureter being rendered impervious by coagulated blood or fibrin†. In such a case the promoting its absorption by mercury, iodine, &c., suggests itself as the most appropriate means of relief. So far for the details: with respect to the general treatment applicable in all cases, they consist merely in regulating the bowels by mild and unirritating laxatives and emollient enemata, and in correcting all errors or irregularities in any of the other functions.

With respect to the consequences: if the suppression be complete, or supervene any acute disease, or that it be original, it generally proves fatal; for, from what we said in relation to the functions of the kidneys at the beginning of these lectures, their operation could not be long suspended without serious injury. One essential operation of the kidneys appears to be, to separate a noxious principle from the blood, and to throw it out from the system; and the severe symptoms which su-

pervene a total and complete suspension of their functions, fully prove how essential they are to the preservation of health; and nature very often endeavours to compensate their inactivity by vicarious discharges, either by vomiting, sweating, or passing off by stool, fluids so closely resembling urine, as not to be distinguishable from it, and unquestionably consist of urine intermixed with the natural fluids, &c. of the organ. Upon the whole, therefore, we may look upon suppression, in most cases, as a formidable disease. The most favourable are those of spasm in hysterical persons.

Incontinence of urine.—By this is to be understood an inability to retain the urine in the bladder, whence it flows away involuntarily; sometimes the patient being unconscious; sometimes, though conscious, he is wholly incapable of resisting the flow. It prevails mostly in early life and in advanced age. In the first case it generally flows from the patient while in bed and asleep, and in general under the influence of a dream; consequently it may be said to pass away voluntarily, but under a delusion. We have already considered some of these cases, and we found that the urine was generally in an unnatural state. In almost all such cases the urine, if examined, will be found disordered to a greater or less extent. A very frequent unnatural condition is a very great tendency to gravel, or even an actual deposition of gravel. From the unnatural and sometimes acrid properties of the urine, the incontinence arises probably from this condition, and, as observed by Dr. Prout, it is probable "that these, favoured perhaps by the position of the body, and probably, also, the morbid sensibility of the bladder, excite so vivid an impression on the imagination, as actually to lead to a voluntary discharge of the urine. Habit," observes the same authority, "and particularly the custom of lying on the back, has considerable effect in keeping up the disease; and in some individuals, in whom the original cause has been long since removed, the affection seems to occasionally recur from this circumstance*."

However, instances of an involuntary discharge of urine, or incontinence of a passive character, are not very uncommon even in young subjects. Dr. Prout says that the urine in such cases generally flows off in the night; but I have seen two or three instances, and, indeed, have now one under my care at the Dispensary, in which the flow is incessant both day and night. In such there appears to be an

* On Diseases of the Urinary Organs, p. 308.

extremely irritable state of bladder, with a torpor of the sphincter. The case above alluded to is that of a girl about fourteen years of age; but nothing seems to relieve. Indeed, such affections often continue till long after puberty, and then disappear spontaneously. It sometimes assumes a hereditary character, affecting almost all the children of a large family, especially the females.

Incontinence in advanced life depends upon a variety of causes, all of which operate by inducing a torpor or inactivity of the sphincter vesicæ. Paralysis of the sphincter will be attended with similar results, more especially if age have given such a stoop forward to the body as that the neck of the bladder shall attain somewhat of a pendent position; in such the flow is unceasing, and the patient is obliged to protect himself from the consequences by the adoption of various appropriate means. It is sometimes connected with disease of the prostate, paralysis from spinal injuries, over-distension of the urethra from a calculus, &c.; and under the head of irritable bladder we have noticed what may be considered a species of incontinence.

Treatment.—The treatment, it is evident, of a disease depending upon so many and such various causes, cannot be based upon any fixed or certain principles. The treatment must vary according to the causes. In children, when associated with the calculous diathesis, this should be most carefully attended to, for while this is allowed to proceed uninterrupted, no remedy directed specially to the incontinence can be of the slightest avail. When the tendency to gravel has been subdued, strengthening the system by tonics, and especially by sea-bathing, will prove of great advantage; and some of the urinary astringents, as uva ursi, may also be given in appropriate doses. Where there appears a want of power or sensibility in the urinary organs, various stimuli, as cantharides, turpentine—the former of which may be applied externally in the form of blisters, as well as administered internally, till the neck of the bladder becomes sensibly affected. In advanced life, in which it depends more particularly upon the inactivity of the sphincter vesicæ, the stimuli may be given the same as above recommended; but it should be recollected that, under these circumstances, the prospects of success are much less than in children, not only because the torpor is greater, and of a much more inveterate character, but in old persons it is often associated with organic disease of some one or more parts of the urinary system. In old persons, in whom the urine is constantly dribbling away, the

urine, if allowed to remain in contact, will excoriate and produce gangrenous ulceration of the surface. Hence it is necessary to have some vessel so applied or attached as that it may receive and retain the urine as it flows, and prevent its contact with the skin. Various receptacles of this sort have been contrived, but their description hardly comes within the scope of our present object.

Pains in the loins.—Many alarm themselves from the prevalence of such, and fancy themselves suffering from calculi. Such pains, however, may arise from various causes: some, for instance, are purely sympathetic; some, again, muscular. It may, therefore, be necessary to consider how those arising from calculi may be distinguished from those of a different character. Inflammation of the kidney is attended with pains in the back and loins, and also with scanty high-coloured acid urine, vomiting, and a high degree of sympathetic fever. If with these there is pain extending downwards and forwards toward the groin, along the course of the ureter, retraction of the testicle, and numbness of the thigh on the same side, with tenderness above the pubes, we may suspect the presence of a calculus, and more particularly in the kidney or ureter if the urine be bloody. The mode of determining the nature of the calculous concretion has been already sufficiently explained.

In cases where the presence of calculus is more equivocal, the long and obstinate continuance of these symptoms should awaken our circumspection, because we should recollect that, although not affording distinct evidence of the presence of stone, they indicate the great probability of such an event. This is still more probable if the individual is subject to gout, has resided much in warm and sultry climates, or has suffered much from chronic inflammation of the liver. In such cases always pay the greatest attention to the state of the urine, and lose no time in correcting any unnatural condition by the use of the appropriate remedies, the principles of selecting and adapting which have been already explained. I need hardly observe, that the constitutional symptoms should also be attended to, and the different functions carefully examined, any errors or irregularities in which should be immediately corrected by suitable remedies and proper modes of treatment.

VELPEAU'S
CLINICAL LECTURES
ON
OPHTHALMIA.

By J. HENRY BENNET, B.L. & B.S.
Sorbon.

INFLAMMATORY AFFECTIONS OF THE
CORNEA.

Coloration of the cornea: The water-green tint—The brown tint—The yellow tint—The dark red tint.—Suffusion of the cornea.—Photophobia and Epiphora.—Disorder of the visual functions.—Acute keratitis: Superficial keratitis—Interstitial keratitis—Deep-seated keratitis.—Termination.—Prognosis.

Coloration of the Cornea.—Returning to the consideration of the anatomical symptoms of keratitis, we must now study the changes which take place in the coloration of the cornea, when it has become the seat of inflammation. When examined in the different stages of the disease, it will be found that the cornea may be of four distinct shades or tints; with these it is important that you should become acquainted, as they will greatly assist you in the diagnosis of the various forms of inflammation we shall have to study.

The water-green tint.—The shade to which this term is applied is met with during the first period of the inflammation, and is not easily distinguished at first sight. Indeed, to form a correct estimate of the change that has taken place, the cornea must be attentively examined, and that on a patient who has only one eye affected. I describe the appearance which it then presents, under the name of the water-green tint, from the likeness which exists between the colour of the cornea and that of a sheet of water spread over a large surface, the transparency of which it very faithfully represents. Viewed sideways, and partially shaded from the light, the cornea has also a peculiarly moist humid appearance. These phenomena are not, in my opinion, to be attributed to any change in the tissue of the cornea itself, but to a change in the aqueous humour of the anterior chamber. I do not, however, attach much importance to this explanation.

The brown tint.—When the inflammation continues, the cornea soon becomes of a light brown colour. On examining it attentively, we also generally find that it is covered, either entirely or partially, with a great number of exceedingly small granulations, smaller even than those which I described as existing in granular conjunctivitis. These granulations give the

surface of the cornea a rough and uneven appearance, which we might aptly compare to that of a mucous membrane in the healthy state, and constitute, no doubt, what has been described by M. Lepelletier under the name of granular ophthalmia. The change which takes place in the colour of the membrane evidently depends on an alteration of its tissue—an alteration which may be referred to the external lamellæ. We shall also see presently that it is a symptom of superficial keratitis.

The yellow tint.—A yellow coloration of the cornea is a far more serious symptom than any we have yet examined, experience having shown that it always indicates a deep-seated affection of the tissue of the organ. The yellow tint first appears as a speck in the centre of the cornea, or as a narrow band or circle round its circumference. This circle may be complete or incomplete; in the latter case it is generally found to occupy the inferior portion of the cornea. It is important that you should become familiar with this symptom, as you might otherwise mistake it for a natural appearance caused by the reception of the cornea within the anterior border of the sclerótica. Such an error would probably be attended with disastrous consequences, the rapidity with which the yellow coloration extends being such, that, unless active measures are adopted to arrest its progress, the entire cornea is invaded, and vision is nearly always more or less injured.

The dark red tint.—This epithet does not convey as clear a notion of the colour which it is intended to describe as the expression adopted by Mr. Wardrop. He calls it the flint-stone colour; and those of you who have paid attention to diseases of the cornea, and have been able to observe it in the state the word represents, must confess that it is strictly appropriate. The change in the colour of the cornea generally commences, as with the yellow tint, in the centre.

Suffusion of the cornea.—Besides the changes in colour which the cornea undergoes, when inflamed, it may also become the seat of suffusion, which constitutes the slightest form of opacity. When this is the case, the transparency of the cornea appears rather dimmed. It might be compared to the surface of polished marble over which the finger has been passed, or to a mirror on which a person has breathed, and which is still obscured by a slight vapour. If this suffusion, this haziness, of the cornea increases, it takes the name of *nebula*, ophthalmologists having fancied that a resemblance exists between the slight opacities which are then ob-

served, and the airy clouds we see on a fine day floating in the air, like flakes of snow, festooned by the rays of the sun. The transparency of the cornea becomes more and more impaired when the inflammation does not abate; as, however, a considerable degree of suffusion is generally accompanied by ulceration of the cornea—a lesion which I intend to examine separately—we will not, for the present, pursue any further the examination of this symptom.

Now that we have studied the anatomical characters of keratitis—those which the Germans call the objective—we must direct our attention to the physiological or subjective symptoms of the disease. Although I have used the terms objective and subjective, I must tell you that I by no means admire them; they ought not, indeed, in my opinion, to be employed, as the words anatomical and physiological, or functional, are decidedly preferable. It is well, however, that you should be acquainted with their signification, as they are frequently used by German writers.

The physiological symptoms of keratitis are—intolerance of light, or photophobia; shedding of tears, or epiphora; pain and disorder of the visual functions.

Photophobia and epiphora.—These two symptoms deserve special attention, as they invariably accompany keratitis; they are also met with in iritis and retinitis. If we consult the various works which treat of ophthalmology, we shall find that most authors look upon photophobia and epiphora as symptoms not only of keratitis and iritis, but also of conjunctivitis, or of any other inflammatory affection of the eye. Reasoning and experience both show, however, that this opinion is incorrect, and that the phenomena in question are always the result of a lesion of the cornea, the retina, or the iris, and never that of simple inflammation of the conjunctiva. Nor will it be difficult to explain how the error originated. Not being accustomed to separate the different species of ophthalmia, confounding under the same name several distinct affections of the eye, they did not perceive that the patients on whom they observed these symptoms had not only inflammation of the conjunctiva, but also inflammation of one of the organs I have just named. Now I ask you, can it be rationally allowed that an inflammatory affection of the conjunctiva—a membrane which has no connection with vision—is capable of producing photophobia? In some cases of conjunctivitis, it is true, you see the patients carefully conceal their eyes, and take every precaution to protect them from the light; but this is not owing to photophobia. If

they do so, it is merely to avoid the pain which the contact of the air with the inflamed conjunctiva occasions. Some patients also keep their eyes closed, and their eyelids immovable, because the slightest motion of these organs gives rise to the painful sensation of extraneous bodies between the eye and the eyelid, to which I have so often alluded in speaking of conjunctivitis. A circumstance which proves also that conjunctivitis is not the cause of these phenomena is, that when this affection exists alone, the patient suffers acute pain, it is true, if the eyelids are separated, but is, nevertheless, able to examine every thing around him without the slightest difficulty. On the other hand, it is extremely easy to prove that a lesion of the cornea may produce these symptoms, as the slightest abrasion of that membrane on a living animal is immediately followed by intense photophobia and epiphora.

The intensity of the photophobia varies in the different forms of keratitis. In chronic and in diffuse keratitis it is but slight; its greatest intensity is, when there is ulceration of the cornea; indeed, it is possible to form a diagnosis of the existence of ulceration in eighteen cases out of twenty, from this symptom alone, without examining the eye. Whenever you see a patient who hides his face in his hands, or in the bed-clothes—who contracts his eyelids forcibly if you attempt to open them—from whose eyes a torrent of tears gushes forth as soon as they are exposed to light—you may be certain there is more or less abrasion of the cornea existing. The contact of the air with the ulcerated surface accounts for the intolerance of light being so great.

Epiphora is even a more characteristic symptom of keratitis than photophobia, no symptom shewing more clearly the difference which exists between the inflammatory affections of the cornea and those of the conjunctiva. In conjunctivitis there is a more or less abundant secretion of mucus, which collects in the inner angle of the eye; but, be the inflammation ever so great, even when chemosis exists to a considerable extent, there is no unusual secretion of tears. In keratitis, on the contrary, however violent the inflammation, there is scarcely any secretion of mucus, whilst the effusion of tears is generally so abundant, that the eyes seem literally bathed in water. This, however, only applies to the cases in which the above diseases exist singly; if they are combined, you will necessarily meet with both epiphora and a mucous secretion. The tears also appear to have acquired irritating properties, which they do not

possess in the healthy state, as they give rise frequently to a scalding sensation, and produce erythema, or even slight excoriation of the surface over which they pass.

If the inflammation runs high, the pain is often severe, so much so as to render sleep impossible; this is more especially the case when the cornea is ulcerated. It generally occupies the orbit, from whence it extends to the temples—to the forehead—sometimes all over the head, and is much more violent in some persons than in others—in the evening and during the night than in the morning. This latter circumstance is one of the reasons which have induced ophthalmologists to think that the inflammatory affections of the cornea are of a rheumatic nature. The exacerbation of the pain during the night, ought not, however, to have led to such a conclusion, as there are other maladies—such, for instance, as secondary venereal affections—in which the same symptom is observed.

Disorder of the visual functions.—In the different forms of conjunctivitis we have only found the functions of the eye impaired, as it were, accidentally, when chemosis exists to such an extent as to encroach on the cornea, and obstruct the passage of light. This is not the case with the disease we are now examining; the slightest alteration in the tissue of the cornea invariably more or less impedes the phenomena of vision. This circumstance alone would suffice to distinguish the affections of the cornea from those of the conjunctiva, were other characters wanting.

In keratitis, vision is more or less disordered, according to the form and activity of the inflammation—according, also, to the stage at which it has arrived. If there is but a slight suffusion of the cornea, the objects which surround the patient merely appear rather dimmed; indeed, frequently no difference is perceived. When, however, the suffusion becomes greater—when it assumes the form of nebula—every thing appears as if seen through a mist, the density of which depends on the degree of opacity which the cornea presents. If there exists an ulceration, or a circumscribed collection of coagulable lymph, between the lamellæ of the organ, sight is very seriously impaired, especially when the lesion is opposite the pupil. Alteration of the tissue of the cornea is not, however, the only cause which may impair the visual functions. The aqueous humour may become affected, and assume a milky appearance; the iris may be inflamed, and the contraction of the pupil which then takes place may be so great, as to obstruct the entrance of

light into the eye; the inflammation of the cornea may also be so intense as to extend to the crystalline lens, or to the vitreous humour.

Keratitis, as I have already told you, is to be met with both in the acute and in the chronic form. It is to the acute form of the disease that I shall now direct your attention.

Acute Keratitis.

Acute keratitis is, undoubtedly, the most common form of the disease. The inflammation may assume the chronic type at the commencement, it is true; but cases of this kind are not very frequent. Acute keratitis may be superficial, interstitial, or deep-seated. Each of these forms must be examined separately.

Superficial keratitis.—Inflammation of the superficial lamella of the cornea is the least serious form of the disease, and often owes its origin to conjunctivitis, in which case the characters of the two affections are more or less blended. It is also the form of inflammation which is generally produced by external violence. The following are the anatomical characters by which it may be distinguished:—The cornea at first presents a slight suffusion, which, if examined with care, will be found to reside evidently in the external lamellæ. In the course of a day or two it loses its polished appearance, and becomes covered with small granulations, which are not always perceptible to the naked eye, but may easily be seen with a magnifying glass. They may be compared, in every respect, to those which we meet with in granular blepharitis or conjunctivitis, and, like them, are probably due to the hypertrophy of the glandular organs which exist in the external membrane of the cornea. Even when the cornea is primitively affected, that portion of the conjunctiva which surrounds it soon becomes inflamed. Some anatomists deny the passage of the conjunctiva over the cornea; admitting, however, that they are right, we must conclude that the two membranes are continuous; and in either case, the connection which exists between them explains satisfactorily the rapid extension of the inflammation from one to the other. You see, therefore, that in superficial keratitis the conjunctiva is nearly always either primitively or consecutively inflamed. Its vascularity is often so great as to conceal the more deeply seated redness of the sclerótica. Numerous vessels are also frequently seen passing from it on to the cornea, under the form of delicate vascular filaments; sometimes they form a kind of triangular or semi-lunar network, the base of which rests

on the conjunctiva, whilst the summit advances more or less on the cornea, and terminates by a small pustule, or by a white speck. If the inflammation increases, one or more small phlyctenæ appear, due to a rising of the external membrane of the cornea; between this and the tissue of the organ a little coagulable lymph, or even pus, is effused, thus giving rise to a small abscess. These abscesses generally open externally; but sometimes, instead of perforating the outer membrane, they extend to the inner lamellæ, and occasion the interstitial form of inflammation.

When superficial keratitis is not accompanied by inflammation of the subjacent tissues, there is but little photophobia or epiphora. The objects which surround the patients are distinguished by them, although they appear enveloped by a mist of variable density. Generally speaking, the affection is not serious, and, if properly treated, may be cured in a few days, the cornea completely recovering its transparency in the cases in which there has been no ulceration.

Interstitial keratitis.—The interstitial form of inflammation is the one which is the best known, and has been the oftenest described; indeed, as it is the tissue of the cornea which is inflamed, it is to this affection that the word keratitis more especially answers. Superficial keratitis may be confounded with conjunctivitis; and deep-seated or internal keratitis with iritis; but the interstitial form can scarcely be confounded with either of these affections. It is, also, to this form that what has been said respecting the general symptoms of keratitis principally applies. The anatomical characters it offers are the following:—At the commencement of the disease the cornea often presents the water-green tint I have before described, but its transparency soon becomes much more diminished, and the patient complains that he cannot distinguish the objects which are near him from one another. The cornea assumes a muddy appearance, and effusion of coagulable lymph takes place between its lamellæ, either extending over the entire membrane, or occupying a more or less circumscribed portion of its surface, and that without there being necessarily any phlyctenæ, any erosion or ulceration of the external membrane. The vascular zone of the sclerotica is exceedingly well marked, and presents the characters with which you are already acquainted. The vessels, advancing in a parallel manner, converge as they approach the cornea, and form a red band of variable width. When there is no ulceration, you will often see very plainly, in the tissue of the cornea, many of them

advancing, under the form of small filaments, towards the centre. In many instances there is little or no inflammation of the conjunctiva.

There is but little photophobia or epiphora, unless the cornea be ulcerated; in which case, on the contrary, the intensity of these symptoms is very great. Interstitial keratitis is decidedly the most dangerous form of the disease, and deserves all the attention the surgeon can bestow.

Deep-seated keratitis.—In this form of keratitis the inflammation occupies that portion of Descemet's or Demour's membrane which lines the posterior surface of the cornea. Having hitherto been but little studied, and but imperfectly known, the symptoms of this affection have evidently been confounded with those of iritis. M. Schindler describes two varieties: in one, the internal surface of the cornea is inflamed; in the other, the anterior surface of the iris. The reasons which have induced him to make this division are not, however, sufficiently conclusive; new researches are necessary before it can be recognised. M. Jüngken asserts that in this form of keratitis, reddish streaks, formed by injected vessels and opaque specks, may be seen on the membrane lining the posterior surface of the cornea. I have myself never seen these appearances, although I have paid great attention to the subject. Indeed, when I take into consideration the distribution of the vessels of the eye, I can scarcely understand how these phenomena could take place. The opacities which M. Jüngken and some other ophthalmologists say they have seen, may also be merely the result of an optical illusion. Reflection of light might easily, under certain circumstances, lead us to suppose that a speck occupies the posterior surface of the cornea, whilst, in reality, it is situated on the external surface of that membrane.

There are several symptoms by which this affection may be distinguished from the other forms of inflammation. The external surface, as also the tissue of the cornea, remains healthy. The water-green tint, which, as I have already stated, probably depends on an alteration in the aqueous humour, is very evident during the first period of the inflammation; the aqueous humour gradually becomes more troubled, assuming a turbid appearance, especially in the inferior portion of the anterior chamber. This may be easily explained: the dimness of the aqueous humour is owing to the effusion of coagulable lymph, which, being of greater specific density than the aqueous humour itself, naturally accumulates in the lower part of the anterior chamber. This may also be

observed in Iritis; but the following symptom is peculiar to the affection of which we are now treating. On examining very attentively the cornea, you will perceive on its internal surface a number of minute spots, of a greyish yellow colour. Very often it is not until the eye has been examined several times that this peculiar appearance becomes manifest. The spots, which appear as if seen through a pane of glass, are either congregated on one part of the membrane, or scattered; they may be compared to the granulations of the external surface of the cornea. Sometimes there is a collection of matter formed between the internal membrane and the tissue of the cornea, in which case the membrane may give way, and the pus fall into the anterior chamber; or the inflammation may become interstitial.

The pain is more severe in deep-seated keratitis than in any other form of the disease. It is principally felt over the orbits, and in the back of the head, and is accompanied by throbbing in the eye, and by a sensation of fulness and distension. This arises from an increase in the quantity of the aqueous humour; the sclerotic, being of a fibrous nature, cannot give way, the eye becomes distended, and an eccentric compression is established, which gives rise to the peculiarly painful sensations I have mentioned. There is less photophobia or epiphora than in superficial or interstitial keratitis; nor will you be surprised at this, if you remember what I told you in speaking of this symptom. Indeed, photophobia appears to depend principally on ulceration of the cornea, and on the contact of the air with the excoriated surface which the cornea then presents. We have an instance of the pain which this contact occasions in blisters. When the epidermis is intact, the patient suffers but little; but as soon as it is taken off, and the cutis vera is exposed, the pain becomes very acute.

I am inclined to think, from what I have seen of this affection, that it is more frequently met with than is generally supposed. If I am right, practitioners would do well to direct their attention to the study of a disease, which, as I have already stated, has been hitherto but little noticed.

From what I have said—from your own observations at the bedside of the patients, you must be now well aware that the three forms of inflammation I have described may really be met with distinct from one another. But you must not think that it is always so; the cases in which they are distinct, after the first few days, may, on the contrary, be considered as exceptions to the general rule. As,

however, even when combined, one form generally predominates over the others, and as the prognosis and treatment of each are different, it is indispensable that you should be acquainted with their several symptoms.

Keratitis does not always follow the regular course I have described. The more serious symptoms, instead of appearing successively, may be present nearly at the commencement of the disease. Thus, in the course of a few days, or even in twenty-four hours, the cornea may become infiltrated with coagulable lymph to such a degree as to resemble a piece of bacon fat. This disorganization of the cornea often takes place after the operation for cataract by extraction, although, before the operation, no circumstance may have existed which could lead you to anticipate such an event. It occurs, indeed, more frequently when the inflammation is the result of external than when it is the result of internal causes. It is very frequent in the different forms of purulent ophthalmia, especially in the Egyptian and in the gonorrhoeal conjunctivitis. In some instances the cornea, although passing on to suppuration, may be only partially destroyed, and become vascularized with astonishing rapidity. It then presents the appearance of a turgid, red, fungous mass, bathed in pus, and half concealed by the eyelid. Mr. Wardrop, it seems, has met several cases of this kind among the troops that returned from Egypt. I have myself met with a striking instance in a man affected with extensive carbuncular inflammation of the two right eyelids. The cellular tissue of the eyelids was mortified; and when we were able to separate them, we found the cornea of a livid red colour, looking like a kind of cherry, and interspersed with white and yellow streaks.

In keratitis the inflammation is generally diffuse, occupying the entire cornea; it may, however, be partial. When this is the case, it is nearly always of a chronic nature; and the part of the membrane which is affected often presents a pustule, a phlyctena, or an ulceration. If the inflammation is limited to a portion of the membrane, and these phenomena are not observed, it follows the course I have already described.

Whatever may be the form under which keratitis appears, its progress is much slower than that of conjunctivitis. This depends not only on the nature of the disease itself, but also on its being nearly always accompanied by other inflammatory affections, such as blepharitis, iritis, choroiditis, &c.

Termination.—Acute keratitis usually terminates by resolution, ulceration, sup-

puration, or mortification. For the present I shall only speak of resolution; the other four modes of termination will be studied at a future period.

Resolution is certainly the most desirable termination of the disease; yet, even when it does take place, the functions of the eye may remain more or less impaired. When resolution commences before any infiltration has taken place between the lamellæ of the cornea, before any collection of matter has been formed, sight is restored in all its integrity. If, on the contrary, conglutinated lymph has been effused in ever so small a quantity, it is rarely completely absorbed, and gives rise, consequently, to opacity of the cornea. Softening of that organ may also take place to a certain extent before resolution commences; when this is the case its surface becomes uneven, or partly depressed; and then, although the transparency of the membrane is not altered, the sight is more or less injured.

Prognosis.—The prognosis of this affection is generally serious; not that any fear need be entertained for the life of the patient, but because the functions of an important organ are often seriously compromised. We ought, therefore, in every case, to do our utmost to arrest the progress of the inflammation as early as possible. The prognosis is not, however, equally serious in every form of the malady. Superficial keratitis may be completely cured, providing, as I have just stated, resolution commences before any effusion has taken place. Deep-seated keratitis is a more dangerous affection, from its immediate connexion with the internal parts of the eye. When improperly treated, the inflammation may invade nearly all the tissues which occupy the interior of the eye, and be followed by the total loss of that organ. The prognosis of interstitial keratitis is also more serious than that of the superficial form; it is this form of inflammation which most frequently gives rise to collections of matter, to abscesses, to hypopion, and to the more serious forms of opacity of the cornea. I would also remark to you, that the importance of the different forms of opacity depends in a great measure on its situation. Thus, a simple nephelion, or nebula, situated opposite the pupils in the axis of vision, will prove a greater impediment to sight than an albugo, or a leucoma, on another part of the cornea.

CLINICAL REPORTS OF DIFFICULT CASES IN MIDWIFERY.

By ROBERT LEE, M.D., F.R.S.

Physician to the British Lying-in Hospital, and
Lecturer on Midwifery at St. George's
Hospital.

FOURTH REPORT

Contains a comparative View of the present state of Obstetrical Surgery in Great Britain, France, and Germany, and the Histories of Forty-Two Cases of Difficult Labour in which the Forceps was employed.

If we compare the reports of the principal lying-in hospitals of Great Britain, France, and Germany, and examine the doctrines inculcated by the best systematic writers of these countries, it is impossible to avoid being struck with the want of uniformity which prevails in all that relates to the operations of midwifery. Although the causes of difficult parturition must be nearly the same in every part of Europe, cases of instrumental delivery are far more numerous in some countries and institutions than in others, and the method of operating is widely different. In England there are few practitioners of judgment and experience who have frequent recourse to the forceps, or who employ it before the orifice of the uterus is fully dilated, and the head of the child has descended so low into the pelvis that an ear can be felt, and the relative position of the head to the pelvis accurately ascertained. The instrument is not employed in this country where the pelvis is much distorted, or where the soft parts are in a rigid state; but it is had recourse to where delivery becomes necessary in consequence of exhaustion, hæmorrhage, convulsions, and other accidents, which endanger the life of the mother. It is used solely with the view of supplying that power which the uterus does not possess.

The employment of the long forceps, in cases of distorted pelvis, has been recommended by Baudelocque, Boivin, Lachapelle, Capuron, Maygrier, Velpeau, and Flamant, whose works contain ample instructions for its use before the head of the child has entered the brim of the pelvis; and the

last of these writers has expressed his belief, that the instrument is more frequently required while the head of the child remains above the superior aperture of the pelvis, than after it has descended into the cavity. "Tout praticien," he observes, "qui a médité sur l'application de cet instrument, est convaincu que l'occasion se présente bien plus souvent d'aller prendre la tête au-dessus du détroit abdominal, que dans l'excavation. Je pourrais apporter en preuve ce qui s'est passé à la clinique d'accouchemens de la faculté de médecine de Strasbourg et dans ma pratique civile*."

These authors also recommend the forceps in presentations of the nates, and to extract the head after the expulsion of the trunk and extremities of the child.

The operation of craniotomy is performed by all British practitioners, whether the child be alive or dead, if the condition of the mother is such as to render delivery absolutely necessary, and the head of the child is beyond the reach of the forceps, or where, from distortion of the pelvis, or rigidity of the os uteri and vagina, it cannot be extracted if its volume is not reduced. This operation is performed, from a conviction, that if neglected to be done, and at a sufficiently early period, the mother's life will be sacrificed; and the life of the mother is considered much more valuable than that of the child.

Some continental authors affirm that we have frequently recourse to craniotomy without due consideration, and without regard to the life of the child; and, whatever the state of the parent may be, they refuse to open the head till they can obtain certain evidence that it is dead. "Nothing could excuse the conduct of the practitioner," observes Baudelocque, "who would perforate the head, without previously knowing with certainty that it was not alive—a circumstance which can alone authorise us to employ the perforator and crotchet."

The same opinion is expressed by Velpeau, who maintains, that even when the child is dead, if the diameter of the pelvis is only 15 lines, or the whole hand cannot be passed into the cavity of the uterus, to turn the child, the

Cæsarean operation is to be performed. When the small diameter is from 12 to 15 lines, he considers hysteriotomy to be necessary, whether the child be alive or dead; and that it is also required, if the child be alive, when the diameter measures from 18 lines to 2 inches and a quarter. Craniotomy, he thinks, must be rarely necessary, for in more than 20,000 labours it was performed only twelve times, by Madame Lachapelle, in the Maternité of Paris.

According to Stein and Plenck, a conjugate diameter of 3 inches, $2\frac{1}{4}$, $2\frac{1}{2}$, or $2\frac{3}{4}$, prevents either nature or the forceps from effecting the delivery. Therefore, if the child be living, the Cæsarean section must be performed, or, if the child be dead, the perforator must be used.

These authors also affirm that a conjugate diameter of 2 inches renders delivery impossible. If the child be alive, the Cæsarean section must be performed; if the child be dead, it is scarcely possible to open the head*.

The reports of 258 cases of Cæsarean section have been collected by Michaelis, 144 of which occurred in the last, and 110 in the present century. Of these 258 cases, 140 proved fatal.

Velpeau states that the operation was performed 28 times between 1810 and 1820, and 61 times from 1821 to 1830. It is well known that many unfortunate cases of Cæsarean operation have occurred in France and Germany, of which no reports have been published; and those who have recently visited the continent have assured me, that this operation, notwithstanding its fatality, is becoming more and more common.

In Great Britain, the reports of at least 26 cases are to be found; and in 24 of these it was fatal to the mother. About 13 of the children were born alive. If correctly informed, there is no eminent accoucheur now practising in London, who has been present at the performance of the operation upon the living body, or who would recommend it, if delivery could be effected by the perforator and crotchet.

The discordance which exists between Continental and British practitioners and authors is not less strikingly displayed, respecting the induction of premature labour. In numerous cases, it

* Mémoires Pratiques sur le Forceps, p. 25, Strasbourg, 1816.

* Merriman's Synopsis, p. 318, Lond. 1826.

has been successfully employed in this country; and it is now fully ascertained that the operation is attended with little risk to the mother, and that nearly one-half of the children are born alive, and continue to live, where it is performed after the seventh month. In cases of great distortion of the pelvis the induction of premature labour at an early period of pregnancy, before the sixth month, is likewise known to be a safe operation, and to render craniotomy and the Cæsarean section wholly unnecessary.

In Germany and Holland it has frequently been employed by May, Weidman, Ch. Wenzel, Reisinger, and Kraus, with satisfactory results.

Baudelocque regarded the induction of premature labour as a useless, if not an injurious, operation; and Dugès has recently characterized it as fatal to the mother and infant, and the source of most frightful abuse.

In the tables of the Maternité, by Baudelocque, Boivin, and Lachapelle, including nearly 60,000 cases of labour,

there is no report made of any case in which premature labour was induced. The last of these writers begins her strictures on the practice by declaring "that she had never either employed that method or seen others have recourse to it."

In 1827, the propriety of inducing premature labour was brought under the consideration of the Academy of Medicine by M. Costa, and in their decision they declared—"Que la question était inconvenante, et elle établit que, dans l'état actuel de la science, il n'existe aucun cas où il soit permis de provoquer l'avortement chez une femme grosse; ni le rétrécissement considérable du bassin; ni le développement de convulsions; ni même l'implantation du placenta sur l'orifice utérin; qu'il n'y a pas de moyen s'assurer de la viabilité du fœtus; enfin, que le plus souvent les accouchemens provoqués sont funestes à la mère et à l'enfant*."

According to this judgment, the induction of premature labour is unwarrantable under any circumstances.

A Table exhibiting a comparative View of the frequency of Forceps and Craniotomy Cases in several Lying-in Hospitals†.

| Lying-in Hospitals. | No. of Labours. | Forceps Cases. | Proportion. | Craniotomy Cases. | Proportion. |
|-----------------------------------|-----------------|----------------|-------------|-------------------|-------------|
| Dublin, Dr. Joseph Clarke | 10,199 | 14 | 1 in 728 | 49 | 1 in 248 |
| Ditto, Dr. Collins | 16,654 | 27 | 1 — 617 | 118 | 1 — 141 |
| Maternité, Paris, M. Baudelocque | 17,388 | 31 | 1 — 561 | 6 | 1 — 2898 |
| Ditto, Mad. Lachapelle | 22,243 | 76 | 1 — 293 | 12 | 1 — 1854 |
| Ditto, Mad. Boivin | 20,517 | 96 | 1 — 214 | 16 | 1 — 1282 |
| Vienna, Dr. Boer | 9,589 | 35 | 1 — 274 | 13 | 1 — 737 |
| Masburg, Dr. C. Siebold | 340 | 35 | 1 — 10 | 1 | 1 — 340 |
| Heidelberg, Dr. Naegele | 1,711 | 55 | 1 — 31 | 1 | 1 — 1711 |
| Dresden, Dr. Carus | 2,549 | 184 | 1 — 14 | 9 | 1 — 283 |
| Berlin, Dr. Kluge | 1,111 | 68 | 1 — 16 | 6 | 1 — 185 |
| Ditto, Dr. Siebold | 2,093 | 360 | 1 — 7 | 1 | 1 — 2093 |

The present state of operative midwifery can afford little satisfaction to those who know the full extent of the good and evil it is capable of producing to society, and who desire that its principles should be as clearly understood as those of the other branches of surgery. Had a faithful report been given of all the cases of artificial delivery contained in this table, with the results of the operations performed, it is impossible that so great a discordance of opinion

could so long have existed respecting the employment of instruments in the practice of midwifery.

I propose in this and the following reports to give a short account of all the cases of difficult parturition in which I have had recourse to the forceps, the induction of premature labour, and craniotomy, with the view of illustrating the various circumstances which

† See Dr. Churchill's Researches on Instrumental Delivery, in the seventh volume of the Dublin Journal of Medical and Chemical Science.

* Archiv. Gén. de Médecine, t. 13, p. 441.

render these operations necessary, and the difficulty and danger with which their performance is accompanied.

I shall first relate those cases in which the forceps was followed by mischievous consequences, or produced no benefit either to the mother or child; and 2dly, those cases in which the lives of the children were manifestly preserved by its use.

CASE LXIX.—On the 28th June, 1823, I was present at the delivery of a woman, æt. 30, who had been in labour nearly three days and nights under the care of a midwife attached to a public institution. It was the first child. The orifice of the uterus was not fully dilated, and very rigid. The vagina swollen and tender, the abdomen tense and painful on pressure. Tongue loaded; urgent thirst; countenance flushed; pulse rapid and feeble. The labour pains for ten or twelve hours had been gradually becoming more feeble and irregular. The head of the child was strongly compressed, and much swollen, and the greater part of it was above the brim of the pelvis. An ear could not be felt, and the hollow of the sacrum was empty. It was determined by the practitioner who had the charge of the case, to attempt to deliver with the long forceps, and he observed, before proceeding to introduce the blades, that it was a case, in which the superiority of the long over the short forceps would be observed in a striking manner, and that in less than a quarter of an hour the delivery would be safely and easily completed, and the life of the child preserved. The blades of the forceps were, however, introduced with great difficulty, and still greater was experienced in getting them to lock. Strong traction was then made for several minutes, and the blades slipped off the head. They were reintroduced, and the efforts to extract renewed, and continued till the instrument again slipped off. This happened several times, but the attempt to deliver with the forceps was not abandoned till the operator was exhausted with fatigue. The head was then perforated, and extracted with the crotchet. Violent inflammation and sloughing of the vagina followed, and about three weeks after delivery it was ascertained that a large vesico-vaginal fistula existed. This woman was abandoned by her husband, and was afterwards reduced in consequence of this

misfortune to the greatest possible misery.

This was the first time I ever saw the forceps applied in actual practice, and I was struck with the vast difference which exists between the application of the forceps upon the phantom and a woman in labour. The unfortunate termination of this case made me resolve carefully to watch the progress and termination of all the cases of difficult labour which I could meet with, and preserve accurate histories of them, which has been done to the present time.

CASE LXX.—On Saturday morning, 12th July, 1823, I was called to see a poor woman, æt. 26, also a patient of a public institution, who had been nearly fifty hours in labour with her first child. The membranes had been ruptured on the Thursday evening, and the pains had been gradually becoming more and more feeble during the afternoon and night of Friday. On Saturday morning the pains had nearly ceased. The pulse quick; skin hot. The pupils were unusually dilated, and there were slight convulsive tremors of the muscles of the face and extremities, with occasional incoherence. The orifice of the uterus was fully dilated. The external parts were rigid, hot, and swollen. The head of the child was firmly squeezed into the brim of the pelvis, but the greater part of it had not passed through it. The bone overlapped much, and a large tumor of the scalp was formed. A copious venesection was employed, and soon after two severe fits of convulsion took place. The blades of the long forceps were applied, but they slipped off the head, as in the former case when an attempt was made to extract, and the delivery was completed by craniotomy. In a few hours consciousness returned, and no more fits were experienced, but on the third day inflammation of the uterus took place, from which she recovered with the greatest difficulty.

CASE LXXI.—April 1832, I was called to an out-patient of the St. Mary-lebone Infirmary, who had been in labour nearly sixty hours, and was attended by one of the parochial midwives. I found the os uteri thick, rigid, and imperfectly dilated, the bones of the head squeezed firmly into the brim of the pelvis, and not sufficiently low down to allow the ear to be felt. The ergot of rye had been administered by the midwife at different times during the pro-

gress of the labour, and it was said to have increased the strength of the pains. Mr. Hutchinson, house-surgeon to the Infirmary, agreed with me in thinking, that the forceps could do nothing but mischief, and that it was necessary to deliver without delay by opening and extracting the head. This I immediately did, and from the long-continued efforts required to draw the head into the cavity of the pelvis, it was evident that the delivery could have been accomplished in no other way with safety to the mother. She recovered rapidly.

On the 11th April, 1833, I was again called to deliver this woman, but being indisposed at the time, Mr. Hutchinson attended her for me. He found the scalp tumid, the bones riding, external parts swollen. Pains strong for thirty hours. He opened the head, and found little difficulty in extracting it.

In the autumn of 1834, I was called to Calmell Buildings to deliver this patient in her third labour. She was on this occasion attended by two gentlemen who were pupils of a public institution, and she had neglected to inform them of what had occurred in her two previous labours. Before I saw her the ergot of rye had been liberally administered, and repeated attempts made to deliver her with the forceps, the blades of which had lacerated the vagina extensively on the left side. The vagina and external parts were enormously swollen and inflamed. The head was so fast wedged in the brim of the pelvis that it was difficult to pass the finger around it. The abdomen was tense and painful on pressure, and the bladder filled with urine. The pulse extremely rapid and full. There was incessant vomiting and complete exhaustion. I immediately opened the head and extracted it with the crotchets, but she died in less than twenty-four hours after.

CASE LXXII.—In the summer of 1833, a general practitioner, of little practical experience, was engaged to attend a woman in labour, who resided in one of the courts between Princes Street and Great Windmill Street. She had previously been delivered of several children without difficulty. On this occasion the labour was protracted, and, without any consultation, recourse was had to the forceps, and she was delivered of a dead child. Soon after, the usual symptoms of ruptured uterus supervened, and she did not

long survive. In the evening I saw the body, but was not permitted to make any examination of it. It was with difficulty that a coroner's inquest was prevented from being held. The surgeon, after this occurrence, soon left the country, and is now absent from England.

CASE LXXIII.—About seven years ago, a medical practitioner, who had been extensively employed as an accoucheur at the west end of London, met with a case of very protracted labour, in which it became evident that the child would not be expelled without artificial assistance. He called into consultation an obstetrical physician of the greatest celebrity, who has been accustomed in his lectures to recommend the employment of the long forceps. At six in the morning, when he was called, the head of the child had not passed through the brim of the pelvis, and was completely beyond the reach of the forceps. At the end of four or five hours, during which time the head had not descended further into the cavity of the pelvis, it was determined to deliver with the long forceps. The blades of the instrument were passed up, and the head grasped and extracted, after the employment of much force; but scarcely had the delivery been accomplished, though there was no hæmorrhage, than the patient became restless, sick, and faint, and threw her arms incessantly around her. She died within three hours, with symptoms of ruptured uterus. The child was alive, and has been reared.

CASE LXXIV.—In the summer of 1831, I saw a case in the Middlesex Hospital, with the late Dr. Hugh Ley, in which extensive sloughing of the vagina had followed the use of the forceps. The instrument had been employed by a medical practitioner of experience and reputation. The child was dead.

CASE LXXV.—In the same year, Mr. Prout, surgeon to the British Lying-in Hospital, requested me to accompany him to a case of difficult labour in Ogle Street, from a thick cicatrix of the vagina. This patient had likewise been delivered some years before with the forceps, and the accoucheur was an eminent operator.

I am uncertain if the first child was alive.

CASE LXXVI.—At 10 A.M. December 6, 1835, I was called to Mrs. N—, æt. 36, residing at 7, Farm Street, Berkeley Square, who had been upwards of thirty hours in labour with her second child. I found the umbilical cord hanging out of the external parts, and without pulsation; the meconium escaping, and the discharge from the vagina very fetid. The head and right arm were jammed in the brim of the pelvis, the orifice of the uterus fully dilated, and an extensive cicatrix, with a thin edge, high up in the posterior wall of the vagina. I immediately opened the head of the child, and extracted it very slowly with my craniotomy forceps, so that no part of the vagina was torn.

The medical practitioner who had the charge of the case informed me that he had delivered this patient with the forceps, of her first child, two years before, after she had remained in labour three days and nights. The child was dead, and her recovery was so favourable that no suspicion existed of the vagina being injured.

CASE LXXVII.—In the month of December 1838, a woman, twenty-four years of age, was admitted into St. George's Hospital, who had been delivered of her first child about nine weeks before. The perineum, recto-vaginal septum, for nearly an inch and a half, and sphincter ani, were all destroyed, and the power of retaining the contents of the rectum entirely lost. The case admitted of no relief except by pressure, preventing the constant escape of the feces. This wretched state had resulted from laceration and sloughing of the parts, from the employment of the forceps in her first labour. The child was dead.

CASE LXXVIII.—In the summer of 1839, I was requested to see a patient whose labour was protracted by a tumor within the pelvis. She had been delivered before of several children, and all her previous labours had been easy and natural. After she became pregnant on this occasion, she thought, from feeling two distinct swellings of the abdomen, that she had twins. When I first saw her, she had been in labour nearly twenty-four hours. The head had scarcely begun to enter the brim of the pelvis, the cavity of which was nearly filled with a tumor, which was probably ovarian. Whenever a pain

came on, the tumor was pressed down before the head. The forceps had been applied, but the head could not be brought before the tumor, though great and long-continued efforts had been made to drag it forward. I opened the head, and had much difficulty afterwards in drawing it down with the crotchet.

CASE LXXIX.—On the 12th March, 1835, I was present at the delivery of a patient in a public institution, where the forceps was applied, and the bones of the fetal head were severely injured. The woman was 27 years of age; it was her first child, and she had been nearly forty hours in labour. The pains had not ceased altogether, but the head had not advanced for many hours, and it had not cleared the brim, though the ear behind the symphysis pubis could be felt. A physician of the greatest experience, and very dexterous in the use of the forceps, applied it; but the head could not be extracted without employing great force for a considerable period. The child breathed for a few seconds, and then expired.

On the following day I examined the head of the child, and found the bones of the skull much injured, and the posterior part of the right parietal bone completely detached from the occipital bone. The patient recovered.

LXXX.—In the evening of the 24th August, 1837, I was called to a lady who had been in labour since one o'clock in the morning; during the whole of which time the pains had been feeble and irregular. At four in the afternoon a dose of laudanum had been given. At 9 P.M. the pains were weak, and she seemed much exhausted. The orifice of the uterus was imperfectly dilated, and the greater part of the head was still above the brim of the pelvis. Near the navel, a part of the uterus projected so much, from some part of the child being pressed against it, that we dreaded rupture of the uterus.

The forceps was applied by the medical attendant, and strong efforts made with it to extract the child, but they were useless; and it became necessary to have recourse to craniotomy. The perineum was lacerated while the shoulders were passing.

The patient recovered, and has since been delivered of a living child without instrumental aid.

[To be continued.]

CLINICAL OBSERVATIONS

ON

THE USE OF THE AIR-DOUCHE IN THE
DIAGNOSIS AND TREATMENT

OF

DISEASES OF THE EAR.

By T. WHARTON JONES, Esq.

[For the London Medical Gazette.]

No. V.

THE injection of ethereal vapour into the tympanum was first tried as a remedy for deafness by Itard, but it is to Kramer we owe the most complete observations on the subject. I have already given some hints of a view different from that of Kramer, which might be taken regarding the pathology of at least some of the cases benefited by ethereal vapours thrown into the middle ear, and of course also regarding the *modus operandi* of the remedy.

According as the case is, in his opinion, one of erethitic nervous deafness or torpid nervous deafness, Dr. Kramer applies the ether raised into vapour by its own volatility at the temperature of the atmosphere, or by means of the application of heat; and for these purposes he employs two different apparatuses, which are described and delineated in his work. The apparatus I have employed is represented in the annexed engraving:—

a. A tubulated glass receiver, into which some drops of acetic ether are put.

b. A chemical stand for supporting the receiver.

c. c. A large Eustachian tube catheter, fitted in a cork and inserted into the neck of the receiver.

d. d. The flexible tube of the air-press, inserted into the wide end of the catheter, and conducting an extremely gentle stream of air into the receiver.

e. A flexible tube, fixed at one end, by a cork, into the small mouth of the receiver. The beak at the other extremity is adapted to fit into the wide end of the catheter introduced into the patient's Eustachian tube.

The stream of air from the air-press is regulated by plunging the beak of its flexible tube, before joining it to the apparatus, into a glass of water, and seeing that the air issues out merely bubble after bubble.

The air from the air-press thus issuing in a gentle stream, becomes, in its passage through the receiver, loaded with ethereal vapour. If it is desired to apply the air loaded with a greater quantity of ethereal vapour, then more or less heat, by means of a wax taper or spirit lamp held for a minute or two under the receiver, may be applied.

This simple and extremely convenient contrivance thus serves the purpose of the two separate apparatuses of Kramer.

Of course, before attempting to inject the ethereal vapour into the tympanum, it must be ascertained that the Eustachian tube is pervious. If it is in any way obstructed, the injection of the ethereal vapour will be found, as mentioned in my last communication, to assist the action of the air-douche. When the Eustachian tube has been ascertained to be pervious, it is nevertheless advisable, every time before proceeding to send in the vapours, to satisfy oneself, by blowing with the mouth, that the catheter lies right, and that there is free passage to the tympanum. It is not enough, either in applying the air-douche or ethereal vapours, that the beak of the catheter be engaged in the Eustachian tube in any sort of way; the axis of its orifice ought to be as near as possible in that of the passage; and to get it so, repeated trials, by blowing with the mouth, or by a very gentle stream from the air-press, must be made, and the catheter shifted accordingly, by rotating it on its axis so as to turn the beak more or less in a direction upwards and outwards, by pushing it a little further in or drawing it somewhat out. After each shifting, it is to be again steadily fixed by the vice of the frontlet. Without the catheter being steadily fixed by the frontlet, the former cannot keep in a proper position, and the subsequent steps of the operation consequently cannot be

performed with precision and effect, nor without unnecessary pain. If the catheter does not lie properly, the stream of air often does not enter the tympanum at all; in which case an obstruction of the Eustachian tube may be suspected where none really exists. On the other hand, without ascertaining exactly if the Eustachian tube be pervious preparatory to employing the injection of ethereal vapours, this treatment may be carried on for a long time without the vapours ever getting into the tympanum. A prickling sensation in the tympanum is in general a pretty good sign that the ethereal vapour has entered.

CASE II. (continued). — *Renewal of deafness—Eustachian tubes pervious, and the tympanic cavities free of any accumulation of mucus.—Treatment by ethereal vapours sent into the tympanic cavities, assisted by general remedies.*

I had not seen or heard any thing of Master C. D. from the 18th of August, 1838, until Saturday, the 30th of March, 1839, when he was brought to me with his hearing in the following state:—Right ear, eight inches; left ear, four inches.

Has had in the course of the winter several very severe attacks of ear-ache; but the hearing, it appears, only became so dull as it is now two or three weeks ago, when he was seized with a nasal catarrh.

Auditory passages in a healthier-like state than before.

Exploration by the air-douche showed the Eustachian tubes to be pervious, and the tympanic cavities free of any accumulation of mucus.

No great improvement in hearing immediately after the air-douche.

Monday, 1st April.—Hearing distance of the right side, nine inches; of the left side, six inches.

Air-douche applied to the right ear. The air entered freely, as on Saturday, but with more gurgling at first.

Vapours from a few drops of acetic ether were also injected into the right tympanum for five or ten minutes.

Tuesday, 2d.—Hearing distance of both sides, about eight or nine inches.

No improvement immediately after air was sent into the tympanic cavities by a forced expiration with the nose and mouth closed.

Left side treated. No improvement immediately after.

Wednesday, 3d.—The above detailed exploratory treatment led me to form the following opinion of the case, which was submitted to Sir James Clark at a consultation to day:—

Diagnosis.—This new attack of deafness is owing, not like the former, to accumulation of mucus in the middle ear, but probably to some change, such as thickening and the like in the mucous membrane lining the tympanic cavities, produced by the neglected inflammatory attacks.

Prognosis.—Some improvement of the hearing may be effected by prolonged treatment, but by no means to the amount obtained before.

Treatment.—The only local treatment which experience recommends is acting on the membrane supposed to be affected, by the vapour of acetic ether injected into the tympanum. This course of treatment, however, is not to be commenced until the state of the throat and of the intestinal mucous membrane has been improved, the nasal catarrh completely gone off, and counter-irritation kept up for some time on the sides of the neck behind and below the ears.

To take an emetic, and afterwards some laxative and alterative medicines. Blisters to the sides of the neck.

Wednesday, 10th.—Has taken the medicines, and has had the blisters applied.

Hearing much the same.

Thursday, 11th.—Right ear, one foot; left ear, eight inches.

Nostrils too tender to allow the passage of the catheter.

R Hydr. eum Cretâ, gr. xxxv.; Pulv. Ipeac. gr. iv.; Extract. Aloes aquos. gr. xij. Fiat pilulæ xij. Sig. Alterative pills; one every night.

R Pulv. Rhei ʒjss.; Sodæ Carbonat. ʒiij; Sodæ Tartarizat. ʒvj.; Sacch. Alb. ʒij. Misce optime in mortario ut fiat pulvis.

Sig. A small spoonful in a wine-glassful of water every morning.

To continue the local treatment.

Friday, 12th.—Hearing same as yesterday. Air-douche and ethereal vapours applied to the right ear; after which the hearing distance was fourteen inches.

Saturday, 13th.—Right ear, fourteen inches; left ear, one foot.

Left ear treated. After the treatment

the hearing distance was one foot and a half.

Monday, 15th.—Right ear, one foot and a quarter; left ear, one foot and a half.

Right ear treated.

After this the right ear heard the watch at the distance of one and a half foot.

Tuesday, 16th.—Right ear, two feet and one inch; left ear, one foot and a half.

Nostril of the left side too tender to admit the introduction of the catheter without pain. The catheter was introduced into the Eustachian tube of the right side and some air blown in, but the nostril was too irritable to bear the presence of the catheter long enough to finish the treatment.

To apply a leech to the entrance of each nostril.

Wednesday, 17th.—The leeches have been applied.

Right ear, one foot ten inches; left ear, one foot eight inches.

Left ear treated.

Thursday, 18th.—Right ear, two feet four inches; left ear, one foot ten inches.

Right ear treated.

Friday, 19th.—Right ear, two feet and a half; left ear, one foot ten inches.

Left ear treated. Immediately after treatment the hearing distance was found risen to two feet and a quarter.

Saturday, 20th.—Both sides much the same as yesterday.

Right ear treated. After that the hearing distance was two feet ten inches.

Monday, 22d.—Right ear, three feet two inches; left ear, two feet five inches.

Left ear treated.

Wednesday, 24th.—Right ear same as at last report.

Left ear, three feet.

Right ear treated.

Thursday, 25th.—Right ear, three feet two inches; left ear, two feet seven inches.

Left ear treated.

Friday, 26th.—Right ear same as yesterday.

Left ear, three feet.

Right ear treated. Immediately after the treatment, three feet and a quarter.

Saturday, 27th.—Throat sore since yesterday. The tonsils large. Noises in both ears.

Right side, three feet; left side, three feet two inches.

Left nostril too tender to allow the passage of the catheter. Right ear treated.

After this the hearing distance was found risen to three feet and a half.

Monday, 29th.—Both sides, three feet nine inches.

Left ear treated with the air-douche only; after which the hearing distance was about four feet.

Tuesday, 30th.—Right ear, three feet seven inches; left ear, four feet.

Air-douche applied to the right ear.

Scarified the right tonsil.

Wednesday, 1st of May. Right and left ears both about four feet.

Air-douche applied to the left side. After this the hearing distance rose to four feet and a half.

Scarified the left tonsil.

The tonsils to be touched with the lunar caustic pencil occasionally.

Thursday, 2d.—Both ears, four feet.

Right ear treated with the ethereal vapours.

Friday, 3d May.—Right ear, four feet three inches; left ear, four feet four inches.

Left ear treated with the ethereal vapours.

Saturday 4th.—Right ear, four feet and a half; left ear, four feet four inches.

Right nostril too tender to admit the catheter. Left side treated.

Monday, 6th.—Right ear, four feet eight inches; left ear, four feet seven inches.

Right ear treated.

Tuesday, 7th.—Hearing of both ears the same as yesterday.

Air-douche only applied to the left side, after which the hearing distance was four feet eleven inches.

Friday, 10th.—Right ear, four feet and a half; left ear, four feet nine inches.

Nostrils too tender to admit of the introduction of the catheter.

Is going to the country for a week. To intermit all medicines during that time.

Monday, 20th May.—Hearing distance of both ears much the same as at last report.

Right ear treated.

Tuesday, 21st.—Right ear, four feet; left ear, four feet seven inches.

Nostrils too tender to allow the passage of the catheter.

Wednesday, 22d.—Hearing much the same as yesterday. No noises in either ear. Nostrils still tender.

Thursday, 23d.—Hearing still the same as yesterday.

Tuesday, 28th.—The watch is heard at the distance of four feet, but hearing is very dull for conversation.

Tonsils improved, but nostrils still too tender to allow the passage of the catheter without some pain.

Auditory passages pretty well.

In consultation again with Sir James Clark, it was agreed to intermit the use of the ethereal vapours, and to subject the patient to the following treatment:—

1. Six leeches behind and below the ear on one side, and two days after, the same number to the opposite side.
2. A blister to the nape of the neck kept open with savine ointment.
3. Three grains of mercurial chalk combined with extract of conium every night; and a draught of Pulnau water every second morning.

Wednesday, 5th June.—Is going on with his medicines.

Hearing distance by the watch, of right ear, three feet seven inches; left ear, three feet nine inches.

I think he takes part in conversation rather better.

Wednesday, 12th.—Hearing the same by the watch, but continuing better for conversation.

Monday, 1st July.—Hearing continues much the same. Some noise in the ears.

Local treatment resumed.

Right ear treated with the vapours of ether; the perviousness of the Eustachian tube being previously ascertained by blowing through the catheter with the mouth simply.

Tuesday, 2d.—Hearing much the same as yesterday.

Left ear treated.

Wednesday, 3d.—Hearing distance of both sides about three feet and a quarter.

Nostrils too tender to admit the passage of the catheter.

Saturday, 6th.—Nostrils still tender.

To apply a leech to each nostril.

Monday, 8th.—The leeches have been applied.

Tuesday, 9th.—Introduced a catheter into the right Eustachian tube, and injected ethereal vapours, very gently, for about ten minutes.

Wednesday, 10th.—Right ear, four feet; left ear, three feet nine inches.

Treated the left ear with the ethereal vapours.

Thursday, 11th.—Right ear treated.

Saturday, 13th.—Left ear treated.

Monday, 15th.—Right ear treated.

Tuesday, 16th.—Hearing continues much the same according to the watch, but the ability to take part in conversation evidently much improved.

Left nostril too tender to admit the catheter.

Right ear treated.

Wednesday, 17th.—Hearing distance of both sides by the watch about four feet.

Left ear treated.

Thursday, 18th.—Hearing the same by the watch.

Right ear treated.

Tuesday, 23d.—Hearing distance of both ears by the watch about four feet nine inches.

As the hearing according to the watch shows no disposition to farther improvement, I think it unadvisable to continue the treatment. The susceptibility to the human voice has, however, increased so much that the patient carries on conversation without any difficulty.

Dismissed, relieved.

REMARKS.—The renewed deafness in this case corresponded very closely with nervous deafness, as it is commonly described; but that it was owing to inflammation of one or more of the parts of the ear the history of the case leaves not a doubt. There still existed the enlargement of the tonsils and the chronic inflammatory affection of the mucous membrane of the throat and nose. The frequent aggravation of the state of the latter proved a great hindrance to the employment of the local treatment of the ear; catheterism having been always desisted from when it caused the slightest distress.

All the improvement of hearing according to the watch that was gained occurred in the first six weeks of treatment. But it is to be remarked there was not a corresponding increase in the power to carry on conversation. This only began to manifest itself during the second course of general treatment, and went on under the influence of the renewed local treatment.

ON DR. HOPE'S CLAIM

TO

CERTAIN EXPERIMENTS ON THE
SOUNDS OF THE HEART;WITH SIR BENJAMIN BRODIE'S LETTER OF
ARBITRATION.*To the Editor of the Medical Gazette.*

SIR,

My attention has been lately directed to the following note, in a recent edition of a "Treatise on Diseases of the Heart," by Dr. James Hope. It may be necessary to explain, that "a certain gentleman" means *myself*, and that the experiments are those published in the third edition of my Pathology and Diagnosis of Diseases of the Chest. They were performed in February 1835, and were the first successful experiments of the kind.

"These experiments have been appropriated by a certain gentleman. At their second performance, on November 3, 1834, I promised him, from friendly motives, the use of them for a forthcoming edition of his book; and immediately before their final performance, in February 1835, I permitted him, as he expressed a wish, to become my conjoint associate, and subsequently lent him my own notes of the experiments, written almost entirely with my own hand. He detained the notes, claimed the experiments, and interdicted me from 'pirating' them. An arbitration by Sir B. Brodie, and a final agreement through Dr. Macleod, decided that the experiments were conjoint, and that each should publish them as such. I did so (Appendix to second edition, page v.); he appropriated them. As he has by this measure rejected the participation which I gave him, I resume my exclusive right as the sole inventor. His bold pretensions to the invention (to which he did not contribute either directly or indirectly) are annihilated by a comparison of my propositions with the results, and an examination of the date (Nov. 3, 1834) when those propositions were placed in writing in his hands; not to mention the previous confidential performance of the experiments with Mr. Henry James Johnson.

"I am reluctantly compelled to make these remarks, in consequence of advantage having been taken of a mistake in Sir B. Brodie's arbitration, to show it to my disadvantage. Sir B. Brodie mistook the question, and arbitrated as if I had not interdicted the opposite party, and not he me. Notwithstanding, the result was entirely in my favour; for he

decided (as I contended) that the experiments were conjoint—not even questioning my right to publish them; and he further bound the opposite party 'carefully to explain what share he (Dr. Hope) had in projecting and planning the experiments in the first instance.'—P. 30.

The *spirit* of this attack on me speaks for itself. The *statements* in it are, in the opinion of some friends whom I have consulted, amply falsified by Sir B. Brodie's letter of arbitration, which, with his recent permission, I subjoin. The origin of this letter was this:—Shortly after the performance of the experiments, Dr. Hope, to my astonishment, claimed them as his, and proposed to refer the claims of each party to the arbitration of Sir B. Brodie. To this proposal I willingly assented, and agreed to suspend the publication of them in my new edition until after the arbitration should be made. With this arbitration Dr. Hope at the time professed himself satisfied; but now, four years after, the above quotation will show how he attempts to misrepresent and evade it. The profession will, however, duly respect the decision of this truly honourable and eminent man, himself one of the most successful experimentalists of the age.

14, Saville Row,
March 19, 1835.

My dear Sir,

I understand from yours and Dr. Hope's statements—

1st. That you and Dr. Hope have both been engaged for a considerable time in researches on the pathology of the heart.

2dly. That Dr. Hope formerly instituted experiments, with a view to illustrate this subject, at which he invited you to be present.

3dly. That since then you and Dr. Hope have been in the habit of discussing questions arising out of these experiments, and that you contemplated making other experiments conjointly.

4thly. That you frequently urged Dr. Hope to proceed with the projected experiments, but that his various engagements prevented his doing so.

5thly. That at last you applied to Mr. Tatum for the use of the new dissecting room, procured animals for the purpose of the experiments, asked several gentlemen to assist you in making them, and invited Dr. Hope to them also.

In addition to all this, I am informed

by some of the gentlemen who assisted you, that the experiments were made almost *entirely under your direction*.

Now, if these statements be correct, I own that I do not see that Dr. Hope can well complain of your making use of the experiments in the new edition of your work now in the press: at the same time I am of opinion that, in doing so, you should be careful to explain what share Dr. Hope had in projecting and planning the experiments in the first instance, and that you should acknowledge whatever assistance you derived from his suggestions at the time of the experiments being made.

I am, dear sir,

Always yours truly,

B. C. BRODIE.

Dr. Williams,
Half-moon Street.

With respect to the latter clauses, I can truly affirm, that in my published account of the experiments, I stated *every particular* in which I derived any assistance from Dr. Hope's plans or suggestions, either before or during the experiments. So far from being conducted with reference to any propositions written by Dr. Hope in November 1834, the experiments were wholly directed by me with the view to decide certain doubtful points described as proper subjects for experiment in the Appendix to my second edition, published in Sept. 1833. Some of my friends (Dr. Alison, Dr. Arnott, Dr. Sharpey, Dr. Scott, and Dr. Spittal) may remember that I visited Edinburgh at the meeting of the British Association in the following September, with the purpose of performing these experiments, and that the only reason why they were not then performed was, that fit animals could not be procured at the time. It was not until several weeks after this, and after many conversations with me, in which I never ceased to argue with him on the deficiencies of his views and former experiments, that Dr. Hope showed me his "*propositions*," and asked my opinion about them. Except in two particulars, the experiments which they proposed were either those that I had already planned to perform, or such as never could be performed; and so I told him at the time. The two excepted points were the precise modes of suspending the action of the valves (by a knuckle and by a bent needle);

and as somewhat similar modes (by two fingers and by two hooks) were adopted in my experiments, I gave him the full credit of having planned them*; although it is obvious that no one could pursue the experimental inquiry which I had long before recommended without using some such means.

Your readers can judge for themselves of the correctness of Dr. Hope's statement which I have quoted, by comparing those parts which refer to Sir B. Brodie's letter with the letter itself. I have marked in italics other parts equally untrue; and the most charitable opinion that I can entertain of their author is, that his "private distractions, onerous duties, and excessive professional engagements" (see his preface), have, in the last four years, impaired his memory.

The character of this sample precludes the necessity of my noticing other minor attacks and criticisms levelled at me in his work. They lose their force, and much of their asperity, from the circumstance that they generally admit their author to have been in the wrong; and judging from many wonderful *changes of opinion and fact* exhibited in the third, as compared with the second edition of this work, we may hope that by a still *more wonderful* change, all will be set right in a fourth!

I am, sir,

Your faithful servant,

CHAS. J. B. WILLIAMS.

Half-moon Street,
Aug. 21, 1839.

OBSERVATIONS ON YELLOW FEVER.

By W. FERGUSSON, ESQ.

Surgeon in the Royal African Corps.

[For the London Medical Gazette.]

THE susceptibility of yellow fever of being conveyed from one person to another, and from place to place, by means of the effluvia arising from the bodies of the sick, is a question which has of late years been occasionally agitated in your own and in other periodicals: the bulk of evidence and of

* "I was present at an experiment attempted by Dr. Hope in Nov. last, at Mr. Field's—he then planned modes of suspending the action of the valves, similar to some of those afterward adopted in my experiments." That experiment failed.—*Pathology and Diagnosis, &c.* 3d edit. p. 170.

authority appear to be ranged on the negative, although the affirmative side of the question has not been without its supporters.

The great magnitude and importance of the question, as well in its scientific as in its political bearing, calls loudly on every one who has had an opportunity of observing the progress of the disease, to contribute something to aid in dispelling the doubt and uncertainty which

yet surround it, however obscure the individual, and however humble the contribution. Having had an opportunity of observing the progress of the disease at Sierra Leone on three different occasions, I therefore venture to submit my mite for consideration.

European residents have been many years settled at each of the following places along the coast of Western Africa, viz.—

| Place. | By whom inhabited. | Latitude. | Longitude. |
|--------------------------|------------------------------|-----------|------------|
| River Senegal | French. | 16° N. | 16° W. |
| Island of Goree | French. | 14 N. | 17 |
| River Gambia | English. | 13 N. | 16 |
| Cackeo | Portuguese. | 12 10 | 16 23 |
| Island of Bissao | Portuguese. | 11 51 | 15 37 |
| Rio Nunez | English, French, Portuguese. | 10 36 | 14 42 |
| Rio Pongo | English, French, Americans. | 10 7 | 13 58 |
| Sierra Leone | English. | 8 30 | 13 — |
| Accra | English, Dutch, Danes. | 5 32 | — 13 |
| Anamaboe | English. | 5 10 | 1 7 |
| St. George Del Mina . . | Dutch. | 5 5 | 1 22 |
| Island of Ascension . . | English. | 7 54 | 14 26 |

Of the above-named places epidemic yellow fever has appeared in the Island of Goree once (1837), in the River Gambia once (1837), at Sierra Leone four times (1823, 1829, and twice in 1837), at the Island of Ascension twice (1823, 1838).

The disease is totally unknown, and has, I believe, never appeared at any of the other stations above named, and several of these have been colonized by Europeans one and two hundred years.

It is by no means a comfortable reflection to those whose lot is cast in such a land, that they incur a constant ability to such irruptions of disease as that which lately desolated Sierra Leone, against which neither prudence nor great care are of any avail as a safeguard : hence it is not to be wondered at, that, on former occasions of the epidemic irruption of yellow fever at Sierra Leone, there were many persons who sought out with great diligence every circumstance tending to show that the disease was not a sporadic, but an imported one. The evidence in proof of an object so desirable entirely failed ; and it is now, I believe, admitted by all classes at Sierra Leone, that on every occasion of its appearance there, it has been the undoubted product of the colony itself.

But while it appears thus clear that at Sierra Leone the disease has never been an imported one, there are, on the other hand, facts sufficiently numerous and cogent to encourage a rather confident opinion, that, at every other part of this station where it has appeared, it has on every such occasion been of imported, not of sporadic origin.

Before going into details, it may be here stated generally, that wherever the disease has appeared on the West African station, at places other than Sierra Leone, such appearance has on every such occasion been preceded, within a very short time, by the arrival of a vessel having the disease on board, and the actual disembarkation of the sick at that place ; and that the disease has never appeared at any part of the station, other than Sierra Leone, excepting after such arrival and disembarkation of persons labouring under it.

Though the observations which I am about to adduce on this much controverted matter are at variance with the opinions entertained by many persons whom I am bound to regard with much professional respect, yet I see nothing which ought to deter me from an honest, and I hope not a dictatorial or presumptuous, statement of my own experience : to this I will add the information

which I have derived from sources worthy of credit, and the conclusions legitimately deduced from our united observations.

To begin with the Island of Ascension. It appears, as stated above, that epidemic yellow fever has prevailed there twice, viz. in 1823 and in 1838. With respect to its appearance there in 1823, it appears by the report of Dr. William Barry, then staff-surgeon, that yellow fever broke out at Sierra Leone in December 1822, and prevailed, with more or less of severity, during the ensuing six months.

The Bann sloop of war arrived at Sierra Leone (it does not appear when), and departed on the 27th March, with "three fever cases on board." Shortly after her departure, the fever cases accumulated so rapidly, that, instead of proceeding to the Island of St. Thomas, as was originally intended, she went to Ascension, and there debarked her sick.

The Bann had communication with the Driver sloop of war at Ascension; with what consequences to the garrison there, and to the crew of the Driver, is shewn in the following extract of an official report of Assistant-surgeon Sinclair, then serving in the Bann:—"Between her arrival (at Sierra Leone) and the departure of the Bann for Ascension on the 27th March, several cases occurred, and the ship left Sierra Leone with three fever cases on board; in a very few days the fever attacked so many, that, instead of touching at St. Thomas, as was the original intention, for cutting wood, she was obliged to proceed to Ascension direct: she arrived there on the 25th April, but the fever had already committed such ravages on board, that scarcely a sufficient number of men were left to carry the sick on shore.

"The Driver arrived at Ascension on the 2d May, at that time very healthy, as well as the garrison on shore; but the Bann had already buried 32 men. All intercourse between the garrison and the sick tents of the Bann was forbidden, and as much as possible between the men of the Bann and those of the Driver.

"In a few days an Admiralty clerk belonging to the Driver, sent on board the Bann to assist at a survey, and Capt. Sawmarez and his servant, sent to join the Bann, were all seized with fever. About the same time the

fever made its appearance among the garrison ashore, in the family of a soldier's wife, who had been washing for one of the Bann: it first seized a boy, and then the woman herself, and in a few days four men belonging to the garrison were attacked. Of the crew of the Bann, consisting of about 130, not so many as ten escaped fever, and 38 died; and of the Island of Ascension, the garrison consisting of 36 souls, five only escaped fever, and 17 died; and of about eight from the Driver, who were exposed to the contagion, four were seized, and three died."

The disease did not again appear at the Island of Ascension until 1838. My information is not sufficiently precise as to the date of its breaking out; however, the events by which that irruption was preceded have been sufficiently ascertained.

H. M. brigantine Forester arrived at Sierra Leone from England on or about the 5th December, 1837, and remained there four or five days, a time when epidemic yellow fever prevailed extensively in the harbour; the disease broke out among the Forester's crew a few days after she left Sierra Leone, on which she proceeded to the Island of Ascension. Lieutenant Rosenberg (the commander) and several of the crew died before the vessel reached that place.

On her arrival there the sick were disembarked at Comfort Core, a place variously reported to me as being from one to three miles from the barracks, where the garrison is quartered.

A rigid quarantine was established on the sick at Comfort Core.

The wearing apparel of the deceased commander, Lieutenant Rosenberg, was, I have been told, taken on shore, and there sold by public auction in the garrison,—the clothes, however, had been previously well and thoroughly washed on board. The disease broke out in the garrison about four weeks after the Forester's arrival, and proved fatal to the commandant, a medical officer, and many of the marines. I regret that dates and numbers are wanting in this statement; the correctness of the main fact may, however, be confidently relied on, viz. that the disease on this, as on the former occasion, did not appear among the garrison at Ascension until after the arrival of a sickly ship, and the actual debarkation on the island of persons labouring under the disease.

These two are, I believe, the only occasions on which the disease has appeared at Ascension; they are, also, I believe, the only occasions on which persons labouring under the disease have been landed there.

With respect to its mode of introduction at the Gambia.

H. M. brig *Curlew* having been appointed to cruise on the windward part of this station, was several times in the harbour of Freetown, Sierra Leone, in May 1837, a time when epidemic yellow fever prevailed there; she left Sierra Leone to proceed to Gambia about the middle of May, and a few days thereafter, while on the passage, the disease broke out among the crew. She arrived at Bathurst, on the Gambia, on the 4th June, and Mr. Tebbs, the Colonial surgeon, who was at that time also in medical charge of the troops, had the sick all removed from the vessel, and taken, not to the hospital, but to his own house, the ground floor of which he had fitted up as an hospital for merchant seamen. Fifteen of the crew died.

Mr. Tebbs, who is reported to have been most diligent in his attendance on the sick, was laid up with the disease on the 17th, and died on the 20th June. A European boy, who had assisted Mr. Tebbs some years as a dispenser of medicines, and whose conduct is also spoken of in terms of high praise, followed his master to the grave in a few days, having been cut off by the same disease. Thirty-three days after this the disease appeared in the house next to that of Mr. Tebbs on one side, and immediately thereafter in the house next to that of Mr. Tebbs on the other side: it then followed an eccentric course over the town, and carried off more than one half of the European population.

The Island of St. Mary, in the River Gambia, has been colonized by Europeans twenty-two years. I have conversed there with several intelligent Europeans who have resided either at Gambia, Senegal, or Goree, uninterruptedly, upwards of thirty years, and by them I am assured that they never either witnessed or heard of the disease at Gambia until the period of the *Curlew's* arrival there.

The total absence of any mention of the disease in the army medical returns or reports from that part of the station serves to corroborate these statements.

It is clear, then, that at the Gambia, as at the Island of Ascension, epidemic yellow fever has never appeared but within a short time after the arrival and debarkation at the settlement of persons labouring under the disease, and that this was the only occasion on which persons labouring under the disease have been landed here.

Epidemic yellow fever having, as above stated, appeared at the British settlement in the River Gambia, and having for some time successively carried off every one whom it attacked, great consternation and alarm were in consequence excited, and several persons, who had it in their power to do so, departed from the place.

Mr. Heddle, a respectable merchant of Bathurst, was among those who migrated. He left Bathurst for the Island of Goree on the 9th of August, accompanied by Mr. Stubbs (an English gentleman) and Mons. Imbert, a resident of Goree, all in good health: the vessel arrived at Goree on the 12th.

Mons. Imbert was attacked with fever on the passage, and was landed in that state at Goree on the 12th; he was taken to his mother's house, and by her he was attended in the most assiduous and affectionate manner until he died. The separation of mother and son was, however, of short duration; for, the same day on which Mons. Imbert died, his mother was attacked with fever of a similar description, of which she died in four days.

Meantime Mr. Stubbs, the other passenger, was attacked with fever on the 12th (the day of arrival at Goree), and died on the 16th.

Mr. Forster, a respectable merchant of Bathurst, left Gambia for Goree on the 17th August, accompanied by Mr. A. Hunter, the Colonial Secretary. Mr. Hunter was attacked with fever on the 19th, which terminated in "black vomit" and death, at Goree, on the 21st.

Between three and four weeks after the occurrences herein detailed, epidemic yellow fever broke out at Goree, and carried off a vast number of the population.

Goree has been colonized by Europeans upwards of 90 years, and it does not appear, either from written record or oral tradition, that the island was ever visited by yellow fever before.

It is hence as clear as any available evidence can make it, that, like the

Island of Ascension and the British settlement on the River Gambia, the Island of Goree has only been visited by epidemic yellow fever on occasion of the arrival and debarkation there of persons labouring under the disease.

The negative evidence afforded by the progress of the disease on this station appears to lead to conclusions precisely similar to those deducible from the positive evidence.

To begin again with the Island of Ascension. It has been shewn that epidemic yellow fever broke out at this place in 1823, and again in 1838, on each occasion shortly after the arrival and debarkation there of persons labouring under the disease. On each of those occasions (if the views herein developed are correct) the disease was conveyed to Ascension from Sierra Leone, but the disease also prevailed epidemically at Sierra Leone in 1829, on which occasion, although several vessels of the squadron carried it away from that place, it does not appear that in that year any person labouring under it was disembarked on the island. In that year the island wholly escaped its ravages.

The fortresses on the Gold Coast have been colonized, I believe, since the middle of the 17th century: it does not appear that epidemic yellow fever has ever been known there, neither does it appear that persons labouring under the disease have ever been landed there.

The several places at which Europeans reside betwixt Sierra Leone and the River Gambia (some of which, such as the Island of Bissao, have been colonized upwards of two hundred years), have never, so far as I can learn, been visited by yellow fever.

I conversed on this subject at the Island of Bissao with several of the oldest and most intelligent Portuguese residents, and was assured that neither while the disease prevailed at Sierra Leone in 1823, 1829, 1837, or 1838, nor on any other occasion, has it ever appeared at that island.

It is, I think, difficult to account for the total exemption from the disease enjoyed by those places, and its appearance at Gambia and Goree, on any other supposition than this, that those intervening places have never been visited by persons labouring under it.

Ascension, on the one hand, and Gambia and Goree on the other, are the extremities of lines radiating from a

centre at Sierra Leone; and were the epidemic appearance of the disease at those extremes to be accounted for by the influence of a generally pervading atmospherical cause, wherein lies the cause of exemption at the numerous intervening stations? and by what means did the disease at once jump from the centre to the circumference?

The connecting links in the chain, from the nucleus of the disease at Sierra Leone to its development at Ascension, Gambia, and Goree, appear to me to have been on every occasion sufficiently obvious, continuous, and unbroken, to render the other mode of accounting for its appearance at those places exceedingly probable, and in the present undecided state of positive knowledge on the subject, that which is least beset with difficulties.

The disease, as has been shown, having been conveyed from Sierra Leone to Gambia, and thence to Goree, occasioned the greatest alarm at the French settlement of Fort St. Louis, on the Senegal, the authorities there acting on the supposition that both at Gambia and Goree the disease had been imported, established a rigid system of exclusion on all vessels from either of those places so long as the epidemic should continue.

The settlement on the Senegal was not visited by the epidemic, neither has that settlement, so far as I can learn, ever been visited by persons labouring under the disease.

It may be considered necessary that some proof should be offered as to the perfect identity of the disease stated to have at times prevailed at the different places above mentioned, and to have been conveyed from one place to another.

With the means of information which I possess, it may be difficult to accomplish this, otherwise than by the evidence afforded by the occurrence of the symptom called "black vomit." This symptom is by no means invariably developed in every case—not even in such cases as terminate fatally—but wherever on this station yellow fever has prevailed in a district, the occurrence of that symptom has been sufficiently frequent to stamp a character on the epidemic not easily to be mistaken—and that symptom was of very frequent occurrence in each of the several epidemics stated above to have been identical with the parent yellow fever of Sierra Leone.

I must in candour state, that the views

adduced in this paper have been dissented from by several of my professional friends of the sister service, now or lately serving on this station, while others have agreed with me.

It has been stated to me that the last irruption of epidemic fever at Ascension (1838) was caused by an extraordinary accumulation of mud and filth in a pit, after an unusually heavy fall of rain. Without questioning the efficacy or the competency of such a cause, I may merely observe, that it is somewhat singular that the power of the mud-pit to generate epidemic yellow fever should have remained dormant until after the actual importation into the island of that disease by the sailors of the Forester; but granting that the pit-full of mud and filth at Ascension was the real cause of the late epidemic at that place, the origin of the epidemics at Gambia and Goree still remain to be accounted for, if that which I have assumed as the correct, or at all events the most probable mode of accounting for their origin, is considered mistaken.

It will be observed that at Ascension, at Goree, and at Gambia, a period of three or four weeks always elapsed betwixt the landing of the sick and the epidemic outbreaking of the disease among the population,—a degree of uniformity worthy of remark, whether the conclusions at which I have arrived be mistaken or not.

Sierra Leone, 10th May, 1839.

DR. KRAUSS ON PARISIAN HOSPITALS AND PRACTICE.

To the Editor of the Medical Gazette.

SIR,

SHOULD the following observations made in a late excursion to Paris appear to you worthy of publication, I shall feel much gratified by their insertion in your excellent journal.—I remain, sir,

Your most obedient servant,

GUSTAVUS KRAUSS, M.D.

15, Maddox Street, August 17, 1839.

During my late visit to Paris, I several times attended the practice of Dr. Ricord at the *Hôpital des Vénériens*, and was gratified as much as formerly by his skill and attention. He has scarcely made any alteration in the treatment of syphilitic diseases. I found that he more frequently used the hy-

driodate of potash in cases of general syphilis than at my last visit two years ago. He begins with small doses, and goes on till the quantity daily taken amounts to sixty grains.

M. Ricord continues to treat both chronic and acute inflammation of the testis by compression with strips of sticking plaster. He also uses compression with success for buboes, particularly when they have passed into a chronic state of induration. In blenorrhagia of the urethra (gonorrhœa), especially in obstinate cases, M. Ricord continues to employ *mèches*, and cauterization by means of Lallemand's *porte-caustique*; believing that the most essential condition to the cure of diseased mucous membranes is to prevent their parietes from touching each other; and, in general, that superficial cauterization with the nitrate of silver is a very powerful remedy in these inflammations.

I use these remedies very frequently in London, and not without success; yet the results in Paris seem to me to be even more satisfactory, perhaps owing to the influence of climate.

The Parisian surgeons continue to tie varicose veins with success. Ricord passes a ligature round the vein, and then fastens the ends of the thread over a piece of elastic bougie. Velpeau continues the method which he has employed these three years; that is, to introduce a fine pin round the vein, and then to tie the vein and skin with a ligature passed round the pin, like a figure of 8. It is worth remarking, that the French surgeon do not meet with the dangerous accidents which are feared in England after the ligature of veins, though this operation has for several years been frequently performed in Paris. But cases for the operation must be carefully selected. Thus, in a case of varicose veins in the leg, I heard Velpeau declare that it was not suited for the operation on account of the great number of affected vessels. It is delightful to see this eminent practitioner going from one patient's bed to another, and examining each case with untiring zeal. Pressure, and counter-irritation by blisters, are still Velpeau's favourite remedies; as is also the starch bandage for fractures, as a substitute for more complicated apparatus; and nitrate of silver in the forms of solution and ointment for various inflammations of the eye. I was somewhat surprised to see the heavy

bandaging of wounds and stumps with heating masses of charpie, and was astonished that Velpeau and other Parisian surgeons had not adopted the cooler method of bandaging used in English hospitals.

The Charité, through its able surgeon, attracts students more and more, as well as young physicians both native and foreign; and, assuredly, the clinical lectures which M. Velpeau gives almost daily, after going round the hospital for two hours, are amongst the very first in Paris both for clearness and solidity.

The section of tendons and muscles continues to be practised with success, but almost solely by those who have specially dedicated themselves to the cure of deformities. Dr. Duval continues to give orthopedic consultations at the *Bureau central d'admission*, which afford him continual opportunities of showing his talent in performing this operation; Drs. Bouvier and Guérin have a fixed number of beds for patients of this class at the *Hôpital des Enfants malades*. Dr. Bouvier has, moreover, a small orthopedic ward at the *Hospice des Orphelins*, where I had especial opportunity of convincing myself of the success of this method. I am more inclined to mention this circumstance, as a late English writer, in the preface of his work on Club-foot, says, that Dr. Bouvier's method is totally inapplicable to the more severe cases. I suppose, though I am not quite certain, that this objection refers to the time of beginning the extension; and though I do not advocate immediate extension, yet I must confess that a glance at Dr. Bouvier's dissertation on the cure of Club-foot will show that although he recommends immediate extension, yet he uses it with such moderation, and so gradually, as to avoid any possible danger; a fact of which I have convinced myself by inspection. It was at any rate important to show that while Stromeyer formerly allowed eight or ten days to elapse, before he ventured on extension, it may be begun with advantage much sooner.

If, however, the remark of the above mentioned writer refers to the mode of the mechanical after-treatment, I must remark, that Bouvier's mechanical treatment possesses obvious advantages above Stromeyer's; and that the orthopedists of Paris, whose skill is universally acknowledged, without any exception consider Stromeyer's apparatus insufficient, especially for the more severe

cases of club-foot; a circumstance which must have a certain weight in the balance.

The memoir which Dr. Jules Guérin read at one of the late sittings of the *Académie des Sciences*, on subcutaneous wounds, and the section of the muscles of the back for the cure of spinal deformities, excited the universal attention of the Parisian medical world; yet they are not quite convinced of the correctness of his opinions; and Dr. Bouvier, in particular, has opposed them.

Without failing to recognise the importance and merits of Dr. Guérin's researches on subcutaneous wounds, we must wait for the further development of his views, to be perfectly convinced of their correctness.

The entrance of air may possibly be an unfavourable circumstance in the cure of subcutaneous wounds; yet it is a fact, that in the section of tendons, even when it is effected by the simplest incision, air frequently enters the wound which may be expelled upon the spot, and is driven out with a particular noise. Yet in such cases the wound heals without suppuration; so that one might suppose that the joining of the lips of the wound with sticking plaster in the usual manner, prevented the farther entrance of the external air, and favoured the healing without suppuration, were it not that we find that even when the lips of the wound are not united by sticking plaster, it still heals without suppuration; so that in this case we are driven to the supposition that while the small cutaneous incision closes through the plastic process of healing, the farther entrance of the external air is prevented. Yet on the other hand, it sometimes happens that on the 1st, 2d, or 3d day, the incision is not yet closed, which is known by its secreting serum, and the wound still heals without suppuration.

A case of section of the tendo-Achillis occurred in my own practice, where in consequence, probably, of the patient's taking cold, inflammation came on and an abscess formed in the incision. About eight days after the operation, when the inflammatory swelling and the suppuration had decreased, I clearly perceived that the air had free entrance, for on pressing the wound it was driven out with a gurgling noise; yet, in spite of this, the tendency of the wound to heal was very manifest. This same case shewed me that there is a difference

in the mode of union of divided tendons, according as suppuration follows the incision or not, for the intervening substance, which, in the first four or six weeks after the operation, felt like a flat thin ribbon, very gradually increased in circumference, until at last, in three or four months after the operation, it attained the size, which in other favourable instances it reaches in three or four weeks. Future experience will shew whether the advantage is to be derived from subcutaneous incisions which M. Guérin expects. They seem to be applicable to some divisions of tense parts (*débridements*), as, perhaps, to the operation for incarcerated hernia, provided the principle is observed, that we may divide unyielding and tense parts without injuring the nearest soft and yielding parts; just as we divide the tendo-Achillis without touching the sheath which envelops it.

Universal astonishment was excited by the proposition which M. Guérin put in execution of dividing the muscles to cure spinal distortion. I was assured by M. Guérin that in one case the result was so instantaneous that the muscles contracted with a peculiar noise, and the distortion for the greater part disappeared. In the other cases, he said, the result was less immediate.

As far as my present conviction goes, I do not deny the admissibility of the section of the muscles for this object in certain cases, though I believe that their number is somewhat limited. It is acknowledged that the muscular system has less to do with producing and keeping up the distortion of the spine, than it has in producing distortion of the limbs and of the neck. In the latter case the tenderness of the muscles is easily recognized, but in distortion of the spine this is very rarely the case. The more careful examination can for the most part detect no tension of the muscles on the concave side of the distortion, even if we put the body in a posture which has the greatest possible influence in removing the distortion. In the public consultations at the *Bureau central d'admission*, I particularly attended to this state of the muscles of the back in distortion of the spine, and, together with other physicians, carefully examined no inconsiderable number of girls affected with lateral distortion; yet our search for muscles in a state of tension was in vain, with the

exception of muscles on the concave side of the lower or lumbar distortion, which sometimes were tense in a slight degree: yet even this seemed rather to be caused by involuntary contraction of the muscles arising from the examination.

M. Guérin maintains that it is easy to put the really shortened muscles, which are only apparently not in a state of tension, into a state of tension and prominence. I do not understand how this can be possible, otherwise than by putting the distorted parts into a situation which strives, as it were, to produce a straightening of the distortion. The shortened state and the tension of the muscle can escape observation only when the muscle is too deep, and lies close to bony parts, which is not at all common.

In distortions of the limbs we see that the deformity yields to appropriate mechanical force, when the resistance of the muscles has been taken off by the division of tendons; but this resistance may be recognized by the tense state of the muscles. It is not justifiable to divide a muscle or its tendon, unless the symptoms of a real shortening of the muscles are present. (This may also be applied to the section of the tendon of the *tibialis posticus*, which appears to have been often performed without reason).

During my stay in Paris, the body of a girl, aged 9, with lateral distortion of the spine, was brought into the amphitheatre of the *Ecole pratique*. There was a distinct distortion towards the right, belonging to the thoracic vertebrae, and a lumbar distortion, much less important, turning to the left. There were no signs of rickets. Dr. Bouvier examined with care the relation of the muscles to the distortion of the spinal column, the muscles on both sides, when measured, scarcely differed either in length or breadth; and there was but little difference in their colour.

There was no tension of the long muscles of the back on the concave side of the thoracic distortion; but the trapezius on this side was more tense than that of the convex side, on account of the greater distance of its points of insertion.

If one tried by extending the vertebral column together with lateral pressure to straighten the curve, (which was possible to a certain extent), still it could not be perceived that the muscles became tense, and their section had no influence in removing the distortion.

This case demonstrated upon the dead body, what is commonly seen when we examine the living one.

I will mention in conclusion that during my stay in Paris I had the opportunity of seeing several very interesting dry preparations of club-foot; partly in the private collection of Dr. Bouvier, and partly in the *Musée Dupuytren*. Several of these preparations were taken from adults, and belonged to congenital varus. They showed me that lateral rotation of the astragalus round its long axis was much nearer and of a less intensity than I had formerly believed. In six cases of congenital varus there is no perceptible rotation of the astragalus round its long axis; in one case of double varus there is an empty space between the astragalus and the articular surface of the inner malleolus; while the os naviculare, with that surface which in the healthy state is joined to the anterior surface of the process of the astragalus, lies on the inner side of that process.

I am inclined to believe that lateral rotation of the astragalus round its long axis is for the most part only apparent, and is to be attributed to that change in form which the astragalus pretty often experiences through the flattening of its inner surface.

The absence of this rotation of the astragalus round its long axis is a very favourable circumstance for the cure of varus.

CASE OF UNUNITED FRACTURE OF THE FEMUR,

TREATED BY EXCISION OF THE ENDS OF
THE BONES.

By T. B. PEACOCK, Esq.

House-Surgeon, Chester Infirmary.

[For the *London Medical Gazette*.]

THOMAS JONES, aged 18, from the neighbourhood of Llangollen, thin, and somewhat sickly-looking, was received into the Chester Infirmary, under the care of Mr. Bennett, on the 20th of November, 1838.

He stated that on the 1st of March his thigh had been fractured by the tree of a threshing machine: he was seen by a country practitioner, who applied four short splints reaching the length of the

thigh; they remained on for five weeks and three days, and, having then become perfectly loose, were removed, a bandage being applied for three weeks longer, when he was allowed to move about.

At the time of his admission he had entirely lost all power over the limb, which was at least two inches and a half shorter than the other, and allowed the most extensive motion in the seat of the injury without any complaint of pain. The fracture, which had been transverse, extended across the union of the middle and lower third of the bone; the two portions were widely separated; the upper projected superficially in front, while the lower was drawn up, and to the inner side: the fragments, when rubbed together, conveyed the impression of a soft body interposed between them.

Notwithstanding the length of time which had elapsed since the occurrence of the accident, it was thought desirable, before having recourse to an operation, to try the effects of extension and friction of the ends of the bones together, which was accordingly done, and the limb then placed on Liston's modification of Desault's straight splint, and tightly bandaged transversely. At first he complained of considerable pain in the seat of the fracture, but after some time, no advance having been made, and the boy feeling very averse to lose his limb till every chance had been afforded him, it was decided to excise the ends of the bones. The operation was performed by Mr. Bennett on the 3d of January. An incision was made on the outer side of the limb in the usual way; the upper fragment, being situated superficially, was readily exposed, and about one inch removed from its extremity. In turning out the lower portion more difficulty was experienced, but at length it was accomplished, and about an inch and a quarter excised. The pieces removed were both extremely atrophied, being indeed reduced to a mere shell of bone filled with fatty matter: they were pointed and smooth, the opposed surfaces being covered with an imperfect kind of cartilage. The wasting had proceeded to a greater extent in the lower than the upper portion.

The operation did not occupy a great length of time, and but little blood was lost during its performance. The bone being brought into its natural position,

the limb was placed on the double inclined plane. In a few days the whole external incision had united, except opposite to the extremities of the bone. In some time longer suppuration ceased entirely, and the limb had recovered a considerable degree of firmness. This favourable condition was, however, of very short continuance. Abscesses formed; a large sinus followed the course of the bone to the trochanter; the limb became as loose as ever; hectic set in; and it was evident the only chance of life afforded him was from amputation. To this he submitted on the 2d of April: the operation, however, produced no improvement in his state; he continued to grow weaker till the 19th, when hæmorrhage took place from the stump, and he died in a few hours. On examination of the limb, the muscles were found pale, watery, and emaciated; the cellular membrane loaded with serum; the arteries, when injected, were scarcely half the size of those in a healthy limb. The upper fragment, to a little below the trochanter where it had been sawn across in the amputation, was reduced to a mere shell, at its widest part not more than the tenth of an inch in thickness: the lower fragment was still thinner; indeed, where the two portions had lain in contact, the texture was entirely absorbed. The atrophy extended through the whole lower part of the bone: at the knee it could be easily cut with a knife. The tibia and fibula were thinned to nearly as great an extent, and the bones of the foot were also perfectly soft, the solid portions being replaced by marrow.

The bones now macerated afford the most marked specimens I have seen of the excentric atrophy described by Mr. Curling, in the 20th volume of the *Medico-Chirurgical Transactions*. I am induced to publish this case, not for its rarity, since such operations have frequently been performed, and their result has usually been the same, but to draw attention to the pathological condition of the bones—a condition the existence of which has been overlooked, but which will, I think, be found of frequent occurrence, and sufficiently explains the want of success which has usually attended all plans of treatment adopted to bring about union in bones which have remained fractured for a considerable length of time.

It has been shown by Mr. Curling,

in the interesting paper to which I have referred above, that in fractures of the cylindrical bones, the portion deprived of the supply of blood furnished by the nutritive artery, being supported only by the small periosteal branches, undergoes a gradual atrophy; the spongy portion increases, while the solid parts experience a gradual thinning; the natural texture being restored only when the perfect union of the fractured ends has allowed the supply of blood to resume its usual course. A bone, therefore, which remains ununited, must be subject to a continued process of atrophy, till, after a longer or shorter interval, its natural texture is so completely lost, that no plan to which we can resort is at all likely to restore the healthy action of the parts.

Chester, August 14th, 1839.

ANSWER TO THE NOTE OF T. WHARTON JONES.

By DR. MARTIN BARRY.

[For the *London Medical Gazette*.]

THE observations of T. Wharton Jones, contained in last week's number of the *MEDICAL GAZETTE*, reduce the whole of the matter in dispute to a mere question of priority as to the discovery in the mammiferous ovum of the germinal vesicle and the germinal spot. On that question the Editor of the *MEDICAL GAZETTE* says, p. 805, "a comparison of dates will determine the mere matter of priority." I adopt his criterion, and, giving the dates, as proved by publication, I leave his readers to judge to whom the priority rightfully belongs. By a glance at those dates, every candid critic will be able to determine whether any one in this country can participate with the professors on the continent in the honour of those discoveries.

Valentin and Bernhardt, having published an account of the germinal vesicle in October 1834, and R. Wagner having sent to Müller's "*Archiv*" an account of the germinal spot in the same year, the discovery of both the vesicle, and the spot on the *inside* of it, were made known to the world previously to T. Wharton Jones's publication of his discovery of the germinal vesicle, and (the object he now

supposes to have been) the germinal spot, in June 1835.

Yet T. Wharton Jones claims the priority of discovery of both vesicle and spot—a claim which the dates above stated satisfactorily refute.

One word more, with regard to the object which T. Wharton Jones supposes to have been the germinal spot. The description he has given seems to belong to a body, not *within*, but *external* to the germinal vesicle, and, if so, one that cannot in reality have been the germinal spot. His description is this:—"On one side of the vesicle there is a small *elevation*, which, *projecting among* the grains composing the walls of the granular sac, *fixes the vesicle in its place*.*"

OBSERVATIONS

ON

COMPLICATED SURGICAL INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.
Late Deputy Inspector-General of Hospitals with the Auxiliary Forces in Portugal and Spain.

As delivered in his Lectures at Sydenham College School of Medicine.)

[Continued from page 583.]

I.—INJURIES OF THE CHEST.

Three classes of injuries: 1. *Superficial*; 2. *Simply penetrating*; 3. *Wounding parts within*.—Why superficial are erected into a distinct class.—Two cases illustrating the fatal consequences occasionally of these.—Singular disposition of lymph in pelvic cavity attending injury of thorax.—Uncontrollable nature of inflammation, and inefficacy of bleeding.—General progress of severe cases when favourable.—The reverse.—Some accidental complications.

In the preceding lectures, gentlemen, your attention has been drawn to the more important distinctions in the nature and treatment of complicated injuries of the extremities, of the head and spine. The injuries of the thorax, abdomen, and pelvis, next require consideration; no less fruitful in varieties and complications generally serious in their consequences, and but too frequently fatal in their ultimate results.

In these injuries we observe the effects of violence upon another class of

organs, intimately connected with the existence of the animal, with the organs and functions, the chief instruments of *organic* or *vegetative*, in contradistinction to *animal* life—the organs on which respiration and circulation chiefly depend.

A comparison involuntarily suggests itself between this class of wounds and those of the head containing the central and chief organ of animal life—between some striking features of resemblance and of dissimilarity. Both present shut and serous-lined cavities, covered and defended from external violence by bone or cartilage, muscle and integuments. Each sac contains the chief and most important organs of the two systems of animal and organic life; giving rise, when injured, to many varied and very complicated effects and symptoms. Here the leading points of resemblance cease.

Let us turn to the brain. In its injuries, we find the ganglionic system often escapes altogether; only secondarily affected when, from violence to the head—rarely until the functions of the brain are not only impaired, but more or less completely abolished.

Precisely contrary results are observed in blows or wounds of the chest. The first shock is always felt in the ganglionic system, in the disturbed actions of the heart and lungs; two of the principal organs of organic life over which the ganglionic system presides. The brain or cerebral system often does not, in the first instance, even sympathize, although the injury be severe; it never bears the first shock; the other organs of vegetative life are far more prone. The cerebral functions are often unembarrassed to the last, unless previously involved by the disturbed and imperfect performance of the purification and circulation of blood, from which the brain draws nutrition and healthy stimulus.

I recal these general facts to your mind, that it may be the more clearly seen where the manifestations of injury are to be sought for. In wounds of the chest, what classes of functions will be the earliest impaired, and in what order and degree? You see at once that the organic functions throughout the body must be those first and chiefly affected. The cerebral system and the functions of animal life, but secondarily; and the first is through sensation. The consciousness of pain; but this even uncer-

tainly, for I have seen fatal cases where scarcely any pain existed. The manifestations of the urgency and nature of the action following an injury of the thorax, are to be sought for in the respiration, the circulation, the degree and site of pain; in the functions of the skin, liver, and kidneys; in the chylipoietic viscera generally.

In the order here indicated, should the investigation proceed, the indications these afford, the relative modifications of injuries, their symptoms and effects, and, finally, what are the chief varieties of these injuries, and their leading distinctions, I will shortly state to you, as far as I have been enabled, in an extensive range of cases, to determine.

There are three distinct classes of injuries of the thorax, each sufficiently broadly defined, and different both in nature, progress, and results.

1. Injuries of the parietes or walls solely, without penetrating the cavities.

2. Injuries penetrating merely, and not injuring the contents.

3. Injuries causing lesion of the contents of those cavities, the heart or lungs.

In this order do they stand, in relative importance and danger.

It would be unnecessary to erect the superficial wounds of the parietes of the thorax into a separate class of injuries, which in themselves and the parts immediately implicated offer no peculiarities, were it not that occasionally simple wounds or injuries, in this situation, subsequently involve the important parts beneath, and produce all the worst consequences of the most complicated. Hence they require careful watching, to observe the first symptoms of such a progress, and arrest the diseased action before it has time to gain violence or work effects beyond the power of medicine to remedy.

The following cases shew the dangerous and peculiar course which these superficial wounds of the parietes of the chest sometimes run:—

Case of a complicated Superficial Wound, subsequently implicating the Lungs and Heart, disturbing their Functions.

James Conroy, wounded May 5, 1836. A musket-ball struck him one-fourth of an inch above the acromion process of the scapula, and, passing deep under the

supra spinatus muscle and integuments of the back, fractured the spine of the scapula, and was extracted near the inner edge of the scapula of the opposite side.

Up to the tenth day, there was no constitutional disturbance, nor chest symptoms of any kind, to denote internal mischief. At this time the discharge became more abundant, amounting quickly to half a pint daily. This continued to the 18th, when it gradually ceased; the wound filling up from the point of the ball's exit.

On the twentieth day a sinus was detected, deep seated, and of considerable size, and about four ounces of healthy matter pressed out. He was placed on a low diet, and the sinus rapidly healed, with the aid of compresses. About the thirtieth day the sinus seemed again to open, and the discharge began gradually to increase; several pieces of bone were detected in the track of the ball, and removed. Notwithstanding, the discharge became thin, green, and at last fetid; the pulse accelerated and small; countenance pale and dejected; hot skin; and headache. The sinus was laid freely open, and more pieces of bone extracted.

On the thirty-fifth day a slough detached in the course of the opening, and exposed the scapula for about two inches. The sinus was found to extend across the back, and several pieces of slough continued to be discharged with the pus, the character of which varied much from day to day, increasing to a pint and a half daily. Compression was again resorted to: the bone became covered, but the constitutional symptoms aggravated; and the parts within the chest began to give evidence of being implicated. In a few days he complained of pain shooting from the wound to the chest; pain on inspiration; cough; hurried breathing; and intermittent pulse. The compressive straps were removed, and pieces of comminuted bone were felt adhering to the sides of the sinus across the back. A slight blush appeared round the edges of the wound, and in two days extended across his back. Thirty leeches were applied, a second time repeated, and his bowels well opened.

He still continued to deteriorate, the erysipelatous blush extending over his chest, from which he was relieved by frictions of Ung. Hyd. fort.; but the

discharge continued increasing to an immense quantity. The sinus shewed a disposition to extend over the shoulder, and burrowed deeply and extensively in the back; and notwithstanding that free incisions were made wherever they seemed required, he became worse. Voice scarcely audible; tongue black and coated; discharge excessively fetid; sloughs appeared on the sacrum. The greatest attention was paid to the case; the sores were examined three times a day, and matter pressed from the cavities and sinuses, while his strength was carefully supported. After a struggle of some duration, he rallied; the wounds healed up well and rapidly; his constitution not recovering until long after, from a state of extreme debility. No permanent affection, nor any organic disease of the lungs, though at one time apparently inevitable, seemed to remain as a consequence.

This is a case of complicated, but, there is every reason to believe, of superficial injury, not implicating the organs within, or the cavity of the chest, until the eightieth day, and then to an alarming degree. It illustrates the mode in which superficial injuries may ultimately cause all the worst consequences of a more serious and penetrating injury, and points out the necessity of watching such cases, and without delay using every effort to arrest any untoward action that may arise.

I have known tetanus follow a superficial wound of the chest, of which the following is an instance:—

Robert Smith received a flesh wound of the breast on May 5th, 1836, which, up to the 9th day, presented no deviation from the usual symptoms and appearances.

On the 10th day the slough separated, and a discharge of healthy pus was established; but he complained of cough and pain in his throat. He was ordered a purgative, and put upon half diet.

Next day pain in the throat was more severe, and twelve leeches were applied, and antiphlogistic regimen enforced.

On the 12th, slight symptoms of trismus supervened, attended with cough and pain in the throat and breast; pulse quick.

V.S. ad 3xvj.

13th.—Trismus more severe.

14th.—He died.

It is unnecessary to dwell further upon this first class, simple generally, and then differing in no way from similar injuries in any part of the trunk or limbs; complicated occasionally, and then presenting, in greater or lesser degree of intensity, those symptoms of which I am now to speak in relation to penetrating wounds of the chest.

Of merely penetrating wounds, without injury to the heart or lungs—and many such are to be met with—the chief and first danger is inflammation of the pleura, leading to adhesion or effusion; the inflammatory action occasionally extending to the substance of the lungs, and leading to a fatal peripneumonia. The following is an example, rendered doubly interesting by its demonstration of a fact which can only be explained by supposing a metastasis of diseased action, or a distant and similar action of secreting surface, induced by some chain of sympathy, the intervening links of which cannot be traced, somewhat analogous to the diseases of liver and distant suppurations established apparently as a consequence of injuries of the head, some instances of which were given while that part of the subject was under consideration.

Case of wound barely opening the cavity of the chest, followed by fatal disease in lungs and cavity, and by effusion of lymph and serum in the pelvis.

John Longson, æt. 23.

Injury.—A musket-shot passed through the fleshy part of the arm into the flesh of the chest, below the left nipple, fracturing but not comminuting the fifth rib, denuding it of periosteum, and lodging upon it without penetrating the cavity of the thorax.

Symptoms and progress.—First day great difficulty of breathing; cold shivering.

Vespere.—Pulse bounding; skin hot.

Opiate of morphia. V.S. ad 3xx. Purgative.

2d.—Cough; no expectoration of blood; pulse as on previous evening.

V.S. 3xvj. Purgative.

3d.—Great pain of chest; respiration quick, short, and difficult; sleepless; unable to lie on left side; pulse subdued; sputa slightly streaked with blood.

Diaphoretic and saline mixture, with a dose of morphine at bed-time.

4th.—Thirst great; skin hot; pulse quick, not very full.

V.S. ξ xij.

5th.—Countenance anxious and distressed; cough severe, with expectoration of blood; great pain and difficulty of breathing; pulse about 100.

V.S. ad ξ xvj. Rep. Mist. et Haust. h. s. s.

7th.—Symptoms continue; ball discovered and extracted.

V.S. ad ξ xij.

8th.—No alleviation.

V.S. ad ξ xvj.

9th.—Relieved, but return of bad symptoms.

V.S. ad ξ xiv.

10th.—Suppuration profuse; pain extending from left shoulder to the abdomen; pulse 64, intermittent.

C.C. ad ξ xij.

11th.—Pulse 66, hard, not intermittent; patient not suffering much.

V.S. ad ξ xij.

15th.—Considerable febrile action has been going on; pulse full, slow, and jerking; action of the heart strong; great prostration. Dose of digitalis increased.

20th.—Has continued losing strength; strong arterial action; cough and diarrhoea; pulse 96, full, and vibratory; pain in chest; tongue clean and moist; patient delirious.

23d.—Has continued gradually sinking; died in the evening.

Treatment chiefly constitutional—strictly antiphlogistic—by diet, purgatives. Digitalis increased from fifteen to twenty-five minims three times a day. Bleeding almost daily, amounting to 168 ounces in the first fifteen days, twelve of which were extracted by cupping.

Post-mortem.—Slender emaciated boy; narrow chest; rib found broken across, but not splintered, at the spot where the ball had been extracted. Cavity of the chest opened into, but in so trifling a degree as to have admitted of doubt, or at least to have escaped notice, had air not been distinctly seen escaping during life. Bone denuded, and no

attempt at union. Strong adhesions of the pleura on both sides; on left side effusion of thick, white, purulent matter; strong adhesions all over the surface. Upper and lower lobe of lung nearly healthy; middle tuberculated, and with one or two abscesses close to the surface, in contact with the pericardium, which was much thickened, and covered with lymph and matter. The whole of the pleura costalis granulated, and covered with the same matter. On the right side the same extensive adhesions existed; the pleura costalis but slightly diseased; the pleura pulmonalis more. Tubercles existed from the cheesy to the suppurative stage. Liver healthy. *Effusion of about four ounces of partially coagulated lymph and serum was found in the base of the pelvis, without any apparent cause in the structure of the parts.*

The progress of this case, with scarcely any favourable intermission, however slight, notwithstanding the vigorous measures taken to arrest, if possible, the inflammatory action, deserves notice. It proves how, even in an uncomplicated case, involving the serous cavities of the chest, with how little certainty we can promise a speedy and favourable result, and how completely beyond the control of art are the consequences which occasionally follow these injuries.

Of these simply penetrating wounds, and of those inflicting direct injury on the organs within, the variety in the effects, symptoms, and results, is scarcely inferior to those which I brought under notice when speaking of the complicated injuries of the head. The usual course of these cases, and their prominent features, are the rapid supervention of distressed and painful respiration; this sometimes preceded by a stage of depression seldom lasting above a few hours: but the breathing rapidly becomes short, hurried, and painful; the pulse sharp in its beat, bounding, and accelerated from 90 to 120; cough occasioning intense pain, often the desire or the attempt to cough without the possibility of accomplishing it; blood-stained expectoration; expiration of air from the wound, but not invariably, for the lung of the injured side frequently collapses, leaving respiration to be performed entirely by the opposite side.

It is necessary to bear in mind that expiration of air from a wound opening

into the cavity is by no means an undeviating mark of rupture of the lungs, for air may enter the cavity from the orifice, and still admit of a limited respiration, and consequently as the lungs dilate air will be expelled by the wound; not from the lungs, but from the cavity.

If bleeding be freely resorted to until the sharp, thrilling, and bounding character of pulse is softened, suppuration comes on in a few days; the chief symptoms become less urgent, and in these injuries the discharge is most abundant, sometimes amounting to one, two, or even three pints per diem. The hæmorrhagic expectoration either ceases, and it is merely purulent, or it may be sanguineo-purulent; occasionally it ceases altogether. If the case go on favourably, the pain of chest and cough diminish; the discharge becomes gradually less abundant; the wounds slowly heal; and the patient recovers—sometimes with but little impaired health, but far more frequently with some cough and expectoration, with inability for active exertion, which always produces an attack of inflammation and hæmoptysis, and not seldom the foundation for a disease in the lungs is laid which ultimately—perhaps at some years distance—destroys life. If, on the contrary, the case end unfavourably, instead of the pain, cough, and expectoration diminishing, or perhaps disappearing altogether, and the discharge abating, there is a fitful kind of intermission: one day the patient is somewhat relieved, the next suffering intensely: the discharge becomes fetid and enormous in quantity, and the patient is carried off at a period varying from six hours to 150 or more days—either by hæmorrhage, suffocation from matter in the bronchiæ, or pressure of fluid on the lungs; or finally, worn out by the great drain on the constitution and long continued irritation, he dies of hectic fever—diarrhœa, and delirium come on, and he sinks exhausted, but apparently not until both the materials and the powers of life are consumed; the pulse in these cases generally until near death preserving a thrilly and febrile character, against which the largest bleedings have only the most temporary effect, often intermittent, and the respiration short, painful, and irregularly hurried.

Such is the general progress of these cases. They are not only productive, however, of many important varieties in

the nature and order of effects (of which I shall speak hereafter), but are liable to many complications of a less regular or of an accidental character; such as lesion of the intercostal arteries, extravasation of blood, emphysema, pulmonary hernia.

When there is a wound of an intercostal artery, it is always desirable, if possible, to secure it, and this, from its known and fixed situation, may generally be effected; or if this fail, a compress may still be so applied as to attain the same end. The actual cautery has been successful when other measures have failed, and no means should be left untried, rather than risk an extravasation of blood difficult of removal, and the signs of which are so far equivocal as to render the treatment obscure and far from satisfactory in the majority of cases. Occasionally, the merely dividing the artery completely across arrests the hæmorrhage. The tenaculum should, however, always be used when possible.

It is a sufficiently established principle in modern surgery, in all ordinary circumstances, to close as speedily as possible the wounds of the thorax. This has a tendency to control any flow of blood into the cavity. It may lead occasionally to another accident—viz. emphysema, or the insinuation of air into the cellular tissue; sometimes enormously swelling one side, or even the whole body. One case I remember, when the patient was so disfigured that it was difficult to recognize him as a man, and quite impossible to distinguish the individual by his features. In such a case, the opening the wound, and providing a free exit for the air, is generally sufficient to obtain the resolution of this swelling.

Sometimes also a piece of lung protrudes, and may even become mortified; in which last case, the mortified part may be excised, and the lung restored to the cavity; or, if the vitality be destroyed, the wound should be enlarged sufficiently to allow of the return of the viscus. If my object were to give a long lecture, rather than to draw your attention to the most important varieties, much more might be added. I have, however, nothing new to communicate on the points just enumerated, and, beyond what I have mentioned, these forms do not require any peculiar deviation from the general principles of treatment for all wounds.

The more important variations in the effects of these injuries, and the nature and order of the symptoms in regard to treatment, will form the subject of the next lecture.

ANALYSES AND NOTICES OF BOOKS.

“L'Auteur se tue à allonger ce que le lecteur se tue à abrégé.”—D'ALEMBERT.

A Treatise on Varicose Capillaries, as constituting the Structure of Carcinoma of the Hepatic Ducts, and developing the Law and Treatment of Morbid Growths; with an Account of a new Form of the Pus Globule. By T. G. HAKE, M.D. &c. London, 1839. 4to. pp. 20, and 6 engravings.

As a subject which has of late created considerable interest, we enter upon a notice of this short treatise by Dr. Hake, of which, however, we shall consider only that part which relates to the probable anatomy of cancer, and on which the dispute between him and Mr. Kiernan has chiefly rested. The new pus-globule is but a single and, as yet, uninteresting fact—one of the thousand of the same class which require some magic hand to place them in intelligible order, or to make them available to pathology or practice. The chief distinctive characters of these globules are their great size and ovate form; they are about 1-850th of an inch in their shortest, and 1-450th in their longest diameter; they contain circular nuclei, within which are enclosed numerous molecules, of various sizes. As yet Dr. Hake has found them only in the carcinoma of the hepatic ducts. The following extract contains nearly the whole of his account of this disease, which is certainly the best part of the essay:—

There is a disease of the liver in the rabbit which consists of carcinomatous enlargement of the ducts, but manifests itself under the apparent form of small abscesses. This appearance is owing to dilatations of the ducts which occur at regular intervals. These dilatations may be either few in number, or so numerous as to occupy the greater portion of the substance of the liver, and to be seen, through the peritoneum, to cover numerous points of its surface. * * *

Having obtained a rabbit, I tied the aorta and portal vein so as to cut off all

supply of blood to the liver. I then opened the hepatic vein. The liver, which was occupied by the disease to the fullest extent, was carefully injected on the following day, and with perfect success. The highly vascular surface of the ducts received the injection from both the hepatic artery and portal vein, but principally from the latter. The white (purulent) fluid within the ducts was in some parts tinged with green, the colour employed to inject the portal vein; in others with the red injection from the artery. On opening different ducts and examining their inner surface, I found it to be the seat of a thick, irregular, morbid growth, which was deeply impregnated with the red and green injections, but in which no vessels were detectable by the naked eye, except the more considerable branches of the hepatic artery.

Having subjected both the outer or vaginal, as well as the inner surface of these highly-injected ducts, to microscopic observation, I found the former covered with an exceedingly minute plexus, derived from the portal vein, with branches of the artery crossing it. This plexus in many parts possessed the characters of healthy vessels; a fact of the highest interest in physiology, since it shows the exact manner in which the portal circulation is carried to the hepatic ducts; and being continued to the inner surface of the ducts, as will be presently shown, it explains the secretion of the bile on the same principle as that of other fluids, viz. by the distribution of vessels over a free surface.

An examination of the inner surface of the ducts proved that the new growth consisted of a plexus of capillaries derived from the portal vein, interspersed with others from the hepatic artery. This plexus, however, instead of presenting a healthy form, was seen to consist of varicose vessels, in some parts dilated to an extraordinary degree and knotted, and in others contracted. Indeed, the entire structure consisted of a plexus of varicose capillary vessels.

Dr. Carswell, in his elegant illustrations of the Elementary Forms of Disease, has supplied a drawing of the affection of which this paper treats, and has the entire merit of having ascertained that it existed in the ducts, the extremities of which, he says, “are dilated into the form of pyriform sacs of various sizes.” * * *

These observations I have been able to confirm by examining the disease in its early stages. At first simple dilatation of the duct, without thickening, takes place; the bile found within the duct at this period of the disease contains globules like those of the blood, but of three or four times their diameter, and occasionally with a

molecule formed on their disc. In a more advanced stage the duct is thickened and pyriform at its egress from the glandular grains of the liver, and contains pus. This thickening of the duct represents the crude state of carcinoma; but as the disease advances, and the whole of the ducts become knotted, and indeed varicose, the structure softens, and presents all the character of medullary sarcoma. The cellular aspect which the disease presents is caused by shoots of vessels in the form of flocculi; and its ultimate softening by the tenuity of the vessels, which increases with their varicose growth.

It happens frequently that the outer surface of the enlarged ducts is coloured, from the presence of congested vessels. By injection, this appearance is proved to be a plexus of capillaries from the portal vein. These capillaries, not being varicose to the same extent as those within the duct, but often of a regular form and diameter, may be supposed to represent the distribution of the portal vein to the hepatic ducts in their healthy state. Branches of the artery also cross these ducts; but their plexiform distribution is reserved for the inner surface, where they blend, without anastomosing, with a similar structure of portal capillaries.

The vessels which connect the enlarged ducts and the glandular grains of the liver are the minute ducts, which are distributed round those bodies. The walls of these capillary ducts, which do not participate in the disease, as well as those of the larger branches, receive injection from the portal vein.

The carcinomatous structure of the ducts is entirely vascular, and consists of a plexus of varicose capillary vessels, which extends in every direction and not over the surface alone. In fact, the diseased vessels commencing from the external plexus anastomose, and proceed to the inner surface of the ducts, while, in the interstices which they leave between them, the pus is collected. The varicose state of the capillaries is almost coetaneous with their formation, the process of their growth being subject to pathogenic laws, if not their first formation. The new vessels do not shoot into an albuminous or any other deposit, as some have supposed; but proceed in the form of flocculi from a vascular base, become varicose, and again give out branches; and their increase alone constitutes the growth of carcinoma, and their different degrees of varix its progressive softening.

Such is the manner in which this morbid growth is developed within the ducts. Its structure is entirely vascular. If a transverse section of the duct be made, the plexus of varicose capillaries which

forms its substance is seen to resemble a honeycomb; and the vessels are so minute, that only the more dilated ones are seen when magnified from twenty to thirty times linear.

Whatever may be the office of the hepatic arteries,—whether to supply the follicles of the ducts with blood for the secretion of mucus, or to separate the salts of the bile, both of which uses have been supposed,—they certainly are involved in the disease in question; for, though fewer in number than the veins, they are equally the seat of varix, or, perhaps, more properly speaking, as respects arteries, of aneurism.

The efficient cause, then, of carcinoma, as existing in the hepatic ducts, is to be found in universal varix of the veins and aneurism of the arteries, as affecting capillaries, and in the simple increase of vessels so affected. The application of this law of morbid development to the study of disease will be found in the concluding portion of this essay.

Thus far Dr. Hake's paper is almost entirely matter of observation, and probably of truth, for his examinations appear well made, and his reputation is that of a skillful and cautious observer. In what follows, however, he descends very far below the level upon which his facts might have placed him. His development of the law and treatment of morbid growths we give at full length.

The fact that all morbid productions; whether cancerous, tuberculous, osseous, or of other kinds, may not only co-exist, but be intimately mingled in structure, that these are found connected with purulent, serous, bloody, and other deposits;—this fact, considered by Bécclard as one of the greatest sources of difficulty in the study of pathological anatomy*, may, at the present era, be viewed as a collective proof that one and the same law presides over the development of all disease. Though the nature of this law has been unknown, authors have not failed to detect an intimate alliance between the various forms of carcinoma, so that scirrhus, cancer, medullary or gelatiniform sarcoma, have been called indifferently by the same name; while tubercle and melanosis have been united in the same class on the one hand, and melanosis and cancer on the other.

When Bécclard, writing of cancer†, said "This tissue has less consistence than

* Anat. Gén.

† Bécclard and Blandin, *Additions à l'Anatomie Générale de Bichat*.

scirrhus, though more than the cerebral substance; is of a milky white, interrupted, when cut, by red points formed by divided vessels: these, in fact, are very numerous; but their walls are very thin, and scarcely support the force of the injection,"—that author was not far off from the efficient cause of the disease; and, had his mind but been in search of that, the probability is that he would have detected the truth, which was thus within his reach.

In tubercle affecting the spleen, I have seen the capillary arteries aneurismal; that they are so in every form of tubercular growth, as well as cancerous, is yet to be proved; meantime, it appears more than likely that, while one common law operates in the nutrition of natural tissues by means of healthy vessels, the deviation from that law is attributable to diseased vessels.

That hemorrhage arises from the rupture of varicose capillaries, is seen in cancerous affections; that it springs from the same causes in all tissues, whether in the pulmonary, cerebral, or any other systems, I would not express a doubt, but that research can immediately decide the proposition. These dilated and attenuated vessels, when the disease which they constitute is superficial, having no mechanical support, become gangrenous; a state which gives rise to the destruction of parts involved in malignant disease, and their consequent removal not by absorption, but by the disintegration of the outer surface.

The capillaries in a healthy state are of a uniform diameter, their size being about that of the blood globule. From this fact it may be implied that, in all tissues which secrete pus, the capillaries are in a state of dilatation; for the pus-globule is generally from one-third greater than, to twice the size of, the blood-globule; consequently the capillaries which secrete the former must be of a proportionate diameter. This simple truth opens to investigation the state of the capillaries through the large class of scrofulous affections, venereal and other abscesses, and suppurating surfaces of every description.

That in the production of all diseases the capillaries are the active agents there can be no doubt; and, when the extent to which these vessels are liable to undergo change in the production of heterogeneous growths is fully understood, it is to be hoped that the practitioner, with his views enlarged, may find a more certain means of controlling their action.

Should this minute inquiry bring other investigators into the same field of research, it is recommended that the examination of the capillaries should be omitted

in no instance whatever, whether in aneurism of the large vessels, varix of the veins, hypertrophy and atrophy of organs, or even in diseases affecting the whole system, as inflammatory and febrile affections.

The scientific treatment of malignant diseases has yet to be discovered. It must be founded on experiments made on animals with medicines for the purpose of ascertaining the effect they produce on the capillaries, and on observations of the effects of remedies on the blood—a fluid evidently involved to a greater or less extent in the production of heterogeneous growths. In the mean time, in cases where excision of the disease is impracticable, but where the artery which is distributed to it, and the capillaries of which are aneurismal, is within reach, a ligature might be tried, without danger and with some hope of benefit. And this might be succeeded by venesection and transfusion, cautiously but regularly performed; an experiment which, in prudent hands, could be attended by no danger, but might lead to results which would advance our knowledge of practice in this most fatal class of diseases.

Dr. Hake may call this the development of a law, but it is a pity that in so early a stage of its development it should have been brought forth, for nothing can save it from the common fate of abortions. His facts are good enough, but his *laus* are gratuitous suggestions. Both they and the whole style and character of the work afford too certain evidence of very rash haste in throwing himself before the public.

MEDICAL GAZETTE.

"*Licet omnibus, licet etiam mihi, dignitatem Artis Medicæ tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso.*"

CICERO.

THE RIVALS IN DISCOVERY.

AMONG philosophers, we suppose, as among good soldiers, each must confess that—

"If it be a sin to covet honour,
He is the most offending soul alive."

Surely not even the *odium theologicum* of olden times surpassed, in the pertinacity of its contests, the fierceness

with which anatomists now-a-days war with the knife. Only see the contents of this month's numbers of our *GAZETTE*: four distinct contests, simultaneously carried on in different regions of the medical sciences, and each fought with scarcely less vigour and anxiety than if the fate of an empire depended upon it. How marked a proof that the amount of the object at stake is no measure of the eagerness of the pursuit!

Of all these controversies, however, none is equal in interest, or has excited so much attention, as that between Mr. Kiernan and Dr. Hake; partly because it has in some measure broken through the curtain of mystery, behind which there lay some years' accumulation of rich treasures of pathology, and partly in consequence of the extreme earnestness with which one, at least, of the combatants has asserted his claim. As our pages have been the arena of the contest, we shall probably not claim too great a privilege in undertaking to place the dispute in a somewhat clearer light than the letters that have been published can, and in expressing our own impartial opinion upon it.

Dr. Hake's case is briefly stated in his own advertisement to the *Treatise* which we have elsewhere noticed. "I first saw varicose capillaries in tubercle of the spleen given me, about ten months ago, at Paris, by M. Andral. I afterwards saw them in softening of the spleen. . . . In a preparation of intestine which I was invited by Mr. Kiernan to inspect, I recognized the same state of the vessels, and communicated to Mr. Kiernan my opinion of its nature; but I had no suspicion of the full importance of this form of disease until recently, when I found that it was identical with carcinoma." From this it is evident that Dr. Hake was acquainted with the state of the capillaries which he called varicose, before he

saw Mr. Kiernan's preparation—a fact corroborated by the testimony of M. Monneret. He was, therefore, in a state to appreciate the value of any preparation in which they were exhibited, or to detect them in any diseased organ; and he has lately found them in a carcinomatous disease of the liver of rabbits.

Mr. Kiernan has been acquainted with the same condition of the capillaries for upwards of five years; it "forms the ground-work" of all his investigations on the anatomy of cancer—investigations not of one form only of this disease, but embracing (as those who are acquainted with his museum know) every variety of it, in every tissue, and under all circumstances.

In reference, therefore, to the first point for decision—the right of honour for the discovery of a varicose condition of the capillaries—there can be little doubt. Mr. Kiernan first discovered it five or six years ago. Dr. Hake, without any knowledge of Mr. Kiernan's investigations, rediscovered it ten months since. There is no evidence in support of Mr. Kiernan's belief that "all that Dr. Hake knows of varicose capillaries he has learned of him:" had he not been previously acquainted with this peculiar condition he could not at once have distinguished it in the preparation of the intestine, nor in the diseased ducts of the rabbit's liver.

Whatever merit, therefore, attaches to the re-discovery of a varicose condition of the capillaries (a condition previously known, but unpublished, by another), must be allowed to Dr. Hake. It must be allowed, further, that he has found them unassisted, in a form of carcinomatous disease; but here his merit ends; and it would have been well for his reputation if he had sought no more, and had been content, without endeavouring to grasp so much as the title of his present book includes. It cannot

escape notice, that this title is different from that by which it was first announced, by the substitution of the special term "carcinoma," in place of the general expression "diseased" hepatic ducts, and by the addition of "developing the law and treatment of morbid growths." There is here an important increase made to the pretensions of his discovery—an increase which, we think, he would have been unable to make, unless Mr. Kiernan had, subsequently to the first appearance of the advertisement, confessed that varicose capillaries were the ground-work of all his investigations. Without this confession, and with only the evidence of previous investigations, and that which Dr. Hake's paper affords, none but the most rash and hasty generalizer could conclude that varicose capillaries constitute the structure of any other form of carcinomatous growth than the one in the bile-ducts of the rabbit, which Dr. Hake describes. To endeavour from his limited examinations to develop the law of morbid growths generally, is absurd; and the attempt which he has made, as our analysis of the work will show, is ludicrous: he has in this shot far beyond his mark. He, or any one else, may now, from what Mr. Kiernan has confessed, be sure that varicose capillaries are of essential importance in morbid growths; but, except for this one fact of their existence in these bile-ducts, no one, we believe, but Mr. Kiernan, yet possesses any available means of demonstrating even a part of their real influence.

For Mr. Kiernan, he may at least congratulate himself that his enemy has written a book, and let the world know how much of his discoveries he has been able to anticipate. But beyond this, he has little to boast of in the result of the encounter; his rash confession of the

importance of his opponent's discovery has unveiled the mystery which he had for years successfully kept hid from all but the most friendly eyes, and has pointed out the road by which, bit by bit, his discoveries may be stolen from him by any passing observer. He has not only opened the secret door by which he alone was once able to enter and view this part of nature's arcana, but he has done all he could to draw every body's attention to it. Besides this, too, he has been somewhat hasty, and by his intended precedent of "waiting at home" for plagiarists, has added no little to the danger of becoming a discoverer. There was enough before to deter observers, in the literary controversies to which they were exposed; but really, if a man is to run the risk of being shot, because he takes the same name for a disease as his friend had previously selected, we scarcely know who would willingly engage in a scientific pursuit, unless the excitement of personal danger could be rendered as agreeable here as it is in some other sports.

It is much to be lamented that disputes concerning priority of discovery cannot be avoided; yet we know not how it is possible to prevent them. If, through fear of being anticipated, a man publishes every single fact directly he has discovered it, we get nothing but raw and ill-digested evidence, which it is scarcely possible to make use of—such as some of that contained in Dr. Hake's book; or those unsatisfactory communications which are so constantly made to scientific societies. If any one wishes to see a selection of medical absurdities, in the guise of discoveries, let him look over the papers communicated during the last two or three years to the French Institute, and published in the *Comptes-rendus*. To obtain the merit of first discovery, their authors are content to

publish the most vague and loose notions of some anticipated result; to hang out hints, like hooks, upon which they may by chance catch some flying new idea, and call it their own. That journal affords the strongest examples of premature deductions, with which we are acquainted; but nearly all the others of the present day are too full of them; and this from the desire which men have to be thought discoverers, and their fear lest, while they are working towards a more just and perfect result of their investigations, some other person should step in and rob them of any portion of their presumed merit.

The fear, however, is a weak one: for it would be better to lose the credit of first observation than to have the discredit of publishing too hastily, and therefore badly. The loss of the honour of discovering truth is less grievous than the disgrace of promulgating error. In the present case, Mr. Kiernan might disregard the little points in which Dr. Hake and others may seem to anticipate his greater results: he must expect that on a subject of this kind, which is occupying the attention of many of the best observers of the present day, (Müller, Valentin, Pappenheim, Langenbeck, Cruveilhier, Carswell, Henle, Glüge, and numerous others) each will find something which Mr. Kiernan had previously imagined to be known only to himself; but he may be quite sure that none of them will obtain such extensive stores of facts, or be able to arrive at the same great result, with the same convincing proofs of its truth, as he will. It is only by making such extensive and complete investigations that plagiarism is to be prevented and true credit obtained. Have Louis' works ever been pirated, or has he been robbed of the result of his patient inquiries? His followers and imitators may feel

assured that at the conclusion of such researches as they undertake, they will arrive at results which could not be hinted at, or obtained—nay, could scarcely be hinted at—without the same labour as they have bestowed on them. These, and these only, are the investigations which set envy and imitation at defiance. If medicine is to make rapid progress it must be by the honestly reported results of inquiries continued for as many years as most men give up days.

THE APOTHECARIES' COMPANY *versus* GREENOUGH.

It is observed by Samuel Frederic Gray, in the Preface to his Supplement to the Pharmacopœia, that it took one hundred and fifty years of litigation to settle the meaning of the phrase "to practise physic," as used in the statute of 15 Henry VIII.; and he thinks that it must be left to time to determine whether it will take as long to interpret the words "to practise as an apothecary." A cause which has just occurred upon the northern circuit, having been tried at Liverpool on the 24th of August, before Mr. Baron Maule, illustrates the difficulty of this legal problem. An action was brought by the Worshipful Society against a young man named Greenough, for practising as an apothecary, not being licensed. It appears that he superintends the shop of his sister, as a druggist; he also attends poor patients, sending them in bills, some of which have been paid. The Society had offered not to proceed farther if Greenough would submit to a judgment, as a pledge that he would not offend again in like manner; but their offer had been rejected. Mr. Watson submitted to the judge, that it was doubtful what constituted a practising under the Apothecaries' Aet. "A per-

son might get a license from St. Andrew's, or call himself a doctor, and then he would be free; so that the security which the public derived from it was, to a great degree, imaginary."

The case is so imperfectly reported, that the only part of Baron Maule's charge which is given, is the remark, that half the penalties belonged to the informer. The jury returned a verdict for the defendant*. Mr. S. F. Gray, in the preface above mentioned, is willing to think that the Apothecaries' Act is merely intended to give the public the assurance, that those who practise under that name have gone through a certain education; while patients who entrust themselves to those who practise under other titles, do so at their own risk. This latitudinarian theory, however, has not as yet been inculcated by judges on the bench, nor encouraged by the verdicts of juries; but as far as the extreme scantiness of the report will allow us to judge, the Liverpool case seems to point that way.

Mr. Watson is certainly mistaken, if he imagines that a St. Andrew's degree will be a shield to any one against the penalties of the Apothecaries' Act; for it confers no legal title to practise in England in any shape. Perhaps, however, he only referred to the imperfect protection afforded by the Act, which does not even attempt to check more than one class of pretenders. Of course, a member of the London College of Physicians might practise as an apothecary, as the Act reserves the rights of the existing corporations; but there are many other points still painfully uncertain. Counter practice, we suppose, is not punishable under the Act; but what shall we say of all the nice gradations of half-contraband practice—between the mere recommending of black draughts over the counter, and the full-blown

violation of the Act by unlicensed bills and visits? We fear that each intermediate step will require verdicts and decisions to fix its legality, unless the legislature should kindly intervene with some declaratory statute.

ON CUTICLE, PUS, AND MUCUS.

By DR. HENLE, of Berlin.

[Concluded from page 797.]

I HAVE sometimes examined the fluid at the very beginning of the flow of mucus in nasal or bronchial catarrh. In these cases I have always found the elementary cylinders of the ciliary membrane, often united together in large pieces, but more often floating separately in the otherwise clear watery fluid; in the mucus from the nose at this early stage the portions of epithelium of the lower part of the nostrils are also found as delicate flocculi in the excretion. But very soon the number of the healthy epithelial cylinders and cells diminishes; mucus-globules appear with simple or complex nuclei, and from this time during the further course of the catarrh, the sputa consist of the characteristic mucus-globules, with kernels splitting in the manner already described. The evident differences of the sputa in the different stages are dependent not so much on difference of form as on the quantity of their solid constituents, and the fine coagulating fluid, by which the globules, even when they do not lie close together, are yet so connected as to form membrane-like expansions or sacculi. In the latter stages of nasal and pulmonary catarrh there occur in the sputa yellowish corpuscles with irregular surfaces, mixed with dark granules of very varied size and inconstant form. By their glistening they may be recognized as globules of fat.

In many cases there are found intermediate conditions between the mucus-globules described above, and the common forms of the cells of epithelium. There are found, for example, many roundish, oval, or polyhedral cells, whose kernel is evident without the use of any chemical means; then the quantity of the mucus-globules may be seen gradually increasing, and at last the kernel is quite obscured. In the latest stages globules occur, which exactly resemble the fat cells just described. It is thus proved (at least in some catarrhal diseases,) that the mucus is not the normally-formed epithelium which is altered after its formation, and

* *Times*, Monday, Aug. 26, 1839.

also that the exudation with the peculiar mucus globules does not take place on the surface of a healthy epithelium; but that the latter is first removed unaltered, and that the formation of the pathological cells of the mucus-globules takes place below the epithelium and next to the mucous membrane. We may, perhaps, suppose that on all mucous membranes, from which we find a secretion of mucus-globules, which do not come from mucus glands, there has previously been a separation of the normal epithelium. In leucorrhœa, I have in the early stages found the number of lamellæ of epithelium very great, in proportion to that of the mucus-globules, and afterwards decreasing, though never completely wanting, because the epithelium of the healthy parts is constantly being regenerated, and is, therefore, mixed with the morbid epithelium of the diseased parts.

I have already mentioned a separation of the normally-formed epithelium, which follows certain morbid conditions of the mucous membranes. The diseased process may terminate with this desquamation, as in a simple gastric affection; but in catarrhs of all kinds, the same separation of the normal epithelium is only the commencement of the disease, and is followed by a new formation, not of normal, but of pathologically altered epithelium, distinguished by the splitting of the kernels of its elementary particles. This latter process may last for a longer or shorter time, till the mucous membrane again produces its healthy cuticle, or it may, as in some chronic cases, continue indefinitely. There are mucous catarrhs of the bronchi, nose, eye, urethra, and female sexual organs, in which, after years, the mucus-globules alone are produced, and in which, after death, one finds the diseased membrane covered by the mucus-globules, and the streaky coagulating fluid, in place of the normal epithelium; but yet without ulceration, without any remarkable swelling, and only more or less reddened; and even the redness may be absent.

When we compare the pathological formation of epithelium with the eruptions on the skin [of which a lengthened and most admirable account is given], we find in the latter, these facts visible to the naked eye which in the former case were discernible only with the microscope. In both there is a separation of healthy cuticle; the differences being easily explicable by the difference of strength in the cuticle of the two surfaces. On the mucous membranes with a firm epithelium, as the conjunctiva, the mouth, fauces, and œsophagus, the same distinct exudations occur as on the skin, producing papulae, blisters, and pus-

tules. Aphthæ extend from the mouth to the cardia, but not further; but the inflammation from which aphthæ result may at the same time extend through the intestinal canal, and they are chiefly remarkable as a symptom of the gastric derangement. The mucus-globules which cover the mucous surface after the removal of the cuticle, and which, when evacuation takes place, are removed with the fluid exudation, cannot microscopically be distinguished from the globules which float in the serum of vesicles and blisters, in the pus of pustules, and in the watery fluid that oozes from raw moist parts of the skin, and which have been long known as pus globules. All these are found in similar stages of development to those of the mucus-globules. If the vesicle raised by a blister be opened very early, when it has risen to about the size of chicken pox, there are, indeed, already pus globules swimming in the clear fluid, whose kernel splits with acetic acid; but there are also others, more like the cells of the deep layers of epidermis, whose nucleus is not split, or only becomes indented by acetic acid.

The pus globules are deposited, like the mucus-globules, on the inflamed surface, and are washed away by the oozing fluid. Their quantity in proportion to that of the fluid is very variable. In the serum of vesicles and blisters it is but small, though more considerable than one might imagine from the clearness of the fluid. The more considerable the proportion of the globules, the more does the fluid acquire the characters of pus, the yellower and the thicker it becomes; and hence, by evaporation, or by the increased formation of globules, vesicles are changed into pustules. Serum and pus have thus the same relation to each other as immature and mature mucus.

I consider the identity of exanthemata and of those diseases of the mucous membranes in which mucus or pus globules (for these are all identical), are found on the surface of mucous membranes, as proved. The latter may be classed under the general name of catarrhs. In a general view of the kinds of internal exanthemata or catarrhal inflammations, it is necessary, as in eruptions, first to separate those which pass a typical course, and are accompanied by fever which cannot be considered merely as a consequence of the local stimulus. Thus, in many eruptive fevers, coincident superficial inflammations of the mucous membranes occur, as of the eyes and air-passages in measles, of the fauces and pharynx in scarlatina, the pustules on the conjunctiva, fauces, and œsophagus, in small-pox; in the injection of the mucous membrane of the

intestine in erysipelas, and other acute cutaneous affections.

Next to these fevers, where the internal exanthem is merely a complication of the external, are those where it is the essential symptom. This is the case in bronchitis and coryza; in all the varieties of gastric and catarrhal fever; in typhus (for the name of exanthem is certainly as well adapted to the intestinal ulcers as to the pustules of small-pox), and probably in some other affections. Cholera is fever, with exanthematous affection of the intestinal canal, whose epithelium, as Böhm has shewn, is always desquamated.

Next to these are the catarrhs arising from external local causes—as cough from irritating bodies, catarrh of the bladder from stone, and, lastly, the catarrhs resulting from constitutional causes, in whatever mucous tract they occur.

Now when one sees that in stimulated or inflamed membranes, immediately after the normal epithelium is removed, new cells form which are so nearly related to those of the epithelium, and that these cells are in no way different from the true pus globules, what would be easier than to regard pus globules as diseased epithelium cells, and suppuration as a pathological formation of cuticle; and further, to explain every glandular secretion by which mucus globules are poured out, as a process related to suppuration or the morbid formation of cuticle? Either idea would be rash; for we cannot regard the increased normal secretion of a gland as pus, and, on the other hand, pus globules form in closed abscesses as well as on open surfaces, and in the former the supposition of a formation of cuticle would, at least, be something very forced. All these phenomena—the formation of cuticle, and of mucus and pus-globules must rather be regarded as species of a general process, on which they are all explained.

Cells with kernels and nuclei, for example, are not peculiar to the cuticle. They are found, in the adult body, in many other tissues; as in pigment in the ganglia and brain, in the fluid of the Graafian vesicle, &c. They exist universally in the earlier periods of life, and they are the first forms produced in the organization of all the new products of the animal body. They appear, therefore, in the plastic exudation on the surfaces of tissues in inflammation or without inflammation, when regeneration is effected normally. A cell with a kernel, and a nucleus within the kernel, is the true primary cell of all tissues.

Regeneration takes place with or without inflammation; and in the former case, with which only we are here concerned, it is either direct (by the first intention) or indirect by suppuration. If, after the cu-

ticle is removed from a surface, the primary cells which then cover that surface immediately form cuticle again, the regeneration is direct, and at once completed. And so in the reparation of cellular and other tissues, the primary cells may at once undergo the same changes which they did in the original formation of those tissues in the embryo; they may at once become the particles of cellular tissue, bone, &c. But in indirect or suppurative regeneration, a part of the primary cells gradually alters, as in the other case, into cuticle or cellular tissue, or bone; but another portion of them are thrown off, and these separated primary cells or pus globules (as they are then called) are always distinguished by their kernels being split by acetic acid. Evacuated with a coincidently secreted fluid, the cells of the latter portion form pus; when the quantity of fluid is small, and coagulates or dries, then they form crusts or scabs over the inflamed surface. Those of the former unseparated portion form the granulations of healing wounds. In all cases, the new cells are formed on the surfaces of the granulations, and the conversion of the granulations into cellular or other tissues takes place progressively from the depth to the surface of the wound; and when the granulations arrive at the surface of the body, the primary cells no longer take the form of cellular tissue, but of cuticle. Such is the process of cicatrization.

ACCOUNT OF A CASE OF ABSENCE OF THE MAMMARY GLAND.

By DR. R. FRORIEP.

THE subject of this case was a woman, æt. 30, who died, eight days after delivery, of peritonitis. When the body was being examined it was at once evident, that while the left breast was well developed and turgid with milk, the right side of the chest presented in the situation of the mamma only a superficial depression, which was limited at the sternum by an S-like border. At this point there was no trace of either a nipple, or a scar, or any alteration of the skin; the skin was not only smooth over the whole side of the chest, but was completely and easily moveable, so that there was no possibility of the breast having been removed by operation or disease.

The mammary gland on the left side was quite normal and full of milk, but on the right side there was not a trace of glandular tissue to be found; then there was nothing beneath the skin but a thin layer of adipose cellular tissue, which was

traced from the sternum to the shoulder. The third and fourth ribs of this side, beneath the depression, terminated just before the anterior edge of the scapula, so that the anterior part of the chest, from that part to the sternum, and between the 2d and 5th ribs, was closed only by a tough tendinous membrane: the 2d and 5th ribs were normal, but were wider apart than on the opposite side. The cartilages of the 3d and 4th ribs of the right side did not appear to be deficient, for at their level there were portions of cartilage attached to the sternum, and united with the cartilages of the 5th and 6th ribs into one mass, which presented grooves on its surface, while indicating that it was probably composed of four pieces.

To this deficiency in the development of the ribs there corresponded also a deficiency in the muscles of the chest; of the pectoralis major there existed only the upper part of the sternal and the clavicular portions; the greater part of the sternal portion was entirely absent; at its attachment to the arm also, there was only that rounded portion of the tendon which properly belongs to the clavicular portion, the flat broad part of the tendon corresponding to the sternal and costal portion was entirely absent. The pectoralis minor was entirely deficient—not a trace was to be found of either its origin or insertion; then parts of the serratus magnus which arise from the 3d and 4th ribs, and the intercostal muscles in the same space, were also wanting: in their place was a firm fibrous tissue, which easily yielded to pressure; the pleuræ costalis et pulmonalis and the lung were perfectly normal. On the left side all the parts of the chest were quite naturally formed.

It is very difficult to give an explanation of this defect of development. It cannot be regarded as an arrest at an early period, nor as the result of any thing occurring subsequent to birth. It seems fairer to suppose, that in an early period of uterine existence, one of the extremities, probably the right fore-arm, was applied on the right side of the chest, and was so fixed by an accidental pressure on this part, that the development of the organs beneath it could not be accomplished. In this way it is explicable how so many and such different parts failed of being formed. There are many proofs of the possibility of pressure thus preventing the usual progress of development, especially in the cases which Cruveilhier relates, and in the investigations of Guilt, Montgomery, and Simpson, on the subject of spontaneous amputations of the limbs *in utero*.

I may here mention an interesting case of this kind which occurred to me a year and a half since. In a new born child,

one phalanx of the little finger and half a phalanx of the ring-finger of the left hand were deficient, but the motions of the remaining parts were quite perfect, and there was no other deficiency. During the first day after birth this child shewed a constant habit of putting those two fingers into his mouth in such a manner that the edges of the jaws pressed exactly on the parts of the fingers where the deficiency existed. When his hand was taken away from his mouth, he immediately, and quite automatically, replaced it in the same position.—*Froriep's Notizen*, April 1839.

PREVENTION OF PITTING IN SMALL-POX.

At a late sitting of the Royal Academy of Paris, a letter was read from M. Legrand on the result of an experiment which he had made on the effect of gold-leaf in the pustules of small-pox. M. Larrey had said last year that the Egyptians and Arabs preserved the faces of their rich young persons from the destructive effects of small pox by covering them with gold-leaf directly upon the invasion of the disease. M. Legrand says, that he applied this method with the greatest success in a young English girl who had confluent small-pox. From the first instant of the eruption to the termination of the suppurative fever, he had covered the whole face morning and evening with fine gold-leaf, such as is used in gilding *à froid*, which he made to adhere by means of a little gum-water. With the exception of a few places at the sides where the gilding was removed by the friction of the pillow, the face, though it had been greatly swollen, was perfectly preserved, and the features retained their beauty. The hands, which had not been subjected to the same treatment, presented some characteristic cicatrices.

In the following sitting M. Larrey said that he had obtained the same result by repeatedly anointing the faces of those who had small pox with sweet oil, as with gold-leaf.

LITHOTRITY PERFORMED ON A SURGEON.

PROFESSOR Sanson has just been cured of stone by lithotritry, the operation having been entrusted to M. Leroy d'Etiolles. There were great difficulties in the case, but they were happily surmounted. M. Sanson did not interrupt his consultations for a single day during the treatment, and will soon resume his course of clinical surgery.—*Gazette des Hôpitaux*, June 29.

VARICOSE CAPILLARIES.

NOTES FROM MR. ARNOTT AND
MR. KIERNAN.

of simple syrup are then to be added with continual stirring, until a homogeneous syrup is produced, which is to stand for 24 hours, and then be poured into bottles. Or, 4 ounces of the balsam may be made into an emulsion with 2 ounces of gum arabic in 2 ounces of water; and this may then be mixed with the oil of peppermint and the simple syrup.—*Journ. de Pharm. du Midi and Schmidt's Jahrb.*

To the Editor of the Medical Gazette.

SIR,

MR. KIERNAN has called my attention to the following passage, which occurs in a recent publication of Dr. Hake; and as the fact therein stated is propounded as a recent discovery, he has appealed to me for my testimony on this point:—

“The new vessels do not shoot into albuminous or other deposit, as some have supposed; but proceed, in the form of flocculi, from a vascular base, become varicose, and again give off branches.”

In answer to the appeal of Mr. Kiernan, and in common justice to that gentleman, I feel bound to declare that I have known of the existence of these vessels, in connection with carcinoma, for three years; that they were originally shewn to me by Mr. Kiernan; that I have mentioned them in my surgical lectures at King's College during the last two years, as the discovery of that gentleman; that the language I used in describing them was, “that these vessels shot into space, and not into any bed previously prepared for them;” and that I had seen such vessels shooting from the inner surface of the peritoneum.

I am, sir,

Your obedient servant,

JAMES M. ARNOTT.

New Burlington Street,
Aug. 28, 1839.

To the Editor of the Medical Gazette.

SIR,

NOR having yet obtained all the information I require, I must defer replying to Dr. Hake's statement, inserted in your journal of last week.

I am, sir,

Your obedient servant,

F. KIERNAN.

33, Beaumont Street,
Aug. 29, 1839.

SYRUP OF COPAIBA.

MOUCHON recommends a syrup as a good form of giving copaiba. Four ounces of the purest copaiba are to be rubbed in a marble mortar with 32 grains of calcined magnesia, till perfect union takes place; 64 drops of oil of peppermint and 62 ounces

A MEDICAL PATRIARCH.

M. Aselar, of Lille, an eminent physician, had twenty-two children; seventeen sons, who all practised physic with success, and five daughters, who were midwives. M. Aselar is now in his hundredth year; he enjoys all his faculties, and still serves the cause of humanity by his advice, and by giving the fruits of his long experience at the consultations to which he is daily called.—*Gazette des Hôpitaux.*

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.
BY DR. VENABLES.

Hæmaturia — Bloody urine may arise from many causes, some of which (calculus, for example) we have already considered at considerable length. But the source of the blood is various, and in many cases very obscure. If the urine contain blood, by allowing it to stand, we shall often find it clot, enveloping the red particles, which are easily recognized in the field of the microscope. Sometimes the blood is found in strings, and, indeed, in some formidable cases, blood almost pure is voided instead of urine. It is evident that urine containing blood will likewise contain the other constituents; hence we shall find both fibrin and serum in such urine. The serum, of course, may be determined either by heating it to 160° Fab., when it will coagulate, or by precipitating the albumen with ferro-cyanide of potassium. In some cases the fibrin is found coagulated, and then appears like worms or bits of hair.

Diagnosis.—The detection of blood voided in very small quantity may prove a matter of some little difficulty, especially if the urine be otherwise very unnatural, and contain matters which can obscure the appearance of the blood. However, if time be given, in general the blood will gradually subside—that is, the red particles—and may then be more thoroughly examined and more certainly determined

under the microscope. The fibrin, too, in many cases will be found coagulated, particularly if the urine be at all acid; and in such cases it often assumes the appearance of worms, as stated above.

But the blood may be derived from several sources: it may come from the kidney, ureter, bladder, or urethra; and it is of the greatest importance to determine from which of these sources the blood is derived. The ancients appear to have been more attentive to these points than many even of the moderns. When blood proceeds from the kidneys, if it arise from calculus, there will be symptoms such as have been already described under the head of renal calculi. When the blood is uniformly diffused throughout the whole urine, and that there are small threads resembling worms, and which consist of coagulated fibrin moulded in the ureter, and afterwards washed out with the urine, there can be little doubt of the renal source of hæmorrhage*. A sudden voiding of blood also with the urine, is considered by Hippocrates as indicating the rupture of a vessel in the kidneys †.

It cannot well be determined whether blood come from the kidney or ureter;

* 'Οκόσοισιν ἐν τῷ ὕρῳ παχέει ξοντι σαρκία σμικρὰ, ἢ ὥσπερ τρίχες ξυνεξέρχονται, τουτέοισιν ἀπὸ τῶν νεφρῶν ἐκκρίνεται.—Hipp. Aphoris. sect. iv. aph. 76.

Si hæc (sc. *urina*) crassa, *carunculas* quasdam exiguas quasi *capillos* habet, aut si bullat, et male olet, et interdum quasi arenam, interdum quasi sanguinem trahit, dolent autem *coxæ*, quæque inter has superque pubem sunt, et accedunt frequentes ructus, interdum vomitus biliosus, extremaque partes frigescent, *urinæ crebra cupiditas*, sed magna difficultas est, et quod inde excretum est, aquæ simile, vel rutum, vel pallidum est, paulum tamen in eo levamenti est, alvus vero cum multo spiritu redditur, *utique in renibus vitium est*.—Cels. de Med. lib. ii. cap. 7.

† 'Οκόσοι ἀπὸ τὰν τομάτου αἷμα οὐρέονσι, τουτέοισιν ἀπὸ τῶν νεφρῶν φλεβίου ῥῆξιν σημαίνει.—Hipp. Aph. sect. iv. aph. 78.

but unless from the mechanical irritation of a calculus impacted, there will be but little chance of ureteric hæmorrhage. In all cases of renal and of ureteric hæmorrhage, but more especially of the latter, if the cause be a calculus, we shall have greater difficulty in voiding the urine, with most of the other symptoms indicative of the presence of calculi in these situations; and in case of the ureteric origin from calculus, we probably shall have more or less of suppression of urine.

But when the blood comes from the bladder, if for the most part comes away towards the termination of the micturition; during the first part, the urine passing off free from blood. Aretæus states, that the blood from the bladder is yellow and thin*. If the urine be thick (says Hippocrates), and that there be a branny or furfuraceous matter suspended in it, the bladder is in a scabious condition†. It is probable that the condition here alluded to is a sort of venous congestion or plethora, which is sometimes observed in the bladder, and is attended with appearances similar to those mentioned by Hippocrates, and in which condition there is a strong tendency to ulceration. The blood which comes from the bladder is sometimes clotted or grumous, and often, as before observed, gives rise to strangury, or even retention of urine‡.

Hæmorrhage from the bladder, like that from the kidney, may arise from a calculus or a diseased condition of the mucous membrane, or from disease of the prostate; but enough has been already said to enable us, unless in very obscure and difficult cases, to determine the nature of the affection.

In highly irritable and inflamed states of the mucous lining of the urethra, blood may be voided from this part. In such cases, however, the hæmorrhage is most active when the patient is not passing any urine. If he pass urine, the blood disappears; but when micturition has ceased, the bleeding recommences, and generally comes away in drops. The urethra, too, in such cases, is always in a highly painful and irritable state. It may, however,

happen that the blood may flow back into the bladder, and thus give rise to phenomena resembling vesical hæmorrhage. But even here the blood will clot more or less in the urethra, as well as bladder, and, by blocking up the passage, produce a temporary obstruction to the flow of the first urine from the bladder; but as soon as this obstruction has been washed away by the urine, this flows freely, and there is no more any symptom of hæmorrhage till the urine has been all discharged.

Hæmatnria, if the blood come from the kidneys or bladder, is a serious affection, because it indicates either the presence of a calculous or some other very serious disease. It may indicate ulceration of the bladder or kidney, but more especially ulceration of the bladder, if the urine, with the blood, also contain pus*. Hæmorrhage from the urethra is not so dangerous, unless when arising in old people, in whom the prostate is also diseased. If the quantity of blood be large, and that it flow back into the bladder, it may coagulate there, and thus present a mechanical obstruction to the flow of urine from the bladder, as we have already observed. Sometimes a small clot forming in the bladder may become nucleus for the deposit of calculous matter, and thus give rise to the formation of a stone in this organ.

With respect to the causes of hæmatnria, they are very various. We have already taken into consideration urinary calculi; but sometimes active, sometimes passive, hæmorrhagy takes place from the kidneys and bladder, owing either to particular conditions of these organs, or to constitutional affections, which, in fact, give rise to a hæmorrhagic tendency or diathesis: such are plethora, local congestions, typhoid diseases, scurvy, &c., the particular action of which it is needless here to detail.

Hæmorrhagy from the urethra is very often induced by the mismanagement of gonorrhœa, more especially by the use of urinary stimulants in the first or acute stage. However, it sometimes depends upon particular organic derangements of the canal itself, when it is more formidable.

Treatment.—The treatment, of course, in a great measure will depend upon the nature and causes of the complaint, as well as upon the source from whence the blood is derived. If the blood come from the kidney, and that there be symptoms of inflammatory action in the organ, and

* Αἱμορραγείε κοτὲ ἡ κύστις· ξανθὸν τε καὶ λεπτὸν τῆδε τὸ αἷμα.—De Caus. et Sig. Acut. Morb. lib. 2, cap. x.

† Ὁκόσοισιν ἐν τῷ ὕρῳ παχεῖ ἔονται πιτυρώδεα ξυνεξυρέεται, τουτέοισι ἡ κύστις ψωρᾷ.—Sect. iv. aph. 77.

‡ Καὶ γὰρ, ἢν τὸ αἷμα λεπτόν τε, καὶ ξανθόν, καὶ μὴ πάχῃ ἢ εὐπαγές, ἀλλ' ἡ κύστις ἐς πολλὸν ἀλίζει χρόνον, καὶ ἥδε δερμαίνουσα καὶ ἐψώσα πηγνύει, καὶ ὧδε γίγνεται θρόμβος.—De Caus. et Sig. Dint. Morb. lib. 2, cap. iv.

* Ἦν αἷμα, καὶ πῶον ὑρῆν, καὶ λεπίδας καὶ ὁσμὴ βαρὴν ἔη, τῆς κύστεως ἔλκωσιν σημαίνει.—Hipp. sect. iv. aph. 81.

the patient be young and vigorous, we must use venesection and the most active antiphlogistic measures. The same means also will be necessary if the hæmorrhage seem to depend upon a congested state of the vessels, more particularly the veins of the kidney. But if the hæmorrhage appear to be more of a passive nature, and depending upon debilitating causes, then a different mode of treatment will be required, and we must have recourse to tonics and astringents. Hæmorrhages of a passive description are apt to occur from various parts, in the latter stages of typhus; and in some instances the kidneys become the source of the blood. In such cases, tonics, especially the di-sulphate of quina, with sulphuric acid, prove highly beneficial. When the bleeding appears to depend upon scurvy, the same means may be adopted; and as the urine in this case is generally neutral or alkaliescent, the mineral acids are obviously suitable remedies. When there are no signs of either excitement or debility, then the balsams may be given with advantage, as of copaiba. In some cases I have given the acetate of lead, with acetic extract of colchicum, and with very great advantage; and if the patient be of a gouty habit, colchicum will be found a very valuable remedy. Dr. Prout states that one of the most formidable cases of hæmorrhage from the kidney which he ever saw, and which baffled for a long time every means that the most experienced practitioners could devise, yielded almost immediately to colchicum, and the use of a strong infusion of uva ursi; and the patient enjoyed an immunity for nearly two years*. Many also recommend the tinctura ferri sesquichloridi; but I think this more suitable to those cases in which the bladder is the source of the blood. If the blood be derived from the kidney or ureter, in consequence of calculus, the means recommended under this special affection should be adopted.

As has been already observed, the bladder may prove the source of blood; and this may depend upon various organic alterations, or even disorganization of the tissue; and also upon mechanical irritants, as calculi. Sometimes fungous excrescences of the mucous lining may prove the source of the blood. I have already detailed the circumstances of the case of a coachmaker, at Witham, who was attacked with symptoms resembling stone—frequent efforts at micturition, with inability to pass his urine in any quantity. The urine contained at times a quantity of blood; and sometimes what passed by the urethra consisted almost wholly of blood. He suf-

fered great pain; and the forcing and straining to pass the urine were not only abortive, but proved highly distressing. On sounding, no stone could be felt. I directed the sulphate of morphia, with acetic extract of colchicum, and uva ursi, for him, with a slight tonic afterwards, and he got completely relieved, and was able to go about as usual for the best part of two years, when he died. The appearances on dissection I have described in a former lecture, to which, therefore, I refer you.

In cases of hæmorrhage from the bladder, we must endeavour to ascertain the cause, and treat it accordingly. Thus, if there be a calculus in the bladder, we must have recourse to the means already advised under that head. If it appear to depend upon some morbid condition of the bladder itself, we must endeavour, as far as possible, to remove or relieve the morbid state; and if this be impossible, we must, as far as can be done, attempt to prevent the consequences of such state. The means most effectual are colchicum, uva ursi, and morphia, with the mineral acids, especially the hydrochloric, and the tinctura ferri sesquichloridi, which latter may be given in combination with the acid, in doses of from twenty to thirty, or forty minims, three or four times a day, till some sensible effect has been produced.

When the blood flows from the urethra, it generally depends upon some highly irritable state of the lining membrane caused mostly by improperly treated gonorrhœa. In such cases, leeches to the perineum or penis, with poultices to restore the discharge, are the most effectual means. I have in two cases seen general bleeding necessary, but generally speaking the means above mentioned will prove sufficient.

In cases where it depends upon chronic disease of the urethra and prostate, as in old persons, the treatment must be regulated by the special circumstances.

In all cases of urinary hæmorrhage, the bowels, and indeed all the functions, should be attended to: rest in the horizontal posture, and a strict abstinence from all excitants adopted, otherwise no treatment, however active or judicious, can be productive of the slightest benefit.

Mucous and purulent urine.—We have already considered the mucous urine under the head of catarrhus vesicæ; and when the urine abounds in mucus, we may almost always consider this as derived from the internal lining of the bladder. The kidneys, perhaps, hardly ever secrete mucus in very large quantity, so that we can seldom have any difficulty in referring such morbid action to the mucous lining of the bladder. "There is, however," says Prout,

* On Diabetes, &c. pp. 293, 299.

"a species of secretion which is usually called mucus, and which, for want of a better name, may be distinguished by that term, which is frequently thrown out in great abundance by the kidneys, when disorganized or containing cysts. This may be sometimes distinguished by its peculiar appearance, and by its property of undergoing a sort of imperfect coagulation or gelatinization, like fibrin, of which it seems to be a modification *." In such cases the urine will be found to contain albumen, for it appears to contain the serum of the blood, and hence its albuminous character. If examined by litmus reddened by a very weak or diluted acid, the urine in such cases will be found alkaliescent, or if not absolutely so, it becomes alkaline very soon after being passed. In very severe or long protracted cases, the urine is voided alkaline, the decomposition of the urea, and the evolution of carbonate of ammonia which is the consequence, taking place in the bladder, or even in the kidneys themselves; and the urine being thus rendered more acrimonious, all the sufferings of the patient are in consequence greatly aggravated.

When the mucus is in small quantity, as in the commencement of the disease, the urine, when first passed, is slightly turbid, but becomes transparent after standing for some time, or after being filtered. In the first case the mucus subsides, leaving the supernatant urine of its natural transparency; but in the second the mucus is retained, and will be found on the filter. But in the advanced stages the secretion partakes more of the purulent character, and the urine is permanently turbid, nor can it be cleared, even by filtration. I fortunately happen to have, just at this moment, a specimen, brought to me a day or two ago by a medical gentleman from the country. Although this has been standing for some time, and has deposited a copious muco purulent looking sediment, the supernatant urine is still opaque. Here is a portion which has been filtered, and it, as you see, continues opaque. Boiling it, however, causes it to become of its natural transparency, and you see the purulent character of the sediment. So, also, the addition of alkalies, as ammonia or potash, as you see in these examples, carries down the sediment, leaving the urine above transparent. Acids have not this effect, although the phosphoric acid, by its solvent action upon mucus, will render urine slightly turbid from this principle transparent, provided pus be not present, and that the mucus have not undergone any great morbid change.

In many instances of purulent urine the urine itself is acid, although the pus be alkaline. You see in the example before you that the urine strongly reddens litmus paper; but the muco-purulent matter upon the filter, as you see, turns turmeric paper brown. This arises from its alkaline qualities. It is stated, that in such cases it may generally be inferred that the pus is derived from an abscess in the neighbourhood of the kidneys, or that the kidneys are only partially affected*. But the bladder is often in such cases the source of the pus, either from ulceration of its internal coat, in which case it is often intermixed with blood and serum, or from the mucous lining taking on a diseased action, like other mucous membranes, and secreting, instead of the natural mucus, a diseased mucus intermixed with pus. If, however, the urine, after the separation of these matters by boiling, prove to be unnatural, we may then conclude that the kidneys are to a certain extent involved. Hippocrates, indeed, asserts that either blood or pus voided with the urine indicates ulceration of either the kidney or bladder†; but the diseased action of mucous surfaces, and the agency exerted upon the properties of their secretions, under such circumstances, were not so well understood in his day.

Most of the causes of purulent urine have been already considered. Inflammation may end in the secretion of pus, with or without ulceration. The irritation of a foreign body, as a calculus, often gives rise to the appearance of diseased mucus or pus in the urine; and ulceration of the bladder, and of different parts of the urinary apparatus, may give rise to the presence of pus. Gonorrhæa also, in which the mucous lining of the urethra secretes a large quantity of pus, and which is washed away at each micturition, will often be attended with a purulent state of the urine; and the same phenomena may result from gleet and stricture, in which latter affection there is very often a gleet discharge, containing pus, and which is frequently produced in very large quantity.

Treatment.—The treatment of mucous or purulent urine, of course, will depend upon the nature of the cause. We have already considered one form of mucous urine, under the head of catarrhus vesicæ. When the bladder is healthy, and merely irritated by the presence of a foreign body, for instance, a calculus, the first effect is an increase in the quantity of mucus secreted. At first, perhaps, the mucus un-

* Ibid. p. 301.

† Ὃν αἷμα ἢ πύον οὐρήν, τῶν νεφρῶν ἢ τῆς κύστεως ἔλκωσιν σημαίνει.—Hipp. Aph. sect. iv. aph. 75.

dergoes no morbid change, and it comes away uniformly diffused through the urine, rendering it slightly turbid; but after a time the mucus subsides, leaving the urine tolerably clear. But after a time the mucus becomes both increased in quantity and altered in its properties, when it becomes viscid and tenacious, as in *cattarrhus vesicæ*. We distinguish the two cases by the general facts, the previous history, and the existing properties of the urine. If there are no co-existing circumstances to which the appearances can be more decidedly referred, we may regard the case as one of stone in the bladder, which view, perhaps, the sound will confirm, and treat the case accordingly. The principles have been already explained.

When, however, the quantity of mucus greatly exceeds the proportion that might be accounted for upon the above principle, and that the urine, though it have an acidulous reaction, yet contains albuminous matter, we may suspect such a state of morbid vascularity in the coats of the bladder as prevails in *cystirrhœa*, which may be treated accordingly—by local or even general bleeding, if the pulse be hard and the fever intense, which is generally the case.

When the quantity of mucus is inordinately large, or comes away in large flakes, and that the urine is white, or of a sort of brownish muddy appearance, or wheyish, and that it remains turbid, even after being left at rest for a considerable time, or that it deposits a sort of pulverulent-looking matter, to be again easily diffused through the urine—if, with these, the urine has a very foul, fetid smell, and an alkaline reaction, and, still more especially, if it contain blood, the coats of the bladder may be looked upon as more or less in a state of disorganization, the effects of which have spread to the kidneys. This condition, though it may be greatly ameliorated by the treatment recommended under the head of *cystirrhœa*, yet it is not in our power to effect a radical cure; and, therefore, all we can attempt is a palliative treatment. In all cases, the state of the urine should be carefully attended to, and morbid conditions, as far as can be, corrected.

In males, mostly, the prostate gland becomes more or less involved in the affections of the bladder above described; and when the irritation is great the secretion of the gland becomes increased, and may be detected in the urine. We have already stated the properties of the prostatic secretion, and how it may be recognized. When the prostate only is affected, the urine, for the most part, has an acidulous reaction; but when the gland is sympathetically or secondarily affected, the

urine, for the most part, if examined, will be found unhealthy, and generally alkaline; and there is nothing which has a greater effect in producing irritation of the prostate than alkaline urine—hence the necessity of examining and correcting such morbid conditions, if present.

With respect to purulent urine, the discrimination between pus and some of the diseased forms of mucus is not very easy. We have already shewn that pus and mucus, examined by the microscope, present a globular structure; the only method, therefore, of determining the matter is by the chemical action of ether, which, digested on pus, dissolves an oily envelop, the existence of which, it is asserted, distinguishes the globules of pus from those of mucus, which latter have no such covering. In cases of purulent urine, if arising from calculus or inflammatory action, it must be treated as already mentioned under the several heads. As the presence of pus, however, indicates rather a reduction of inflammatory action than its acmé, the antiphlogistic measures should be less active than in the intensity of inflammation. Probably, in most cases the means detailed under the head of ulceration of the bladder would not be inappropriate under any circumstances. When the discharge of pus assumes a chronic character, hydrochloric acid, the tincture of sesquichloride of iron, colchicum, the balsams, and the different urinary astringents, seem the most appropriate remedies, the exhibition of which has been already treated of at sufficient length in some of the former lectures, to which therefore I refer.

INFLAMMATORY AFFECTIONS OF THE
CORNEA.

Acute Keratitis, continued.—General treatment.
—Blood-letting.—Blisters, Setons, Moxas,
&c. &c.

THE description I have just given of acute keratitis must have proved to you how extremely important it is that the treatment should be well understood. If, however, you consult what has been said on the subject by different authors, you will find that it yet remains a complete chaos. Indeed, nothing can more clearly show the utility—nay, the necessity—of studying the inflammatory affections of the eye, in

the tissue which the inflammation attacks, than the confusion which reigns in the treatment of keratitis: it is one of those diseases against which nearly every remedy has been in its turn tried, lauded, and then abandoned. With some practitioners every thing succeeds; with others, every thing fails. Some advocate general measures, to the exclusion of local treatment; others, again, uphold local applications as being the most beneficial. This diversity of opinion originates, no doubt, in the little attention which has been paid to the diagnosis of the different forms of keratitis, and to the opinions which nearly all ophthalmologists entertain respecting the specific nature of the disease. I do not flatter myself that I have solved this question, but I think I am now able to say, that in one case the disease may be cured, whereas in another a favourable termination is not to be expected—to say why a remedy succeeds, or why it does not succeed; otherwise the distinction I have established between the various forms of keratitis, by separately studying the inflammation of each part of the cornea, would be of no value; precision in the diagnosis of disease being only desirable as a means of throwing additional light on its treatment.

The treatment of acute keratitis, like that of most other diseases, is general and local.

General treatment.—When treating of the inflammatory affections of the palpebræ, I proved by a number of facts that little reliance, comparatively speaking, could be placed on general treatment, and that it ought only to be considered as an adjunct to local measures. This cannot, however, be said of keratitis, against which general treatment stands pre-eminent, although it is still frequently necessary to resort to local applications. I shall now merely speak of the treatment of acute keratitis, setting aside every thing relating to the various phenomena by which it may be complicated.

The therapeutical agents which enter into the treatment of keratitis may be divided into two classes. The first comprises blood-letting and external derivatives; the other, purgatives and alteratives.

Blood letting.—When the inflammation is intense, it is well to commence the treatment by general blood-letting. I need scarcely add, that the quantity of blood abstracted must be proportioned to the constitution of the patient, and to the state of his health at the time. Much discussion has arisen as to whence the blood should be taken—from the veins of the arm, or from the temporal artery. Judging *a priori*, arteriotomy would seem

most likely to produce the desired effect. I have not myself resorted to this operation often enough to speak very decidedly on the subject: I must, however, say, that neither the cases in which I have practised it, nor the arguments brought forward in its favour, have yet convinced me of its superior efficacy. Some practitioners have also asserted, that when venesection is employed, the external jugular vein ought to be preferred to the veins of the arm. This appears rational; but when we consider how difficult it often is to obtain a sufficient quantity of blood from the jugular vein, and how important it is, at the same time, that the progress of the inflammation should be arrested, I think we cannot but prefer the usual plan of performing venesection in the bend of the arm.

Another important question is, the extent to which bleeding should be carried, and the manner in which it should be practised. I have made numerous experiments with a view to elucidate the point, and have come to the following conclusion. If the patient is young, robust, and of a plethoric habit of body, I bleed copiously, to the extent of eighteen or twenty ounces, and repeat the bleeding the next day; sometimes, also, the third day, as the inflammation, which at first rather subsides, might otherwise reappear. If, on the contrary, the patient is rather weak, I take a smaller quantity of blood at first, and repeat the bleeding at greater intervals. With patients of an ordinary constitution, bleeding night and morning, for several days, according to M. Bouillaud's plan, appears to be attended with beneficial results. General bleeding, in most cases, gives great relief. The following day you will nearly always find that the cephalalgia, the burning heat, the epiphora, and the photophobia, are much less intense; but they do not disappear entirely, and indeed often return. The loss of blood seems merely to act against the tendency of the system in general to inflammation; if no other measures are adopted, the disease either remains stationary, or assumes the chronic form.

Leeches are by no means so efficacious a remedy as general bleeding, yet in some instances they ought to be preferred; when for instance, the patient is of a weak constitution, or of a lymphatic temperament, or when the circulating fluid has been impoverished, or its quantity diminished, by disease or by previous bleeding. When a patient is in this state, fifteen leeches applied behind the ear will have as beneficial an effect as copious general bleeding in a robust person. Leeches may be applied to the mastoid region, to the temples, to the inner canthus of the

eye, or to the internal surface of the eyelids. I seldom, however, apply them to the inner canthus, as I am not aware that any great advantage is to be derived from this expedient, and in private practice they very frequently alarm the friends of the patient, by the swelling and infiltration they produce. Nor do I apply them to the internal surface of the eyelids, the relief they give to the patient being too slight to counterbalance the trouble they occasion.

The abstraction of blood by cupping may be classed along with leeches, and resorted to in similar circumstances. It is generally attended with beneficial effects when the inflammation tends to become chronic.

Blisters, Setons, Mozas, &c.—Blisters applied to the nape of the neck have been much employed in the treatment of keratitis. If, however, the effects they produce are minutely analyzed, we shall find that they exercise much less influence over the march of the disease than is generally supposed. Combined with other measures they may be useful, but alone they cannot cure; indeed, I am inclined to think that the application of blisters to the neck—the region which is generally chosen—does more harm than good. In some persons, especially children, they occasion a local reaction, which is followed by swelling of the lymphatic glands of the neck. When the keratitis is cured, the blister is allowed to heal, but the lymphatic system has been excited, and the swelling of the glands continues. In many instances I believe that children have been looked upon as scrofulous, although the presence of the characters which are supposed to denote this affection was to be attributed solely to such a cause. Little benefit, you see, is to be derived from blisters when employed in the usual manner; I wish, therefore, to direct your attention to a peculiar mode of applying them to which I have frequently recourse; I allude to the application of blisters over the eyelids themselves—a measure which is nearly always followed by the most beneficial results. This plan of treatment, which I ought, perhaps, to have described when speaking of local remedies, has been tried in purulent ophthalmia, but we have no satisfactory account of the essays which were made. At first it seems irrational, and even dangerous; when, however, we examine the subject more minutely, we find that it is neither in contradiction with practice nor theory. It was, indeed, from theoretical views that I was induced to make use of the remedy. Recollecting that I had seen obstinate cases of ophthalmia disappear under the influence of the irritation caused by an

external affection, it occurred to me that a large blister over the eyelids might, by producing a kind of artificial erysipelas, be followed by the same results. I had already at that time studied the distribution of the vessels of the eye and of the eyelids, and was aware of the intimate connection which exists between them. Being anxious to ascertain the practical value of these ideas, I resolved to try the plan on the first obstinate case of ophthalmia that presented itself. This I had soon an opportunity of doing on an old soldier, who had just returned from Africa: both his eyes were violently inflamed, and I had a large blister applied over each. I was not, I must confess, quite easy with regard to the result of the step I had taken, and was consequently much pleased to hear him say the following morning that the pain had considerably abated. In two or three days I was able to open the eyelids, and then found that great amelioration had taken place. The eye continued to improve for about ten days: the affection then appearing to be stationary, I had again recourse to blisters, with the same beneficial results as before. This patient was not however cured, but we must not forget that he was labouring under one of the most obstinate forms of ophthalmia—keratitis accompanied by granular conjunctivitis. Since then I have employed blisters over the eye more than a hundred times in every form of inflammation, principally with a view to ascertain when they ought to be used. I have found them an extremely useful remedy in conjunctivitis, in superficial and in deep-seated keratitis, and especially in ulcerated keratitis. The counter-irritation they produce appears to dissipate the congestion of the tissues, to arrest or prevent the effusion of coagulable lymph, and to modify the ulcerations, if any exist. They are not, on the contrary, very beneficial in blepharitis, purulent ophthalmia, in inflammation of the interior of the eye, nor even in keratitis when the inflammation has assumed the chronic form: in this case topical applications are the best remedies we can employ.

Some few years ago, when I wished to ascertain the comparative efficacy of this remedy in the different forms of ophthalmia, I employed it nearly indiscriminately; but now that I know in which form it is likely to prove the most beneficial, I have recourse to it much less frequently. Another reason which often deters me from applying blisters when I otherwise should, is the repugnance which patients, especially in private practice, manifest towards them. This repugnance is founded on the supposition that the application of a blister in this region will occasion great pain, and be followed with much disfigure-

ment. The blisters themselves are, however, much less painful than is generally supposed, and the pain which was felt before nearly always abates in a very short time after they have been applied. If you question a patient with a view to ascertain the fact, you must remember that he is suffering two distinct kinds of pain—that caused by the blister, and that caused by the ophthalmia; you must, therefore, endeavour to make him distinguish between the two. The alarm which females generally shew, from the supposition that the application of a blister over the eye will be followed by more or less disfigurement, is also without the least foundation, for the epidermis alone being destroyed, the skin soon loses the red tint which it has at first. I have seen persons over whose eyes four or five blisters had been applied successively, without the slightest trace of redness a few weeks after. Still, as these prejudices are difficult to overcome, I should not advise this plan of treatment unless you think it necessary.

When blisters are applied over the eyelids, some precautions are necessary; I will, therefore, tell you briefly what is to be done. The patient must close his eyelids gently, without contracting them, as they would otherwise be more or less folded, and the blister would not cover their entire surface. The blisters must be then carefully applied, in such a manner as to be in contact with every portion of the external surface of the palpebræ, and over it is placed some lint or cotton to fill up the cavity of the orbit, in order that compression may be equal. A bandage carried a few times round the head and over the eye will suffice to keep every thing in position. You will generally find the eyelids much swollen the next day, when the blister is taken away; it must be dressed as usual, without any attempt being made to see the eye. In the course of two or three days the swelling diminishes, the eyelids become hardened, and the eye may be freely examined. Although the pain generally diminishes in the course of a few hours, the amelioration produced by the blister is not very sensible for a day or two. The symptoms are then found to abate, and they continue to do so for about ten days, when it becomes after requisite to repeat the blister. It is necessary that you should be aware that the amelioration does not take place at first, as you might otherwise be led to despair of any effect being produced, and employ some other remedy, to which the subsequent improvement would be attributed.

In conclusion, blisters over the eyelids seldom effect a cure alone, but they nearly always diminish the violence of the disease, even when every other plan of treat-

ment has failed to do so, and thus enable you effectually to overcome the malady. I have repeatedly found this the case in obstinate inflammatory affections of the cornea accompanied by ulceration.

Many practitioners have of late endeavoured to substitute for the cantharides plaster some other substance capable of producing vesication, in order to avoid the action of the cantharides on the urinary organs. Various therapeutical agents have been tried, among which ammonia and tartarized antimony occupy the first rank; indeed, so much attention has been paid to this last remedy, that I cannot pass it over in silence. I have frequently employed it under the form generally used, that of an ointment. It gives rise to a crop of numerous small pustules, and the effect, as also that of ammonia, seems to me similar in every respect to that produced by blisters, on which, you know, I do not place much reliance, when applied in the usual manner.

Setons are often productive of benefit. The irritation they occasion in the subcutaneous fibro-cellular tissue appears to exert more or less influence over the inflammatory affections of the cornea, whereas blisters, which are applied to the skin, appear more especially to act on the affections of the conjunctiva. There is, indeed, some analogy between the fibro-cellular tissue, which is the seat of the irritation when a seton is used, and the tissue of the cornea, on the one hand, and the organization of the skin, and that of the conjunctiva, on the other. I do not know whether these theoretical ideas are correct, but the remark which preceded them is certainly justified by practice. Although setons sometimes give rise to erysipelas, and to abscesses, I have often recourse to them when the keratitis resists the action of other remedies.

CLINICAL REPORTS

OF

DIFFICULT CASES IN MIDWIFERY.

By ROBERT LEE, M.D., F.R.S.

Physician to the British Lying-in Hospital, and
Lecturer on Midwifery at St. George's
Hospital.

[Continued from p. 832.]

FOURTH REPORT.

Forty-two Cases of Difficult Labour, in which the Forceps was applied.

CASE LXXXI.—In June 1833, Mr. Evans, of Mortimer Street, requested me to see a patient who had been nearly thirty hours in labour with her first

child. Though the pains were strong, and the head was at the outlet of the pelvis, it had made no progress for ten hours. Twelve ounces of blood were drawn from the arm, and a stimulating enema thrown up. After waiting several hours without any change taking place in the situation of the head, and exhaustion occurring, I applied the forceps with great ease, and delivered in less than half an hour. I took off the blades when the head was passing, to prevent laceration of the perineum. The child breathed, but died in a few minutes. The umbilical cord was found twisted three times round the neck; and this was probably the cause of the difficulty experienced in the labour, and the death of the child. Ever since the occurrence of this case, I have endeavoured to ascertain, before applying the forceps, whether the cord surrounded the neck, and pulsated.

CASE LXXXII.—On the 26th January, 1834, I was called to deliver a lady, *æt.* 26, who had been thirty hours in labour with her first child. The head of the child had remained ten hours in the pelvis without making any progress, and she was much exhausted. The parts were not very rigid, and no difficulty was experienced in applying the forceps and extracting the head; but in doing this, in spite of all the care I could employ, the perineum was slightly torn. The cord was twisted firmly round the neck of the child, and it did not pulsate. The child could not be made to breathe. Inflammation of the vagina took place, but no sloughing. In a few months the health was restored, and she has since had three labours, which were all perfectly natural.

The ergot of rye had been given before I was called to this patient, and it had the effect of increasing the pains, but not advancing the head.

CASE LXXXIII. — April 1835. I delivered a patient in the lying-in ward of the St. Marylebone Infirmary, with the forceps. The cord was round the neck once, and it pulsated very feebly. The pulsations of the heart continued for some time, but the child could not be made to respire. Inflammation of the uterus followed. Had this case been left to nature, which I now think it might safely have been for some

hours longer, it is not improbable but the child might have escaped.

CASE LXXXIV.—On the 8th July, 1839, I was called to a patient 37 years of age, who had been in labour with her first child about fifty hours. The os uteri was not fully dilated, and it was thick and rigid, and was pressed down with the head through the brim of the pelvis. The pulse was 60; tongue loaded. The pains were strong and regular, but produced no effect in advancing the head. An attempt had been made to deliver with the forceps, but only one blade could be introduced. Fourteen ounces of blood were taken away, and an enema administered. For a short time after this the head seemed to advance, but in four hours the pains had nearly gone off, and she seemed much exhausted. The head was perforated, and, from the difficulty afterwards experienced in extracting it, there could be no doubt that delivery was impossible by any other means. No bad symptoms followed.

On the 9th July, 1839, at 11½ A.M., I was called to another case of protracted labour, in which it was proposed to deliver with the forceps, though the head was so firmly impacted in the brim of the pelvis that it was impossible to pass the finger around it without much difficulty, and giving great pain. The bones were squeezed over one another very much, and all the soft parts of the mother were swollen and tender. It was the first child, and the labour had lasted the whole of the Sunday night and Monday until the Tuesday forenoon, when I first saw her. The pulse was excessively rapid; the tongue loaded; countenance swollen; great general exhaustion. The meconium was passing, and the discharges were extremely *fætid*.

After opening the head I was obliged to employ long-continued and great force before I could succeed in extracting it.

For several days she was in a state of great danger from retention of urine, and violent inflammation of the vagina. The symptoms, however, subsided without any sloughing or permanent mischief in the parts.

On the 26th of the same month, 1839, another case, somewhat similar, occurred to me in private practice; but in it there was distortion of the brim, and

a hard cicatrix of the vagina, the result of injurious pressure in a former labour. Here, also, it was proposed to use the forceps.

CASE LXXXV.—Mr. Cathrow, of Weymouth Street, on the 20th April, 1838, requested me to see a woman residing in Weymouth Mews, 35 years of age, and whose labour was greatly protracted. It was the first child. The head was sufficiently low for the forceps, and it was easily applied; but by no force that we dared exert would the head move forward, and it was perforated. The extraction of the head with the crotchet was a tedious and difficult operation; she, however, recovered favourably.

CASE LXXXVI.—August 19th, 1834, I attended a lady, 36 years of age, who had a very protracted labour from rigidity of the os uteri, and feeble irregular uterine action. Dr. H. Davies saw her with me, when the pains had nearly ceased, and considerable exhaustion had taken place. Blood-letting, cathartics, and anodynes, had produced little effect upon the os uteri in the earlier part of the labour. Dr. Davies applied the forceps with his usual dexterity, and soon extracted the head. The child never could be made to respire in a regular manner, and died in convulsions in a few hours.

Hæmorrhage of the most dangerous character followed the birth of the child; and after the placenta was extracted, a severe rigor took place, and for many hours the pulse could scarcely be felt at the wrist. She, however, ultimately recovered, but her life was certainly exposed to the greatest danger, by our delaying too long to deliver, in the expectation that the head of the child would come sufficiently low for the forceps.

CASE LXXXVII.—In the case of accidental uterine hæmorrhage, on the 24th October, 1835, in the St. Andrew's Parochial Infirmary, and which has been related in the Second Report, I delivered with the forceps, but the child was dead. The cord was round the neck.

CASE LXXXVIII.—August 17, 1836. Mrs. A—, ætat. 25, in the eighth month of her fourth pregnancy. Yesterday (the 16th August) dined on currie and rice, and ate bacon and eggs

at tea. At one o'clock on the morning of the 17th, awoke with violent pain in the back part of the head, and sickness, for which she took a strong cathartic. A physician was called to her soon after, and ordered five grains of calomel and an antispasmodic draught, which relieved the symptoms. During the forenoon she remained in a drowsy state, without complaining. At mid-day a fit of convulsion occurred. At 3 P.M. another and more violent fit followed. I saw her soon after this: the pulse was extremely rapid and feeble, and it became altogether imperceptible at the wrist on the abstraction of eight ounces of blood from the arm. More blood would not flow from a large orifice in the vein. The orifice of the uterus was slightly open, and the labour pains were commencing. I ruptured the membranes, and discharged the liquor amnii. An hour after, four ounces of blood were removed from the temple by cupping, when the pulse again became imperceptible. At 6 P.M., the os uteri being fully dilated, and the head in the pelvis, I delivered with the forceps. The child was dead. The convulsion fits continued, and she died at 8 P.M.

CASE LXXXIX.—On the 1st of March, 1836, a middle-aged woman, accustomed to the use of stimulants, was attacked with convulsions in the first stage of labour. Twenty-five ounces of blood being taken from the arm, without any relief, she was delivered of a dead child by the forceps. The fits continued afterwards till she died. The head was examined after death, and the vessels of the brain were reported to have been unusually distended with blood. Both this and the preceding case would probably have terminated fatally whatever plan of treatment had been adopted.

CASE XC.—In August 1836 I was called to a case of puerperal convulsions in the lying-in-ward of the Saint Mary-lebone Parochial Infirmary. The patient had been long in labour, and had experienced fourteen severe fits. The head being sufficiently low, and the parts dilated, I applied the forceps, and delivered with great care, but the child was dead. She had only one slight fit after delivery, and no bad effect followed the use of the forceps.

CASE XCI.—On the 16th February, 1839, Mr. Tucker, of Berners Street,

called me to see a case of puerperal convulsions. It was the first child, and no relief followed blood-letting and the other remedies. The head was within reach of the forceps, and I applied and locked the blades without difficulty; but by no force which I could justifiably exert would the head advance, and I was compelled to have recourse to craniotomy.

CASE XCII.—16th December, 1828, I was called to deliver a woman, residing in Currier Street, St. Giles's, who had been in strong labour upwards of 48 hours. The head of the child was jammed in the brim of the pelvis, and the pains had nearly gone off. Pulse 120. Great restlessness and delirium. The vagina hot, swollen, and tender. Discharge very offensive. Abdomen tense and painful. Retention of urine. To satisfy my own mind, I endeavoured to apply the forceps, but the attempt to pass the blades produced so much pain that I was forced to desist, and open the head. An hour and a half elapsed before I could succeed in extracting the head with the crotchet. Hemorrhage followed the removal of the placenta, but it was arrested by pressure over the fundus uteri, and the application of cold to the external parts, and she recovered.

Mr. George Curtis, of Dorking, was present at the delivery. The size of the child was much greater than usual.

CASE XCIII.—On the 15th August, 1837, Mr. Jones, of Carlisle Street, Soho Square, requested me to see a case of face presentation, in the St. Anne's Parochial Infirmary. The head of the child had not passed completely into the cavity of the pelvis. The face was greatly swollen, and also the vagina of the mother. The head had long been stationary; and, as the pains were becoming more and more feeble, it was certain the delivery would never be completed without artificial assistance. I applied the blades of the forceps with great difficulty, but found it impossible to lock them. The head was perforated; and the force afterwards required to extract it with the craniotomy forceps was so great, that I regretted having endeavoured to deliver before lessening the volume of the head. The patient did not, however, suffer any permanent injury from the operation.

CASE XCIV.—On the 11th August, 1838, I was requested by Mr. Cocke, of Cleveland Street, to see a case of difficult labour, in which he had made an unsuccessful attempt to deliver with the forceps. It was the first child. The labour commenced at 12 o'clock on Wednesday, and had continued till 5 o'clock A.M. of Friday. The forehead was behind the symphysis pubis, and for many hours the head had not advanced; it entirely filled the cavity of the pelvis. Mr. Cocke had applied the blades of the forceps, and locked them with great care; but though he made strong traction cautiously for a considerable time, the head could not be made to advance, and he had recourse to perforation. So great was the difficulty afterwards experienced in extracting the head with the crotchet, that he sent to request my assistance; and I did not succeed without considerable difficulty in delivering with the craniotomy forceps. No mischief, I believe, followed.

CASE XCV.—Tuesday morning, the 2d January, 1838, I was called by a medical practitioner to a case of protracted labour in Portland Street. The patient was a young woman who had been in labour with her first child since the Friday evening. The os uteri was fully dilated, and the head so low in the pelvis that the ear could be felt behind the symphysis pubis. The pains had been gradually diminishing in force, and had no effect upon the head. The bladder was filled with urine. After drawing off the urine, I applied the blades of the forceps with ease over the sides of the head, and locked them; but the head could not be moved, although I continued for a considerable period to employ even more force than I considered justifiable in attempting to extract the head. After perforation, so much force was required to draw the head through the pelvis with the craniotomy forceps, that I regretted having attempted to save the child.

The umbilical cord was round the neck; and Mr. — informed me afterwards, that he had felt the cord before the blades of the forceps were applied, and that there was no pulsation in it.

CASE XCVI.—Mrs. W. æt. 30, first pregnancy. Labour commenced at three o'clock on the morning of Sunday, the 10th Nov. 1833. At eight o'clock in

the evening, when the os uteri was considerably dilated, but the pains irregular and ineffective, thirty drops of laudanum were administered, and the same quantity two hours after given.

At 4 A.M. of Monday, the membranes were artificially ruptured, and a drachm of the ergot of rye given in four doses at intervals of twenty minutes. It produced nausea, but had no effect upon the uterine contractions.

In the afternoon of Monday, when I first saw the patient, the head of the child advanced so little through the brim of the pelvis, that I could with great difficulty touch the ear behind the symphysis pubis. The os uteri was imperfectly dilated, and rigid. The vagina and perineum also rigid. The pains strong and regular. Pulse 80; head clear; urine passed through with difficulty.

V. S. ad $\bar{\text{f}}$ xij. An enema and warm fomentations were recommended.

At four o'clock on Tuesday morning, I found the head of the child in the same situation, the os uteri still imperfectly dilated, and the vagina swollen and tender, and the neck of the bladder compressed. The pains had almost entirely gone off. The abdomen was tense and painful. Tongue loaded; urgent thirst. The tone of her voice was completely altered, and her strength was so greatly reduced, that it was evident she could not be delivered without artificial assistance. An attempt was made to apply the forceps, but the second blade could not be introduced, and the head after being perforated was extracted with the crotchet.

The child much exceeded the average size, and this appeared to have been the chief cause of the difficulty experienced in the labour.

No bad consequence followed.

CASE XCVII.—On the 21st September, 1836, at $3\frac{1}{2}$ P.M. I was called to the St. Marylebone Infirmary, to deliver a woman, æt. 25, who had been in labour forty-six hours. Since midnight the head had remained stationary. The os uteri was fully dilated. The greater part of the head had passed through the brim of the pelvis, and an ear could be felt behind the symphysis pubis. I applied the forceps to the head without much difficulty, and locked the blades, but though I employed strong extracting force for a considerable time, the head

could not be brought forward. I therefore opened it, and employed the craniotomy forceps to extract it. Mr. Bishop was present.

On the following day this patient was free from pain and every unfavourable symptom, and recovered rapidly.

CASE XCVIII.—4th Feb. 1829, I was called by a medical practitioner to a patient who had been in labour two days and two nights. It was her second labour, the os uteri was only half dilated, and the head, swollen and firmly compressed by the brim of the pelvis, was so high up that the ear could not be reached with the finger. The vagina dry and swollen. The pains continued, but had no effect upon the head. Mr. — had attempted to apply the forceps, but he could not get the blades over the head.

After perforating, the head could not be extracted with the crotchet till its point was passed up and fixed on the outside, near the angle of the jaw. A great part of the bones of the cranium had been torn away before this was done. Slight uterine inflammation followed.

This woman had been delivered once before by craniotomy.

CASE XCIX.—On the 2d August, 1839, Mr. Kennedy, of Tavistock Square, called me to see a patient, 31 years of age, who had been nearly sixty hours in labour with her first child. The head of the child had passed into the cavity of the pelvis, where it was so firmly impacted that it was evident the expulsion of it would never be accomplished by the natural efforts. I ascertained, by auscultation, that the child was alive, and I had no difficulty in applying the blades of Smellie's short forceps, and locking them; but fully half an hour elapsed before I could succeed in extracting the head, and this could not be effected without employing great force, more than I would have employed had I not been certain, from hearing the pulsations of the heart of the fœtus, that it was alive when the operation was commenced. The child shewed no signs of life after delivery, and considerable inflammation and sloughing of the vagina of the mother followed. The bladder and rectum happily escaped uninjured.

It would have been much better practice in this case had I abandoned the attempt to deliver with the forceps,

when I found that the head could not be extracted by moderate traction.

The unwillingness to resort to craniotomy, with a knowledge that the child was alive, led me to commit what I believe to have been a serious error, and which would have been avoided had the condition of the mother only been taken into consideration.

The following case occurred to my friend Dr. Blakeley Brown, of Curzon Street, on the same day :—

CASE C.—Elizabeth Nottage, æt. 28, married, 178, Drury Lane. Small and delicate in person; has had four children, and always very quick labours; the last child was born before any one arrived to assist her.

August 1st, at 8 A.M. I was called to attend her. She said the liquor amnii had escaped at 6 that morning, and about three quarters of an hour after the pains first came on, and so severely and strongly that she thought she should have been delivered before I could come.

On my arrival at 8 P.M. the pains had a good deal subsided, and on examination I found the os uteri dilated to about the size of a crown piece, rather low down in the cavity of the pelvis: the liquor amnii escaped in considerable quantity while making the examination.

After waiting an hour, and there being only two or three very slight pains, I left her, and returned at 11 A.M. She said she had had two sharp pains since I was gone, but on examination I could detect no alteration. After waiting some time, and there being no return of pain, I left her, with directions to be sent for if the pains came on.

At 11½ P.M. I was sent for, and on my arrival found the pains had returned every quarter of an hour, and they now came on every five minutes, but without forwarding the labour.

At 2 A.M. August 2d, the head was resting on the perineum, the pains coming on regularly, but without power to expel the head.

At 7½ A.M. the pains were getting weaker; the head was just in the same position, the ear could be felt, and the finger passed round the cavity of the pelvis, which was of ample dimensions.

The patient was now becoming exhausted, and I applied the forceps without any difficulty and extracted the head in a few minutes. The body shortly followed; and immediately afterwards the placenta was expelled.

The child (female) was apparently dead; there was the *slightest* pulsation in the cord. The warm bath and artificial respiration were tried, but without avail; the face and trunk were quite purple, and meconium passed in large quantity.

The uterus contracted well, and the patient recovered without any bad symptom.

[To be continued.]

CLINICAL OBSERVATIONS

ON

THE USE OF THE AIR-DOUCHE IN THE
DIAGNOSIS AND TREATMENT

OF

DISEASES OF THE EAR.

By T. WHARTON JONES, Esq.

[For the London Medical Gazette.]

No. VI.

IT is to be remarked, that, as we cannot always tell beforehand how far successful the injection of ethereal vapours into the tympanum may prove, their employment at first can be looked upon only as experimental. The following is an example of such experimental treatment :—

CASE IX.—*Experimental treatment by ethereal vapours sent into the tympanic cavity.*

Friday, March 22d, 1839.—Mr. Q. R., aged 28, has been deaf for ten or twelve years; can hear the watch only when it is applied close to his ears; has noises in the ears; auditory passages bedewed with wax; membranæ tympani somewhat opaque.

Introduced a catheter into the right Eustachian tube. Found the guttural orifice contracted, and the lips of it as if glued together, requiring some little manipulation to make an entrance for the beak of the catheter.

The stream of air did not at first enter; it afterwards penetrated in small quantity, and by and by pretty freely, with a whistling and gurgling sound.

The left nostril is so contracted from an injury formerly received, that the smallest catheter cannot be passed.

Prognosis.—I pronounced an extremely doubtful prognosis; but as the person was very desirous to have something done, I agreed to give the ethereal vapours a week or fortnight's trial.

Saturday, 23d.—Hearing in the same state. Right ear treated both by the air-douche and the ethereal vapours.

Monday, 25th.—Hearing in the same state. Right side again treated, the left nostril not admitting the catheter.

Tuesday, 26th.—Hears the watch, though it does not touch the ear, on the left side. On the right side hears the watch at a more decided distance from the ear.

Wednesday, 27th.—Right ear, a quarter of an inch; left ear, an inch and a half. Noises in the ear much abated; they occur now only occasionally. Right ear again treated.

Thursday, 28th.—Hearing distance of right ear perhaps rather more than yesterday; left ear, two inches. Right ear again treated.

Saturday, 30th.—Right ear, two inches and a half; left ear, four inches. A stream of air enters the right Eustachian tube pretty freely. Right ear again treated with the ethereal vapours.

Monday, April 1st.—Right ear, three inches; left ear, four inches and a half. Right ear again treated.

Tuesday, 2d.—Right ear, five inches; left ear, seven inches. Right ear again treated.

Wednesday, 3d.—Both ears, nine inches. Still some buzzing in the right ear.

Thursday, 4th.—Has had a good deal of buzzing in the right ear, and thinks he did not hear conversation so well yesterday as he has been doing since the commencement of the treatment. Right ear, seven inches; left ear, eight inches. Right ear again treated.

Saturday, 6th.—Hearing the same as at last report. Buzzing in the ears only now and then. None yesterday. Right ear again treated.

REMARKS.—A thing worthy of notice in this case is improvement of the left ear, though untreated, keeping pace with or even outstripping that of the right, which was treated.

The improvement was much greater than I anticipated, and was such as would fully have warranted a perseverance in the treatment.

When the ethereal vapours prove beneficial, as in the case just related, I know of no other indication for the continuance of the treatment than that already mentioned in regard to the air-

douche, viz. in the absence of any counter-indication, perseverance until, I will not say hearing be restored to the natural standard, but until improvement stops. I have, however, met with a case in which the right ear, which at first heard the watch at the distance only of five inches, came, in the course of a fortnight's treatment, to hear it at about two feet, and the left ear rose from three inches to about one foot nine inches; but after that improvement stopped, notwithstanding the treatment was persevered in; the hearing gradually fell back to its former state, without any perceptible symptoms, good or bad.

In carrying on the treatment by ethereal vapours there is one essential point to be attended to, and that is to go on regularly day after day, or at least every second day. The treatment carried on at irregular intervals, proving here as unsatisfactory as the irregular treatment of a case of chronic ophthalmia.

In communication No. IV. I ask, in regard to the proximate cause of the deafness in cases No. V. VI. and VII. "Was it owing to thickening or other change in the texture of the membrane lining the tympanic cavities, and consequently of the membranes closing the fenestræ? Or was it owing to some change in the labyrinth in general? Or to some affection of the auditory nerves in particular?"

"It would be of the greatest importance if these questions could be satisfactorily answered, because the state of the ears under consideration appears to be more or less that of a large proportion of habitually deaf persons, and because we should then be more likely to ascertain the signs diagnostical of its commencement, and thus be able to adopt early and perhaps efficient treatment on general principles. An inflammatory origin is scarcely to be doubted. This subject will be farther considered in another communication."

The following case illustrates in some degree the question here proposed:—

CASE X.—*Recent inflammation and tumefaction of the mucous lining of the Eustachian tube and cavity of the tympanum of left side.*

Friday, 29th March, 1839.—Mr. S. T. aged about thirty, complains of uneasiness in the left ear, with noises, and dulness of hearing. Feels that air cannot be forced into the tympanum by

attempting to expire with the nose and mouth closed. Has lately had a cold in the head.

On the left side the external auditory passage is healthy, as also the membrana tympani, except that it is perhaps not so transparent as natural.

On the right side the external auditory passage is also healthy, but the upper part of the membrana tympani is gone, so that the whole chain of ossicles traversing the cavity of the tympanum is visible. In front and behind the handle of the malleus the hollow of the tympanic cavity is seen. The ossicles are of a yellowish white colour, and there appears to be no inflammation.

Mr. T. remembers many years ago having some affection of the right ear.

Mr. T.'s father and grandfather have suffered from affections of the ear and deafness.

As an exploratory measure, introduced a catheter into the left Eustachian tube, (which caused some uneasiness from the tenderness of the nasal passages), and applied the air-douche: the air did not enter freely; now and then only a small quantity entered with a shrill whistling sound.

Diagnosis.—I infer inflammation and tumefaction of the mucous lining of the Eustachian tube and cavity of the tympanum.

Thursday, 11th April.—Hardness of hearing increases. Noises in the ear. A tendency to, but not actual pain. The right ear is also somewhat affected. The mucous membrane of the throat spongy. Cannot force air into the left tympanum.

Again explored the left Eustachian tube by means of the air-douche, and found it quite impervious.

To apply leeches to the nostrils.

Saturday, 20th.—Hearing distance of left side, four inches; of right side, eleven inches.

Has applied about five leeches to the nostrils, but without benefit.

Does not feel pain in the ears, but a fullness, and when he stoops a beating of the carotids. The noises do not exist in the right ear; throat somewhat more inflamed and painful on swallowing the saliva, but not in swallowing a bolus of food.

To be let blood to ξxij . Leeches to the throat. Calomel and James' powder at bed-time, and an aperient next morning.

Tuesday, 23d.—The pain and fullness in the ear gone, and the buzzing diminished.

Tuesday, 7th May.—Has been confined to the house, and since stirring about again as usual, the noises in the left ear, which had ceased, have again become perceptible.

Hearing distance on both sides the same as on Saturday, April 20. Throat better.

Applied the air-douche to the left ear. Felt on introducing the catheter some contraction of the guttural orifice of the Eustachian tube. The air entered pretty freely, with gurgling. Hearing rather diminished immediately after.

Saturday, 11th.—Left ear three inches. After having ascertained the perviousness of the Eustachian tube by the air-douche, ethereal vapours were sent into the tympanum. Hearing rather diminished immediately after the treatment. General health indifferent of late.

Monday, June 24th.—Has been in the country since last report, and is now much better in health. The hearing of the left ear is also very much improved.

REMARKS.—Inflammation and tumefaction of the mucous membrane of the Eustachian tube, left side, was in this case evident, and it is not to be doubted but that the lining membrane of the cavity of the tympanum was similarly affected, whatever other part of the ear may have been involved. After the Eustachian tube had become pervious by the subsidence of the inflammation and tumefaction, the case, as far as regards the left ear, resembled in all respects one of nervous deafness as commonly described, even to its being hereditary. "There is no doubt," says Kramer (*Die Erkenntniss und Heilung der Ohrenkrankheiten*, p. 41), "that diseases of the ear are hereditary: in many families, several or even all the members labour under a greater or less degree of dulness of hearing, *especially with the nervous character*." In the case under consideration there were sufficient indications of inflammation in parts not at all connected with the auditory nerves, to show it was not nervous deafness merely, if there was any nervous deafness at all; besides the deafness under which the father of this patient laboured appeared to be owing to organic changes from previous inflammation in the ears. The subject of Case II. might be said

to have laboured under hereditary deafness, but which was evidently not nervous. In addition to the grandfather, whose case has been already noticed, I have had the sister also of the subject of Case II. under my care for an inflammatory affection of the middle ear and membrana tympani. I may say in almost all the cases of hereditary deafness I have met with, the proximate cause of the disease, so far as it could be ascertained, was more or less organic change of the middle ear and membrana tympani, in consequence of previous inflammation. Hence, instead of the idea very commonly attached to the expression "hereditary deafness," viz. that it is owing to a hereditary predisposition of the auditory nerve to fail in its powers, we might adopt the more positive and tangible one, that it is very often the result of inflammation of one or other of the accessory parts of the ear—inflammation, however, to which the parts are hereditarily predisposed.

As to the morbid state of the ears actually existing, in many of the cases of the nature under consideration, we have perhaps an example in what is recorded by Mr. Savage* of the ears of Joseph Hall. "The lining membrane of the tympanum and Eustachian tube showed evident signs that it had been the seat of inflammatory action during life; thus instead of being delicate and transparent, as it is in a healthy state, when its existence as a continuous membrane hardly admits of demonstration, in the right tympanum and Eustachian tube it was red, and half a line in thickness, and in the left upwards of a line† thick, and covered by a tenacious,

bloody mucus." * * * * "The lining membrane of the Eustachian tubes was so much thickened and villous, that although a probe could be carried through them without the least difficulty, yet during life this thickening must have been sufficient to oppose the passage of air considerably in the right tube, and to obstruct it entirely in the left." This corresponds in general with what has been found on dissection in other cases.

The lining membrane of the tympanic cavity being fibro-mucous—periosteum and mucous membrane—inflammation of it will vary in its nature and consequences. It may at one time be simply the catarrhal affection of a mucous membrane, at another time the violent purulent otitis interna, in which the surrounding osseous textures become so readily involved. The morbid state of the lining membrane of the middle ear I am attempting to illustrate appears to be rather of an intermediate nature. It is the "phlegmasie sans secretion" of Deleau. The parallel which I have already drawn between the structure and pathology of the derivative lacrymal organs and the middle ear, if cautiously employed, will prove of material assistance in illustrating further this point.

In affections of the external auditory passages, we sometimes see the lining integument at the bottom tumid, and lying over the membrana tympani, in the same manner as the conjunctiva does over the cornea in chemosis. This state accompanies affections of the auditory passages, which prove very intractable, and are productive of considerable deafness. In tumefaction of the lining membrane of the cavity of the tympanum, it cannot fail but that sometimes the membrane of the fenestra rotunda will be overlapped in a similar manner—a condition which would be a very efficient cause of deafness.

As the cases which have been related give a sufficient idea of the details as connected with the use of the air-douche in the diagnosis and treatment of diseases of the ear, and as the number at the head of this article warns me that it is for the sixth week that I encroach on the columns of the MEDICAL GAZETTE,

mercury has rather a tendency to rise. Hence, at a given temperature of the atmosphere, the air-douche produces in the part of the body against which it is directed, no greater cold than a draught of wind.

* London Medical Gazette, July 20th, 1839, No. 43, p. 617.

† It is to be remembered that the old English line is one-twelfth of an English inch, and that the Paris line is one-twelfth of a Paris inch. The Paris inch being somewhat longer than the English inch, the French line is nearly equal to one-tenth of an English inch. It is to be remembered moreover that the cavity of the tympanum measures from without inwards about three-twentieths of an inch. This estimation of the morbid thickness of the lining membrane of the tympanum, therefore, I am inclined to think is somewhat overrated. If not, the cavity of the tympanum on the left side must have been entirely obliterated. I take this opportunity to mention in regard to the theory Mr. Savage has founded on the coldness of the air as it issues from the air-press, that a stream of air immediately on issuing from the air-press, directed against the ball of a thermometer, brings the mercury down two or three degrees; but when the air traverses the whole length of the flexible tube and cateters before playing on the ball of the thermometer, the

I will now conclude this series of contributions, only repeating the request made at the commencement, that they be received as they have been offered, viz. as imperfect observations on a subject, not, indeed, easy of investigation, but by no means incapable of it.

LETTER FROM THE PROFESSOR OF MEDICINE,

CONCERNING THE RECENT APPOINT-
MENTS AT GLASGOW.

To the Editor of the Medical Gazette.

SIR,

As you have, in a recent number, entered upon the late appointments in the University of Glasgow far too slightly for the gravity of the facts, and the indignation and disgust they have excited amongst all parties, I beg to put you in possession of a slight sketch, for the accuracy of which my name will, I trust, be a sufficient pledge.

When I accepted the office of Professor of Medicine, thirteen years ago, I concluded that my duties would be held to be fulfilled by a six months' course of daily lectures on the practice of physic; for as to that course of instruction which in modern times, and in certain schools, had been comprehended under the name of theory and institutes of medicine (and which, as artificially divided at Edinburgh in my time, had comprised physiology, pathology, and therapeutics), it undoubtedly depended on my own estimate of the nature of my charge to undertake it in a separate course of lectures or not, as I should judge proper. Now I doubted, both from reflection and from experience, of the necessity of such a course. Physiology was the natural and necessary appendage of the professor of anatomy. Into general therapeutics I could not but enter to some extent from my own chair; and as to pathology, as a distinct subject, if it mean the exhibition of morbid structures or results of diseases, I own that I have permitted myself, perhaps, rather an unusual extent of scepticism as to its utility. I distrusted myself the less on the general principle, as I knew that, in the London schools, in which our most accomplished physicians had been formed, a course of

lectures on the theory of medicine had never yet been judged expedient. Settled, however, at Glasgow, I was to go by public opinion; or rather, the University was obliged to furnish any line of instruction which, from time to time, the public boards should exact from their candidates. Thus pressed, I was prevailed upon, in the second or third year of my residence, to undertake a separate course of lectures on these subjects—a course which, though only delivered twice a week, was already nearly equivalent to the three months' courses delivered in London on all medical subjects indifferently. In the progress of events, finding the double duty greatly too much for my health, I profited by the assistance of my eldest son, who, for a further period of about two years, employed himself diligently in extending and delivering these lectures. When I lost his services, by his obtaining the Radcliffe Fellowship, I invited Dr. Rainy to take the class off my hands, on the condition of extending the course, which I now began to be pressed about, to the same length as the others delivered in the University; and the entire duty, thus satisfied to the most rigorous extent, has ever since that period been discharged, with the highest credit and applause, by that gentleman.

The position was, undoubtedly, advantageous to Dr. Rainy: it was eminently favourable to the increase of a reputation of which, however, he had already laid the deep foundation among his fellow-citizens; but it was one of very great labour, and it is not to be denied, but rather strongly to be insisted on, that its highest advantage was the security it seemed to afford him (and this increasing, of course, with every adding year) of eventually obtaining the separate chair, if ever it should become one.—*Heu vatum ignaræ mentes.*

What, then, has destroyed the fair and just hopes of Dr. Rainy's ambition? Inquire at Glasgow. Inquire not only in our walls, but at 'Change or market; every where the answer will be the same:—Party, party, party! Ask for what reason the teacher of a class, constantly increasing, and become steadily and uniformly productive—a class recently of 140 pupils—has been dispossessed? A satisfactory answer to this demand can, I should say, only be sup-

plied by two parties: by Lord John Russell, and his political adherent, Mr. Oswald. As to any advantage in these arrangements reserved to myself (a charge now brought forward by the *public virtue* of an ephemeral scribbler as matter of obloquy), it will scarcely be held censurable by any just man, or spoken of in disparagement as a bargain, when it is considered that my interest in my own lectures, as a source of emolument, merged in Dr. Rainy's taking my place; that I had an author's copyright, as it were, in what had been done already; and that, in every arrangement made by the Professors in Glasgow (and every where else) with assistants, such considerations necessarily obtained; and, as I believe, to an extent often far more onerous to the latter than I had exacted, and my colleagues sanctioned. No corrupt bargain this, my Lord John Russell, but an honest protection of one's own intellectual property; nor can I conveniently refer to any passage in the history of my own times, in which men, even in the highest offices, like those held at present by yourself and your distinguished colleagues, have been found to disdain the provision which usually signalizes their retirement. But this is not quite all: Dr. Rainy has been deprived of his position, and I, as well as himself, of its contingent advantages, under quite unprecedented circumstances.

I left Glasgow, in May, a sexagenary invalid—in fact, exceedingly ill, and doubtful of my own recovery. In this condition I wrote to Lord John Russell, requesting leave to resign my chair in favour of my son, Dr. D. Badham. This letter was dated the 27th of May. The reply of the minister lamented my infirmities, and any inconvenience to which I might be submitted; but, on public grounds, he declared his inability to listen to any thing of which the principle was so incompatible with the public good; yet, in six weeks afterwards, the advantage of this public (Lord John Russell's and mine) was found to require the ejection of an approved and esteemed teacher, and the destruction of the results of seven years' toil and perseverance!

I had received Lord John Russell's reply with resignation. I blamed him not; but for what has followed—the dismemberment of my office, without the courtesy of an inquiry how it might

affect one—the dismissal of my friend, and the mutilation of my income—I was, indeed, unprepared. Now one of two things: either Lord John Russell, at the date of his reply to my application, did not think it his duty to listen to a sort of recommendation (of a Royal commission) issued some twelve years ago, in regard to the institution of a new Chair; or the process by which he became enlightened was so sudden, that he ought in all reason to have mistrusted it. Precipitation the most undeniable is, I apprehend, the least inculpation to which his Lordship has subjected himself; and even this is a light charge compared with the singularly injurious treatment inflicted on the party who has been set aside; for I challenge the whole force of the whole Radical party, even as it exists in Glasgow (where it is in perfection)—or by whatever other title it more delights to be distinguished—to satisfy the public why Dr. Andrew Buchanan was put in, and why Dr. Harry Rainy was put out. As elements, however, for the discovery of truth, I have to state, that the death of the former member for Glasgow (Lord William Bentinck); the election of Mr. Oswald as its representative (of that Mr. Oswald whose bills against the independence of the University are fresh in memory); my own application to Lord John Russell; his Lordship's answer; and the appointment of the two new professors (who might be said to have come down upon us as from a parachute, had they not been themselves, both of them, at that instant, rivals and candidates for a lectureship on forensic medicine, within the College walls, about to be instituted by ourselves)—are all events that took place within a few summer weeks.—I remain, sir,

Your most obedient servant,

CHARLES BADHAM.

Brighton, August 26, 1830.

P.S.—What could possess a writer in the *Lancet*, who indites a letter, affronting, as usual with that publication, and meant, of course, to be injurious, to put the editor only in possession (as he declares himself to be) of his "name and address." One marvels that he should not rather have given his communication the credit and consequence of both. His obloquy has but little moved me; nor will I be rash enough to provoke one who is, I dare say, in a fair way of

obtaining a professorship for himself (*sic itur ad astra!*), and eating the epichorial sheep's-head in better society than he apparently enjoys at present; for one is almost tempted to say to such an adversary, if there were a reasonable chance of being understood,

“———— Quis tecum sectile porrum
Sator, et elixi vervecis labra comedit?”

“Say with what cobbler eat'st thou, nothing loth,
Thy seeth'd sheep's muzzle, and its turbid broth?
What sunless close, apart from human ken,
What wynd, yet unbaptized, conceals thy den;
Where, for Iatric charge pronounced unfit,
Detraction feeds thee, who had'st starv'd on wit;
Woo, having cast thy scruples all away,
Drain'st in too frequent drams an hireling's pay?”

OBSERVATIONS

ON

COMPLICATED SURGICAL
INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with
the Auxiliary Forces in Portugal and Spain.(As delivered in his Lectures at Sydenham
College School of Medicine.)

[Continued from page 555.]

II.—INJURIES OF THE CHEST.

The most important of the various effects of these injuries.—1. On blood-streaked sputa; their absence in some very severe injuries; at other times produced by mere contusion; not therefore a sure indication of different degrees or kinds.—2. Want of vitality, proneness to excessive suppurative and sloughing action; tendency also to excessive action of skin.—3. Permanent tendency to engorgement and inflammation of lung.—4. Possibility of great pleuritic mischief affording but little indication of its existence; occasional inefficiency of bleeding.

THE general features and the simpler forms of these injuries were considered in the last lecture. The more complicated forms, and individual symptoms and effects, which often stand forward as the leading feature of a case, giving a distinguishing character, and essentially modifying the treatment proper to such cases, both merit and require description, from their practical importance.

1. Bloody sputa, even in the worst forms of injury, do not always occur at first; their absence, therefore, must not be taken as a proof of the slight nature of the injury. The contrary to this must

also be borne in mind, viz. that a mere contusion, which shall not, with proper treatment, be followed by any serious after consequences, will give, as a first indication, pain of the chest, difficulty of breathing, and expectoration of blood. The following abstract of a case furnishes proof of the first proposition; it further shows all the worst effects, unattended by many of the worst symptoms, of these injuries.

—West, æt. 29, March 16th, 1836, was admitted; a bullet having entered about an inch below the right clavicle at the centre, and passing directly through the first rib backwards, emerged behind the right shoulder. He had not expected any blood; pulse was weak and hurried.

Bled to 3xvj., and an opiate administered.

Symptoms and progress of case.—

Accelerated circulation from time to time, pulse gaining a wiry character; no expectoration of blood; pain generally referred to the lower portion of the right lung. Difficulty of breathing, occasionally relieved by the expulsion from the wounds of large quantities of fetid matter; restless; much troubled with a short cough; *râle muqueux* over both lungs; difficulty of swallowing, referred to the chest; skin hot; tongue dryish. Died on the tenth day.

Treatment.—Sixty-eight ounces of blood extracted in the first eight days, lowering the pulse and alleviating the symptoms. Tincture of digitalis in doses of twenty minims. Opiate the first and two last nights.

On 7th day, Emp. Lyttæ to abdomen, to alleviate pain.

Post mortem.—The ball passed immediately through the first rib, comminuting it, and driving a portion of cartilage, and several portions of bone and a piece of jacket, into the apex of the superior lobe of the right lung. In passing out, it fractured second rib and injured the scapula. The left lung perfectly healthy, with the exception of some slight adhesions: these considerable over the surface of the right lung. A considerable quantity of fetid matter in the thoracic cavity. The whole of the right lung was considerably gorged with blood, and in a slight degree hepatized, but in other respects not diseased. The *plenra costalis* and *pulmonalis* were both immensely thickened and granulated; the *plenra pulmonalis* from a line to

a line and a half in thickness, (as you may observe in this preparation). The liver was enlarged, florid in colour, slightly gorged, but otherwise healthy. The other viscera healthy.

This case furnishes many features worthy of note besides the principal one for which it is quoted, viz. the absence of hæmorrhagic sputa in so severe an injury: the difficulty of swallowing, referred to the chest, seems to have arisen from the pressure of fluid on the œsophagus. The pain was referred to the engorged and not to the injured part of the lung, accompanied by a pain of abdomen, which must be considered as a sympathetic pain. The *râlemuqueux* seemed not confined to the part where suppuration existed, but to be spread over the whole chest. The excessive formation of fetid matter and spontaneous relief by its ejection, also deserve attention.

2. A general feature of these cases is the want of vitality, all parts speedily ulcerating or sloughing, and the copious and unusually abundant discharge, with the great and general debility resulting from such long continued and extensive suppurative action. The following case is well marked, but I am sorry that the notes of the post-mortem have been mislaid.

William Ford was struck by a canister-shot under the acromial end of the clavicle on the right great pectoral muscle, near the anterior edge of the deltoid; the wound appeared superficial, with uneven edges, running towards the summit of the shoulder; complained during the first few days of headache, attended with febrile symptoms.

10th day.—Suppuration was established, and already considerable.

13th.—Suppuration more profuse; slight bleeding from the surface of the wound: a swelling of an œdematous character somewhat suddenly appeared in the left thigh and leg, extending from the upper third of the thigh to the ankle, rendering the limb double its natural size. Pulse slow; patient feverish; thirst; bowels costive.

18th.—Wound of a dull red colour; granulations dark and sluggish; deltoid puffed up, from fluid extending over the shoulder down the course of the *infra-spinatus* and *latissimus dorsi*. On sitting upright, an enormous quantity of matter was pressed out from the wound

by the action of the muscles; the back appears inclined to slough over a great part of its extent; countenance sunk; eyes bright; pulse slow and feeble; breathing agitated, hurried, but not oppressed; pain in the lower part of left side; cough frequent; leg and thigh still swollen, excessively painful when moved; no such sensibility about the wound; fluctuation and a crackling feel about and above the knee-joint; sound over the chest rather dull; immense fetid discharge; slept well last night; skin cool; bowels open; bandage to limb.

19th.—Appeared worse; swelling of thigh much diminished; tow and tepid water to the back. The 20th, a marked change took place in the character of the discharge; it became dark and grumous: perspirations. Evident signs of great debility and the supervention of hectic. The right side of the chest gave a dull sound.

23d.—Hippocratic countenance; a quantity of blood issuing from the wound; extremities cold. He suddenly roused; screamed with a pain in the right side, which continued for some minutes; after which he lapsed into the same exhausted state as before, lingered for an hour, and expired. The left side much larger than the right.

The slowness of pulse was remarkable from the commencement; an inability to any healthy inflammatory action, shown by the speedy supervention of the suppurative to an extraordinary degree, and subsequently sloughing, sufficiently marked a loss of that vitality which is capable of resisting such processes. The rapid diminution of the swelling of the limb, on the days succeeding the application of the bandage, seemed to indicate either a communication with some distant sac or cavity, or a remarkable absorption, such as we observe in a metastasis. The laborious breathing in the commencement gradually diminishing towards the end, and the sudden pain of the right side, and enlargement of the left, lead to the belief that a large quantity of matter had suddenly made its way into the thoracic cavity.

Not less peculiar and evident, in a great number of cases, is the great and often uncontrollable tendency to excessive action of skin, and continued restlessness of a febrile state.

3. In all severe cases, and occasionally even in slighter ones, there remains,

after the wounds are entirely healed, as a permanent consequence, a proneness to engorgement and inflammation, rendering any active exertion dangerous or impossible, and resembling much the effect I have pointed out as almost invariably observable in the brain after concussion.

Case of probably penetrating wound, with recovery, leaving a permanent tendency to engorgement and inflammation.

Thomas Dean, æt. 25, a blacksmith, always healthy; short, fair, of sanguine temperament.

On 1st, 1836, received a gun-shot wound: the ball, entering the chest at the anterior portion of the fourth rib of right side, passed outwards and downwards, having carried in a portion of belt and cloth, and emerged about two inches below the base of the scapula of the same side.

1st day.—Great difficulty of breathing; blood-stained expectoration; much hæmorrhage from wound in the back; bled to 3xviij. on first arrival; further relieved by hæmorrhage; pulse after both full and bounding; patient of plethoric and robust habit. Evening, the pulse was weak and slow; a tickling cough attended, with little pain in chest.

2d.—Had passed a tolerably good night; no pain, save on coughing, which is followed by expectoration of blood. Pulse rose, and became full and strong.

V.S. ad 3xx. Digitalis, ℥xv. ter die.

3d.—Favourable night; free from pain, except, as before, on coughing; expectoration of blood continues; pulse rising.

V.S. ad 3xvj.

From this period, with occasional recurrence of pain, and disposition to febrile action, he went on favourably to end of third month, when cured.

In March 1838, I found him incapable of great exertion; and if he took cold, or any active exercise, he was subject to an attack of pain in the wounded side.

This is also illustrative of the good effects of prompt and free depletion, which, in the case before us, evidently and effectually kept the inflammatory action, to which there was a great tendency, in check.

4. It may constantly be observed, in reference to these injuries of the thorax, that considerable pleuritic mischief may exist, with trifling disturbance to pulse and breathing, and that even fatal wounds do not always give immediate signs. Of these important facts abundant proof is furnished by the following cases. In the case of West, already given, there was no expectoration of blood.

Case of injury to spine and thorax; symptoms chiefly referring to spine, and not to chest.

George Cusack, wounded August 1, 1836, by a ball which penetrated the thorax, near the heads of the ninth and tenth ribs, one of which it fractured. On the introduction of the finger, the lung was felt acting against it. Died the 11th day: symptoms during the whole period chiefly of spinal injury.

On 2d day some difficulty of breathing complained of.

On the 3d day, delirium; great febrile action; profuse perspiration on the face; body hot and dry; pulse rapid and rather hard, 120; respiration 48 in the minute.

4th day.—Temporary retention of urine; pain of right shoulder, near the lower angle of scapula; pulse 96, soft; respiration natural.

5th.—Pain of right side of chest, round the wound, increased on full respiration; no cough or spitting of blood, and respiration pretty tranquil; pulse 80, soft, and of good character; tongue furred.

6th.—Very little pain when he lies quiet; respiration tranquil, but he cannot take a full inspiration; so on to the 11th day. Breathing on the 7th day noted as neither laborious nor hurried, and the patient free from cough. He was carried off by tetanus.

I have already referred to this case in speaking of injuries of the spine, the ball having lodged in one of the dorsal vertebra, and refer now, therefore, to the points in connection with the chest injury. There was a wound of the diaphragm; abrasion of liver and kidney; no opening could be detected in the lung, although air had been forcibly expelled. The lung on the right side was found adhering firmly to the ribs, with the exception of a portion opposite the wound, where the pleura being free, a cavity existed, containing a considera-

ble quantity of yellow-coloured turbid serum. The pleura much diseased, and thickened. On inflating the lung, air was found to escape in the direction of the wound.

Case of gun-shot wound penetrating the thorax and lung.—Fractured rib anteriorly and posteriorly, and scapula, and injury of subclavian vein.

Michael Mahoney, wounded May 16th, 1837. A musket-shot entered the left breast immediately under the clavicle, fracturing anteriorly the second rib, and in the same direction penetrated the superior lobe of the left lung, penetrating again the pleura costalis behind, and fracturing the same rib a second time, near its spinal attachment; after which, making its way through the scapula, it fractured the body of that bone, and lodged under the integuments at its inferior angle. On the 19th the ball was extracted, and at this period the effects of the wound on the constitution assumed no serious character; so much so, that, without examination, any injury of the pleuritic cavity could not have been anticipated. On the 21st, the breathing became more laborious, and symptoms of pleurisy appeared. He was bled to Oij. with considerable relief; the bowels were freely opened; and the symptoms continued favourable until the 24th, when a profuse hæmorrhage occurred from the anterior wound. On removing the clot, which in a great measure filled the wound, the blood appeared to be of a venous character. Cold water was applied to the shoulder and chest, and all hæmorrhage ceased. The subclavian artery could be felt distinctly pulsating at the bottom of the wound, on introducing the finger. On the morning of the 26th, considerable hæmorrhage occurred, perhaps a pound. The subclavian artery, by the officer in charge, was tied external to the scalenus anticus muscle. The hæmorrhage did not again occur. A few hours after he complained of pain in the arm, and it was considerably colder than the other; it was then rolled in flannel. He gradually sunk, and died twelve hours after the operation.

Post-mortem.—Dissection shewed the course of the ball, as already described, and the ulceration—almost obliteration—of the subclavian vein; also, inflammation of the coats of the artery at the same point.

Here we find, that although the cavity was penetrated, and the lung wounded, yet no chest symptoms for nineteen days indicated the serious mischief done. Although not bearing on the present subject, I cannot omit pointing out that the ligature of the artery was uncalled for; and even had that been the vessel ulcerated, no good result could be hoped from its ligation when the vein was implicated; mortification was naturally to be expected, and there is little doubt would have taken place had the patient lived. It is necessary to bear in mind always, that whereas in the upper extremity the collateral circulation may generally be depended upon for carrying on the life of the limb, even when suddenly called upon by a wound or ligation of the principal trunk, yet if the capillaries, already taxed to the utmost, have further to contend against venous congestion, they become unequal to the increased effort; and therefore, when the vein is implicated with injury to the trunk of an artery, sphacelus almost inevitably results.

Sergeant Wolfe; fracture of sternum and lesion of left lung; died, 8th day.

Ball penetrated the sternum; drove in three splinters on the lungs, and lodged in the substance of upper lobe of left lung, two inches from the surface. It was found at the mouth of the wound after death, probably protruded by action of lungs. Left lung collapsed and healthy, except for two inches, which was inflamed around the wound. Chest full of bloody serum and clots of blood (coagulated); effusion of serum into pericardium greater than natural; all other viscera natural.

1st day.—Pulse, aspect, and functions, regular; no chest symptoms; ball supposed to have glanced off.

11 at night.—Pulse quick and full; face flushed.

V.S. ζ xxx.

2d.—Great pain of chest; countenance anxious; pulse quick and full; inspiration painful.

C.C. V.S. ζ xvj.

3d.—Symptoms much improved; less pain of chest; less cough; countenance improved; not much pain in the wound; pulse strong and full.

V.S. ad ζ xvj.

4th.—Pulse quick and sharp; pain in

back; cough; hurried respiration; restless; hot skin.

5th.—Pulse quick and small; shivering fits, accompanied with cold perspiration, and returning every two hours, have come on. During the night orderly officer called, for hæmorrhage, which was florid and mixed with air and mucus, from wound; his face purple; relieved on being bled to syncope.

6th.—Pulse again quick and full.

V.S. 3xxxvj.

In the evening cold and shivering; then delirium.

7th.—Tongue dry; encrusted with brown delirious; small pulse.

8th.—Died.

In this case it may be remarked, that the symptoms did not immediately supervene, that there was an intermediate day's relief; the rigors on the 5th day preceding a violent hæmorrhage; arrested by venesection producing syncope. The purple face, cold perspirations, and delirium, ushering in death, are all worthy of note, and render the case a good instance of the irregularity of the manifestations in these injuries.

In some cases already detailed to you, good evidence has been furnished of the importance and value of early and free depletion. In many instances, however, even this active and energetic mode of treatment utterly fails in controlling or arresting the disastrous effects which follow each other in rapid succession, until death concludes the case.

Case of severe injury, on the progress of which large depletions seemed to exercise no influence.

Henry Calvert, wounded October 1st, 1836, by a musket-ball, which entered near the external inferior edge of scapula, passing across and inwards, fracturing the eighth rib, and entering the chest. Emphysema speedily supervened around the wound; hæmoptoe; lips purple; pulse quick; respiration painful, oppressed, short, and accelerated, with a sense of impending suffocation.

V.S. ad 3xx.

2d.—Bad night; great oppression of chest; disposition to cough, without being able to do so; pulse full and strong.

V.S. ad 3xxv.

3d.—Same symptoms; bowels constipated.

4th.—Still difficult respiration; *râle muqueux*; pulse quick and hard; bowels unmoved.

V.S. ad 3xxvj. Mixture, with digitalis, ℥℥xx. pro dosi. Active enema administered.

5th.—Suffers much from difficulty of breathing; pulse 120, hard and bounding; of full habit of body, to which, in some degree, may be attributed the severity and unyielding nature of the symptoms; skin hot.

V.S. ad 3xxvj.

6th.—Worse; pulse sharp and frequent.

V.S. ad 3xxvj.

7th.—*Râle métallique* and *bruit de soufflet*; respiration inaudible in lower portion of left lung; pulsation of right auricle and ventricle stronger than left, and louder in a marked degree. Died in the afternoon.

Post-mortem.—The ball had entered between the seventh and eighth ribs of right side, towards their posterior third. The right lung was wounded, collapsed, and hepatized in its upper portion; the lower was gorged with blood. The cavity of the pleura contained nearly two pints of bloody serum. Heart and abdominal viscera healthy.

Here we see, although the treatment commenced very shortly after the injury was inflicted, and that more than seven pints of blood were abstracted in six days, aided by full doses of digitalis and active purgatives, with starvation, no impression whatever seemed made upon the disease or its progress.

[To be continued.]

RESEARCHES IN EMBRYOLOGY.

MR. JONES'S REJOINDER TO DR. BARRY.

To the Editor of the Medical Gazette.

SIR,

DR. BARRY's pertinacity in the attempt to fix upon me a charge of disingenuousness and want of candour towards Professors Valentin and Wagner, is the only reason that induces me to notice his communication of last week.

He says, after mentioning the date of publication of the observations on the

ova of the Mammifera, by the above-mentioned gentlemen, "Yet T. Wharton Jones claims the priority of discovery of both vesicle and spot—a claim which the dates above stated satisfactorily refute." This is a pure invention on the part of Dr. Barry. I am not aware that any thing I ever wrote or said can be construed into such a meaning; and I do not perceive that you, Mr. Editor, in the remarks reprinted in the last number but one of the *MEDICAL GAZETTE*, advanced any claim of priority in my behalf.

It is a very different thing to claim having made an observation independently and about the same time that a similar observation was made in another country, from claiming priority of discovery. Therefore, whilst I never disputed the claims of Valentin and Wagner, and fully admit the correctness of Dr. Barry's dates, viz. that Valentin and Bernhardt's memoir was published in Germany in October 1834, and that Wagner's observation regarding the germinal spot was announced in Müller's *Archiv* for 1835, but, with a note, by the Editor, saying, that the paper had been received in 1834;—whilst, I say, I fully admit all this, it does not the less remain a *fact*, that I, without any knowledge of M. Coste's observations, did, independently, and by the mere dint of my own study and dissection of the mammiferous ovum under the microscope, discover both the germinal vesicle and the spot on its side in the beginning of September 1834.

From the dates above mentioned, then, it appears that my observations were made one month before Valentin and Bernhardt's memoir was published. In regard to Wagner I am more nearly equal with him, as, though his observations were made in 1834, they were not published till 1835. Mine, also, though made in 1834, were not formally published till 1835.

I here beg to anticipate an objection which Dr. Barry will most likely at once start, and that is, "What proof is there that T. Wharton Jones made his observations in September 1834?" The best way I can meet this is to give the following short history. It was in Glasgow, in the house of Dr. Mackenzie, my observations were made, and they were communicated and demonstrated to Dr. Mackenzie, Dr. Rainy and others, at the time. A month or two

after, meeting Dr. Allen Thomson*, in Glasgow, I mentioned the circumstance to him, and being in Edinburgh in the beginning of February 1835, I demonstrated the vesicle and spot to Dr. Sharpey, then Lecturer on Anatomy in Edinburgh, now Professor in London University College. As to the memoir which was read before the Royal Society in June 1835, it was sent out of my hands in February 1835. Before passing out of my hands it was seen by Dr. Sharpey, and after passing out of my hands it went successively through those of Dr. Mackenzie, Dr. Rainy, and Professor Burns of Glasgow; by the latter it was transmitted to Dr. Lee of London, who communicated it to the Royal Society. The memoir was afterwards referred to Mr. Owen. I have no doubt if Dr. Barry is anxious for any farther information, he will receive it on application to the gentlemen named. Mr. Owen will be able to explain, if he have not already explained, to Dr. Barry the reason why the memoir was not published in the *Philosophical Transactions*; and whether or not, at the time it was read, it was considered wholly destitute of novelty. I have no doubt also but that Mr. Owen will inform Dr. B., if he have not already informed him, that he, Mr. O., has seen me demonstrate the vesicle, and the spot on its side, and that in a way more likely perhaps to show the vesicle as it really is than by the process of crushing.

The facts now stated show that I have no need to seek to disallow the just claims of others in order to uphold my own. And I believe, Mr. Editor, Dr. Barry will not now be bold enough to question what you have already stated, viz. that the germinal vesicle, and the spot on its side, were discovered quite independently in this country and on the continent about the same time.

But this is not the main point in dispute, as Dr. Barry would have it appear. This is merely an episode: the main point in dispute, I beg it to be remembered, is contained in my communication of the 20th of July, the object of which was to disprove the assertion, that the study of embryology is "one to which the attention of physiologists in this country has scarcely begun to be

* I would here beg Dr. Barry to refer to Dr. Allen Thomson's article, "Generation," in the *Cyclopædia of Anatomy and Physiology*, Part xiii. Feb. 1838, p. 452.

directed," and to expose the unfounded nature of the "pretensions to novelty, originality, and correctness, which Dr. Barry has introduced into both series of his 'Researches.'"

With many apologies for the encroachment on your valuable columns to which this controversy has given rise, I remain, sir,

Your obedient servant,
T. WHARTON JONES.

36, George Street, Hanover Square,
Sept. 2, 1839.

FUNCTIONS OF THE GREAT SYMPATHETIC.

To the Editor of the Medical Gazette.

SIR,

I WOULD not for a moment be supposed to impugn the accuracy of Mr. Wells's experiment; but what I must still be allowed to contend for is this, that no positive inference can be drawn from this solitary case (involving as it does so many remote contingencies), to warrant an universal application. It appears to be founded upon the *non causâ pro causâ* species of reasoning, the fallacy of which is apparent. Mr. Wells says, "my object is to show that some substances exert their poisonous action through the agency of the nervous (ganglionic) system alone, and that the cerebro-spinal system has but little influence over this action. If this be so, the inference is obvious even without any direct experiment: they must act through the medium of the ganglionic system. And should my experiments be verified by such a course as that recommended by Dr. Christison, no fact in physiology could be better established."

Mr. Wells will excuse me when I say that this at the outset savours a little of what logicians would call an hypothetical syllogism, the consequent being admitted before the antecedent has been proved. One of the suggestions which appears to militate against his present position is this, that in almost all the experiments which have been recorded, the ganglionic system has been observed to be the *last* affected, for on opening the thorax immediately after death—the death of the sentient system—the heart was found pulsating, and all the motions resulting from ganglionic sti-

mus were proceeding with the utmost regularity; and the supposition certainly appears, to say the least of it, a little anomalous, that the system which conveys the peculiar effect of a powerful agent is itself only indirectly susceptible of its impression. In Mr. Wells's future experiments he should be particularly careful to observe, when death has been induced by a *primary* or exclusive action upon the sympathetic nerves, whether or not the functions proper to this system are capable of being maintained for any length of time after the sensitive life has been destroyed; if not, the alternative pointed out by the old doctrine will still come to our rescue.

In the meanwhile any fact is valuable which tends to throw a light into the darkness which surrounds us; and if Mr. Wells should find his opinion unequivocally confirmed by further observation, he will have the not unenviable satisfaction of knowing that he is right, and that Müller, Brodie, Magendie, Emmert, Coullon, Krimer, and a host of other distinguished physiologists, are *wrong*.

I trust to be able shortly to publish, in a condensed form, some practical observations on the nature and treatment of certain sympathetic local affections, which I think I have satisfactorily traced to their source—ganglionic irritation.

I have the honour to remain, sir,

Your most obedient servant,

R. H. ALLNATT.

August 30th, 1839.

ANALYSES AND NOTICES OF BOOKS.

"L'Auteur se tue à allonger ce que le lecteur se tue à abréger."—D'ALEMBERT.

Cure of Club Foot, Bent Knee, Wry Neck, Spinal, and other Deformities. With Remarks on the late Progress of Art, and on the necessity of a public Institution for the Relief of the Poor labouring under deformities. By GUSTAV KRAUSS, M. D. &c. With Cases and Wood-cuts. London, 1839. 8vo. pp. 42.

THIS little essay is sensible and judicious, and though chiefly intended for the general reader, will also be advantageously consulted by the surgical student. The following extract will show

that the author has attempted to designate the varieties of club-foot by some new terms; it is possible that although they may not be generally adopted, they may still be of service, by fixing the attention of the learner on the species of this deformity.

"1st. The *Tip-foot* (Horse-foot, *Spitzfuss, pes equinus*.) When the sufferer walks on his toes, and the heel is drawn upward. In this class may be included the *knot-foot*, (*pie-d-bot en des-sous*;) where the patient walks upon the back of the foot.

"2d. The *Cross-foot* (Club-foot inward, *Querfuss, varus*.) When the sufferer walks on the outward edge of the foot, or the outward part of the dorsum, the point of the foot being turned inwards.

"3rd. The *Outbow-foot* (Club-foot outward, *Schräggfuss, valgus*.) The sufferer treads upon the inward part of the foot; the point of the foot, and sometimes the heel, are turned outward.

"4th. The *Heel-club-foot* (*Fersen Klumpfuss, talipes calcaneus*.) The patient walks upon the heel.

Sparks from the Wheel of a Man not grinds;—a Light on the Pharmacopæia. London: J. Butler, 18mo. pp. 82.

This little 18mo. belongs to a class of books respecting which we can seldom speak in terms of praise. It is professedly designed for those students (by courtesy so called), "who work more to pass than to learn; who fear an edifice hard by Bridge Street, and dread the approach of Thursday nights." Much, indeed, is it to be deprecated that there should be individuals who enjoy the cognomen of "medical students," and are about as well suited for the profession as was the popinjay, who pestered Hotspur, qualified for fighting. As long, however, as there are such personages, so long (on the principle of demand creating supply) will there be no lack of primers and "readings made easy," adapted for their use and capacity. There is this novel feature in the work before us, that the subjects are treated of in a humorous and facetious style, wherever there is an opening for mirth, with the design of riveting the attention and impressing the memory of the student. The most important of the pharmacopœial preparations are selected, and

their composition and decomposition explained in a lucid manner. The author appears well qualified for his task, and is, we have no doubt, from the brilliancy of his scintillations, a *grinder* of the first order.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam nihil, dignitatem *Artis Medicæ* tueri; potestas modo veniendi in publicum sit, dicendi periculum non recuso."

CICERO.

CURIOUS MEDICAL LAW-SUIT.

It has sometimes been doubted whether *Forensic Medicine* or *Medical Jurisprudence* is the fitter title for the science where law and medicine meet. The former is now generally preferred, and is certainly best suited to the majority of topics discussed; to those parts of medicine, namely, which are made the subjects of discussion in courts of justice. On the other hand, when the social relations of our profession are to be settled by law, medical jurisprudence seems the apter phrase, as it signifies the application of law to medicine, while the more modern name rather means the converse.

The peculiar genius of the continental nations has led them to attempt to fix by law many of those rights and duties of the medical profession which are here left undecided; yet still more remain unsettled, and are left to the decision of courts or magistrates, according to the spirit rather than the letter of their codes.

The Court of Cassation, at Paris, has just decided this new and important question—"Can a physician agree to give his medical services, for life, in return for a perpetual annuity, or a sum of money paid down?"

It appears that by a verbal contract, on the 22d of February, 1833, Dr. Mojon, formerly *médecin en chef* in the army, and Professor of the Faculty at

Genoa, agreed to perform the duties of physician during his whole life, for the Baroness de Feuchères and her household, as long as she resided in France. The Baroness, in return, agreed to give M. Mojon, his wife, their children, and their descendants in a direct line, an annuity of 10,000 francs (400*l.*); terminable at her option by paying down 200,000 francs (8000*l.*)

In consequence, Professor Mojon and his family established themselves at Paris, and the agreement was executed until October 1837. At this period, the Baroness having broken off with M. Mojon without any plausible reasons, he cited her to appear before the Tribunal of the First Instance, in order to obtain the execution of the contract; and she was adjudged to pay him either the annuity, or the two hundred thousand francs. She appealed to the *Cour Royale*, which, on the 22d of April, 1838, confirmed the judgment of the court below. She then appealed to the Court of Cassation, but with no better success, being still saddled with the painful choice of annuity or capital; besides having to pay the costs of three law-suits, which must be no joke, even in France, where law, we believe, is not quite so expensive a luxury as in this country.

The Baroness de Feuchères maintained that the agreement was contrary to the articles 1131, 1133, and 1780, of the Civil Code, which declare that it is not permitted to make a contract by which one loses one's independence and liberty. She did not complain of losing her own independence, but charitably suggested that the doctor lost his by so stringent a bond. On the other hand, the Attorney-General, who appeared for Professor Mojon, denied that a contract of the kind destroyed the independence of the physician, as he was still able to exercise his profession, and manage his private affairs. The agreement, he as-

serted, was neither contrary to public order nor sound morality; nor was it against the law; for the article 1780, which prohibits a perpetual engagement, is applicable only to servants and workmen, and cannot be made to comprehend so liberal and noble a profession as the art of healing. The patient who is attended by a doctor of medicine cannot be called his master, and does not stand in that relation to him.

We must confess that if a life-contract between master and workman is void by the Civil Code, on account of its destroying the independence of the latter, the agreement between the Baroness and Professor Mojon would seem to be of a voidable kind. This would be still more evident, if the objection had been made on the part of the physician instead of the patient; but if the bond bears the true slavish stamp discountenanced by the law, it is well to annul it, even if the objection comes from the wrong side. An agreement like that of Professor Mojon certainly entails the loss of independence for life; especially, if he was compelled to follow the Baroness in her journeys through France. Suppose she chose to live one month at Paris, a second at Marseilles, and a third at Strasburgh, what would become of the Professor's private practice, or his family affairs? Perhaps there was an understanding that she generally lived at Paris, and would not frequently require his services elsewhere; otherwise even 10,000 francs a year for an indefinite period would have been an insufficient remuneration for one of Dr. Mojon's rank in the profession. It is possible, indeed, that the courts, when severally deciding against the Baroness, may have been influenced rather by the spirit than the letter of the code. They may have thought that the contracts which the law intends to annul are not those by which independence is destroyed in the finer sense of the term,

but those by which the poor might be seduced into selling their fairest birth-right—liberty—for food and raiment. In every European country so many wretched beings are constantly living on the brink of famine, that unless the law interposed its humane prohibition, there would be great danger of the revival of serfage, if the indigent were allowed to sell their very life for drachmas.

We do not know what the English law says to these bargains, but we should hope that it repudiates them: yet the candid must allow that some approximations to slavery take place even in England. The friendless children, for instance, who are drafted from our workhouses into the service of needy householders, are in a state which has not many of the attributes of freedom. The contracts made for them by the parish authorities are seldom advantageous, and the threefold choice of toiling for a painfully inadequate reward, of returning to the workhouse, (and that perhaps a union bastille!) or of starving, might seem to leave the serf but little to envy. After all, however, the state of the parish child, though a reproach to civilization, is better than that of the serf chained to the soil; for while the *adscriptus gleba* is exposed to still harder usage unrebuked by law or custom, and has scarcely a hope of advancement, the alumnus of Marylebone or St. Pancras may appeal to boards and magistrates, and may rise to anything that he is fit for. Now, it appears from the decision of the Court of Cassation, that the French law, though jealous of the liberty of every citizen, and utterly disallowing serfage under any disguise, has no apprehensions for the freedom of family physicians, and looks without alarm on the life-long services of Dr. Mojon, and the perpetual annuity which rewards them. Although a physician may become the slave of fashion, or

the slave of theory, the French law does not fear that he will be made the slave of his patient. Yet among the ancients this was so common, that a scholar of the last century wrote an essay, *De servili medicorum apud antiquos conditione*. In stating the fact so broadly he fell into an exaggeration, with the intention, we believe, of vexing Dr. Somebody, his acquaintance.

Every human being must be satisfied with the defeat of Madame de Feuchères, and yet every one must see the imprudence of a bargain of this sort, by which the patient may be compelled to see a physician for half a century, who has outlived her liking in a month. The *Gazette Médicale* has just been informed, that on the 24th of August the Baroness sent a tipstaff to summon M. Mojon to attend her professionally!

If forensic medicine is the science where law and medicine touch, this encounter of doctor and patient, after three law-suits, may be truly called a medico-forensic meeting. The handsomest and most sensible thing the lady could do on such a visit, would be to pay the Professor the large fee of 200,000 francs imagined in the contract, and restore him to the freedom concerning which she was so anxious.

STATE OF THE POOR OF GLASGOW.

It is now about six months since we reviewed Dr. Cowan's Essay on the Vital Statistics of Glasgow, and gave an abstract showing the increase of disease and mortality in that great city*. After mentioning some of the methods by which the state of Glasgow might be improved—such as building hospitals, forming drains, and teaching the poor to clean and whitewash their houses—we added, “the evils are so enormous that one might imagine there

* MEDICAL GAZETTE, March 2, 1839.

must be a slowness to subscribe in the good town of Glasgow."

This conjecture is unfortunately confirmed by the "Fourth Annual Report of the Glasgow University Lying-in Hospital and Dispensary," which has just reached us. In a town where fever and small-pox multiply their ravages, until the number attacked by the former disease in 1837 is estimated by Dr. Cowan at 21,800; where the constant influx of Irish indigence adds to the number of those whom disease finds helpless and destitute; in a town, finally, where commerce enriches not few and far between, but hundreds and thousands; we should have imagined that an institution like that whose Report is before us would have been fostered by the warmest patronage, and that merchant and manufacturer would have hastened to alleviate those ills of which they were in some measure the cause. Instead of this, the subscriptions and donations for the year 1837 amounted to £86. 15s. 3d.; and even this ridiculously minute sum was greater than the preceding year. Adding fifteen guineas from the College of Glasgow, ten pounds from the City, the fees of students, amounting to £44. 8s., and two other small items, the whole income was £165. 14s. 3d. One might be inclined at first to suppose that this lamentable deficiency of subscriptions arose from the institution being destitute of distinguished patrons, and that it had usurped the title of "University," though in reality only the obscure Charity of a few second-rate traders. The fact is, nevertheless, that among the office-bearers we find the Lord Provost, the Sheriff of the County, the Principal of the University, the Rev. Dr. Brown from the Clergy, and the Dean of Guild. How with this scanty sum the Directors contrived to treat 125 cases in the hospital, and 297 at home, besides 1837 Dispensary patients, is really a difficult problem;

but we fear that the line which separates economy from parsimony must often have been overpassed.

The Report gives a melancholy picture of the state of the poor of Glasgow. The streets in which they live are ill paved and badly lighted; many, indeed, being wholly without lamps. These dwellings are often "quite ruinous, unfit for lodging human beings, and such as would be condemned by any board of inspectors." The authors of the Report suggest the establishment of a board of this kind, and also of a building society, to supply the poor with better rooms at more moderate rents. Both these suggestions are worthy of attention; but while the former could not be carried into effect without an Act of Parliament, the latter might be realized by any association of philanthropists, or, indeed, by a single one. Spirit drinking is making frightful advances among the lower classes of both sexes. The Reporters advise that Temperance Societies should open small shops where the poor might obtain hot broth, tea, coffee, chocolate, &c. for a trifle; they also wish for an increase of the duty on malt* and spirits, and the punishment of drunkenness; and they justly suppose that the want of amusements is an exciting cause of intemperance. Unfortunately, the passion of the day is too exclusively a dry utilitarianism, and innocent entertainments for the common people are neglected, or scouted. The Reporters do not mention the establishment of public baths at a low rate, though this is one of the most crying wants in every part of these islands. The Report is sensible as well as benevolent; but we acknowledge that the amazing tenuity of the hospital and dispensary income disheartens us, and makes us apprehend that if Glasgow is to be much improved, it must be by assessment rather than subscription.

* We do not agree with them on this point, as we have no wish to add to the price of beer.

ENGLISH PRACTITIONERS AT WIESBADEN.

IN our number of August 17th, we observed that if the English at Wiesbaden would but manifest their natural predilection for British practitioners with sufficient firmness, the government of Nassau would allow them to practise, in spite of the letter of the law. This prediction has been fulfilled, as appears by the following letter in the *Times* of September 5th.

To the Editor of the Times.

Sir,—An anonymous letter appeared in your paper some days ago, extracted from *Galvani's Messenger*, which stated that Dr. Downie and myself were prevented from practising during the season among our countrymen in Wiesbaden. It may, therefore, interest some of your readers to know, that one of the last official acts of the late lamented Duke was the removal of the restrictions against English medical men, as will appear in the following answer to an address presented to his Serene Highness from a numerous meeting of English residents and visitors, Sir David Cunynghame, Bart., in the chair:—

Your obedient servant,
EDWIN LEE.

"Colonel Sir David Cunynghame, Bart, and the other English gentlemen who signed the address sent to his Serene Highness the Duke of Nassau, declaiming against the police regulations forbidding two English medical gentlemen to practise medicine, are hereby informed that his Serene Highness has been pleased to order, that although it is by the police regulations forbidden foreign medical persons to practise without being previously examined, the said gentlemen and all other English residents and visitors shall not in future be prevented from placing themselves under the care and availing themselves of the professional assistance of medical persons from their own country.

"Wiesbaden, Aug. 19th, 1839.

"Government-office,
"By order of the Minister of State."

UNIVERSITY OF GLASGOW.

REGULATIONS REGARDING DEGREES IN
MEDICINE AND SURGERY, AGREED ON
29TH APRIL, 1839.

Medicine.

1. EVERY Candidate for a Medical Degree must lodge, with the Clerk of Senate, a Certificate of moral character, by two respectable persons, with evidence

that he has already attained the age of twenty one.

2. He must produce evidence of having attended, for four years, some University where medicine is regularly taught, or the medical lectures delivered in London or Dublin. In each year he must have attended, at least, two courses of lectures six months' duration (except in the cases hereinafter specified), and one year of the four, must be spent at the University of Glasgow. If one year only, then attendance must have been given on, at least, three courses of lectures delivered there, two of them being of six months' duration.

3. He must produce certificates of having attended one or more courses of lectures on the following subjects; each course, with the exception of Forensic Medicine and Botany, being of six months' duration: if of less extent, then two courses will be deemed equivalent to one of six months.

Anatomy and Physiology.

Chemistry.

The Theory or Institutes of Medicine.

Practice of Medicine,

Materia Medica and Pharmacy.

Midwifery.

Surgery.

Forensic Medicine, not less than three months.

Botany not less than three months.

Anatomical Dissections, six months.

A General Hospital, two years,—

said hospital containing eighty beds at least, and in which the student must spend at least one half of the period of his attendance in the physicians' wards.

Neither hospital attendance, nor anatomical dissections, shall be considered as equivalent to a course of lectures.

4. Each candidate for a medical degree must announce his intention, and lodge with the clerk of Senate the above testimonials, together with an English essay on some medical subject chosen by himself, two months before the time of graduation; that is, on or before the 1st of March or the 10th of June, yearly, otherwise he cannot be admitted for examination till the following term. All tickets of attendance lodged by candidates shall be certified, not excepting those of the current session; but the certified botanical tickets of the current session shall not be received until the 1st of April. No student shall be entered in any medical class later than the 1st of December, without the special permission of the Senate.

And it shall be strictly required of every candidate for graduation, that he produce evidence of his name having been enrolled in the Library Book on or before

that day, with an express certificate of his regular attendance, by each professor on whose lectures he attends.

Note.—In order, further, to insure attendance, all students of medicine must inscribe their names, once a fortnight, in a register kept for the purpose, stating the lectures, &c., which they attend.

5. Every candidate shall undergo full examinations on all the subjects included in the curriculum, and shall further, give satisfactory evidence that he possesses a competent knowledge of the Latin language.

Surgery.

1. The regulations respecting certificates of age and moral character, are the same as those under the head of Degrees in Medicine.

2. Candidates for the degree of Master of Surgery shall produce evidence that they have attended medical lectures in one or other of the Universities or Schools already specified, for four years, during which they must have attended one or more courses on the following subjects; the extent of each course, with the exception of Forensic Medicine, being six months, or the equivalent two courses of a shorter duration. The candidate must have attended not less than three courses of medical lectures in the University of Glasgow. In each year of his study he shall have attended, at least, two or more courses of lectures of six months duration.

Anatomy.

Surgery.

Chemistry.

Theory or Institutes of Medicine.

Practice of Medicine.

Midwifery.

Materia Medica and Pharmacy.

Forensic Medicine.

Anatomical Dissections, six months.

A General Hospital two years,—

in which the student must attend one-half of the prescribed period in the surgical wards, and the other half in the medical.

3. The regulations as to lodging certificates of attendance, with an essay, in English, and as to the candidate's knowledge of Latin, are the same as under the head Medical Degrees, only the essay is to be on a surgical subject.

The days of graduation are the last Wednesday of April, and the first Wednesday of August.

The fee to Library, &c. for the degree of M.D. is..... £15 0 0

The duty on stamp for ditto ..10 3 0

25 3 0

The fee for the degree of Chirurgiæ Magister is10 10 0

N. B.—These regulations are applicable to all candidates for degrees, who enter the University of Glasgow for the first time, in the session 1839-40, although they may have commenced their medical studies earlier elsewhere. But those who have attended medical classes there previous to that session, are to be admitted to examination, according to the regulations which existed at the time when they began to study medicine. The former regulation, requiring the study of Botany to have been prosecuted in a University, is still applicable to those candidates who had commenced their medical studies previous to 1839.

EQUIVOCAL GENERATION.

SCHULTZE and Schwann have examined some of the phenomena of equivocal generation. The former filled a glass vessel with distilled water containing various organic substances, and closed it with a cork, through which two bent glass tubes were passed; the water was then boiled, and while the vapour was rising in the tubes, a Liebig's apparatus was attached to each; that of one containing some concentrated sulphuric acid, and that of the other some concentrated solution of potash. The air could thus be easily renewed, but whatever germs there were in it would be destroyed by having to pass through the concentrated acid. The whole apparatus was then placed at a brightly lighted window, and by its side an open vessel containing an infusion of the same organic substances: infusoria were generated in the latter, but in the former not a trace of them could be discovered.

The result of Schwann's experiments is the following:—

If a closed glass sphere, filled with atmospheric air, and containing besides a small quantity of infusion of muscular tissue, be exposed to the boiling heat of water, after several months there will be observed neither the formation of infusoria, nor any putrefaction. And it will be just the same though the air be renewed, if that air which is introduced be previously exposed to a high temperature.—Müller's *Archiv Jahresbericht*, clxxvi.

[These experiments seem to settle this long disputed question. They are the first in which every possible entrance for living ova dispersed in the atmosphere has been closed, and in a case of this kind it is evident that a single negative result is worth many positive.]

VARICOSE CAPILLARIES.

To the Editor of the Medical Gazette.

SIR,

IN the leading article of the *MEDICAL GAZETTE* of last week, you remark that an observer not previously acquainted with the varicose condition of the capillaries, could not at once have distinguished it in Mr. Kiernan's preparation of intestine, nor in the diseased ducts of the rabbit's liver.

In reference to this remark, I beg to say, that so obvious is the peculiar condition of the capillaries in question, that he who runs may see. Mr. Kiernan did me the favour to show me the preparation under the microscope, at a time when I was not at all prepared for any morbid state of the capillaries, and before I had been made acquainted with the recent attempt to wrest from him the merit of his discovery. I can only say, that I had not been one minute looking at the preparation through the microscope, when I exclaimed, "Why, here are varicose capillaries!"

But the term "varicose" does not, in my mind, adequately express the real condition of the capillaries in this preparation. These vessels possess other characters equally obvious, and not less interesting in a physiological point of view; upon these, I presume, Mr. Kiernan did not dilate, otherwise the public would have, ere this, been made acquainted with his description through the same channel by which their varicose condition was so hastily made known. It is to be hoped that now Mr. Kiernan will be allowed to describe the whole of his valuable observations for himself; the scientific public have sufficient guarantee that no hasty observations, nor crude generalizations, will be put forth by the anatomist, who unravelled with the most complete success the minute structure of the most complicated gland in the body.

I am, sir,

Your obedient servant,

R. B. TODD.

LECTURES
ON THE
CHEMICAL HISTORY, PATHOLOGY, AND
MEDICAL TREATMENT
OF
CALCULUS,
AND THE VARIOUS DISORDERS OF THE
URINARY SYSTEM.
By DR. VENABLES.

Gonorrhœa virulenta.—Perhaps it may be supposed that the consideration of this disease does not properly come within the scope contemplated in these lectures. The effects, however, are sometimes so serious, and urinary affections can be so frequently traced to gonorrhœa as one of their remote or exciting causes, that the nature and effects of this affection are not so wholly irrelevant as to render it an illegitimate object for special consideration.

Gonorrhœa may be defined a specific inflammation of the lining membrane of the urethra in the male, and of the vagina in the female, attended with a specific infectious purulent discharge. The ancients, though erroneously, supposed gonorrhœa to be only a preternatural discharge of semen, whence its name*. It mostly arises from impure connection, and hence it is necessary to define it a *specific* inflammation, with *specific* discharge of an *infectious* nature. By an infectious discharge is to be understood a discharge possessing the properties of exciting, in a susceptible surface, a disease precisely similar to that of which itself is the offspring, or forms an essential part. Inflammation may be excited in the urethra or vagina by various irritations, and purulent discharges may be the result; but

such inflammations and purulent discharges want the specific character and the infectious properties which distinguish gonorrhœa.

The first symptoms of gonorrhœa generally appear within the first four days after impure connection. In very susceptible persons it will frequently appear within the first twelve hours; but when the susceptibility is very obtuse, a week, a fortnight, or three weeks, or even more, may elapse before the symptoms develop themselves. It also commences variously: in some a mere sensation of heat, or slight smarting, on making water, and which continues for a period varying from a few seconds to several minutes, ushers in the disease. In others there is a sensation of itching more than of smarting, and the first urine comes out in a gush, for in consequence of slight agglutination of the urethra, the urine cannot flow immediately, as when the passage is pervious; hence the patient feels that the urine is at first slightly impeded, the penis swells, and at last the agglutination gives way, and the urine gushes forth. The first effect is irritation of the lining membrane, in consequence of which it not only secretes mucus more abundantly, but this mucus becomes slightly deranged in its properties. The patient's attention, probably, is first attracted by observing that the linen presents the appearance of small spots, stained as if with the white of egg; but no fluid of this kind can be forced out from the urethra, but the urethra is found glued together at or near its orifice by a glutinous exudation of this sort. When these symptoms have continued for a time, longer or shorter, according to circumstances, the whole body of the penis becomes swollen, and puts on a highly inflamed and irritable appearance. The discharge, which had at first the appearance of a whitish glutinous matter, and secreted in but small quantity, now has be-

* *Γονη, semen; πῦρ, fluo.*

come copious, of a yellowish green purulent appearance, and, indeed, possessing all the characters of true pus, and which you may observe exemplified in this instance. In some the discharge is scanty and thin, and then assumes less of a purulent character, although equally virulent in its nature. In others, again, the pus is thick, yellow, and discharged in very large quantity.

During the disease, especially if the inflammatory symptoms run high, in irritable habits a degree of sympathetic fever prevails proportioned to the intensity of the irritability and the activity of the inflammation. But in almost all cases there is some degree of constitutional disturbance, even though it do not amount to what may be strictly termed fever: such are, frequency of pulse, always with some degree of hardness, slight elevation of temperature, dry skin, and tendency to thirst.

The symptomatic fever is often associated with local derangements in other parts. Thus we sometimes see inflammation of the absorbents of the penis, inflammation and swelling of the inguinal glands, giving rise to what is named sympathetic bubo, and the testicle very often becomes swelled and inflamed as in *hernia humoralis*. In many instances ulterior and much severer consequences ensue, and various other important organs become involved: thus the irritation and inflammation may spread to the prostate, bladder, ureters, and even the kidneys. When the inflammation in the urethra is very severe, and spreads to the contiguous parts, those in contiguity become affected: hence we may have tenesmus, with various other affections of the rectum.

When the kidneys become involved various affections of the back and spine take place, according to the peculiar predispositions of the patient. One consequence of the state of the urethra is a thickening of the lining membrane, and consequently a corresponding diminution in the stream of the urine, owing to the partial obliteration, or rather reduction of the size, of the passage. This thickening of the mucous lining often not only becomes permanent, but increasing, ultimately lays the foundation of future organic stricture. The stream of urine is sometimes twisted, forked, or split into two, as in organic stricture. In some cases the bladder becomes so extremely irritable that the patient is harassed with an incessant and irresistible desire of passing the urine. Hence he is called upon almost every five minutes, yet but a spoonful or two of urine is voided, which produces the most intolerable pain.

Chordee.—This is another very frequent and extremely painful consequence of go-

norrhœa. It arises from the deposition of coagulable lymph in the cells of the corpora cavernosa of the penis, which being consequently distended, when erection takes place the corpus spongiosum does not receive a corresponding distension, and hence a curvature of the penis, with a most intense pain, ensues. The primary and essential morbid action, it is said, is confined to the extremity of the urethra, from its orifice to the distance of an inch backwards; and the discharge proceeds from the lacunæ in the mucous lining*.

In females the discharge takes place from the vagina, nymphæ, &c. In them the symptoms are much less intense and much milder, but in many cases the urethra becomes affected, and then the symptoms are much more severe. But much will depend upon the peculiar habit and irritability of constitution of the individual.

Causes.—The exciting cause of gonorrhœa is impure contact; at least in the greatest majority of instances. That this is, however, invariably the case, would be a very unphilosophical assumption, as it would involve the impossibility of generation, and consequently that gonorrhœa must have been coeval with the origin of the human race. This is too great an absurdity to be entertained even for a moment. The circumstances, however, which operate effectually in the generation of gonorrhœa have not been thoroughly investigated, and are not therefore perfectly understood. A mere inflammatory action of the lining membrane of the urethra, even attended with a purulent discharge, is not sufficient for the production of the disease; there is something peculiar or specific in the nature of the inflammation, by which a peculiar virus, possessed of specific properties, is generated. It would be a very useful investigation to determine the circumstances which originate gonorrhœa: it is very probable that it has its origin with the female sex, and that a promiscuous intercourse is one of the essential, and perhaps one of the most effectual causes, which operate in engendering gonorrhœa.

Diagnosis.—It perhaps may appear superfluous to discuss a subject such as this head embraces; but I would remind you of the too ready admission of every sore about the genital organs being venereal, and the very baneful and destructive practice to which, some years since, it

* This includes the period from admission into the hospital to discharge and return to duty. The average period before the disappearance of all symptoms of gonorrhœa, were from about four to six days, but two or three days are allowed to establish more securely the convalescence.

gave rise. Every little sore, every herpetic eruption appearing on the glans, or about the prepuce, were formerly pronounced venereal, and in many the constitution ruined by the poisonous agency of mercury. Upon these occasions, too, the influence of the mineral upon the supposed diseases for the cure of which it was administered, were hardly ever taken into account, but each particular form had its quantum of mercury determined by weight, and so many ounces were required for a chancre; so many more for a bubo; and so many for the individual forms of secondary symptoms. Many indeed have had reason to lament these theories, and many have they brought to a premature end. There are many eruptions which attack the genitals of both male and female, and which closely resemble the primary forms of syphilis, but which really have no other analogy or alliance with this disease than the mere resemblance. Mistakes, however, in this case, are not so serious in relation to the system as those we have just been considering; but still a correct diagnosis is often matter of great moment, as involving family considerations of great importance, and which are very often referred to the practitioner for his consideration; and his judgment decides the question. It should therefore be recollected that females even the most pure and virtuous are subject not only to an increase of the mucous secretion of the vagina and parts in the neighbourhood, but that the secretion itself becomes altered in its properties, and acquires morbid qualities. Leucorrhœa is a very common disorder in females, and in many cases the discharge assumes a completely purulent appearance. Sometimes this is accompanied with great irritation of the urinary passages, and the general and individual symptoms sometimes so closely resemble those of gonorrhœa, that they can hardly, if at all, be distinguished. It is necessary therefore, in such cases, involving the character, and perhaps the future respectability and happiness of the parties, to be extremely cautious in your conduct, and guarded in your opinions.

But there are cases of still greater difficulty, and that in some of the diseases of the above character attacking females; the secretion becomes not only diseased in appearance, but absolutely acquires acrid or irritating properties, from which, in married women, the husband suffers, and very serious and injurious suspicions are excited. I have seen several instances of this sort, and, indeed, they are often very difficult to deal with. In those which I have seen, there was no purulent dis-

charge from the urethra in the male, although there was a smarting on making water, and sometimes a slight mucous discharge staining the linen, described as occurring at the very commencement of gonorrhœa. In gonorrhœa there is often a sort of acrimonious secretion from the lining of the prepuce and glans, and in some it looks like white detached patches; but I have seen no such appearance in the spurious or pseudo gonorrhœa. In true gonorrhœa the discharge invariably ultimately becomes purulent. If, therefore, the inflammation run high, and all the other phenomena of gonorrhœa attend, and that the history and general circumstances of the case involve no doubtful circumstances, then we can have little hesitation in deciding or pronouncing an opinion. But if the circumstances be mysterious, and involve questions of serious family moment, for myself I would rather err upon the safe side. Should it afterwards turn out that you were wrong, your mistake will be attributed to a good feeling, and will not lower you in the estimation of either party.

Treatment.—Two modes of treatment have been adopted for the cure of gonorrhœa—the antiphlogistic, and the stimulant and astringent. The first, unless of late, has not been very extensively practised; and what has been termed the antiphlogistic, in activity falls very far short of that which the term comprehends in relation to other acute inflammatory diseases. Bleeding has not been very generally practised or recommended in gonorrhœa; and yet I do not see why, in inflammation liable to involve the most important of the urinary organs, we should not bleed as boldly as in similar inflammations, occupying other and perhaps less important parts. One of the first means, then, which present to us is venesection, proportioned and repeated according to the intensity of the symptoms, and the violence and extent of the inflammatory action. With venesection we may employ leeches to the perineum, or along the body of the penis underneath, more especially in the neighbourhood of those parts of the urethra which evince most sensibility on passing the urine, or on slight compression. Still further to moderate inflammation and allay fever, a relaxed state of system is necessary. Many for this purpose prefer the saline purgatives; but if the inflammation be very severe, and that the irritation in the urinary system be very great, the salines will to a certain extent aggravate the distress. In such cases castor oil, or some other purgative, as infusion of senna, which do not

excite the urinary apparatus, will be preferable, till the violence of the inflammatory action has been reduced.

We know that, in the highly sensitive state of the urethra, a stimulant which, in its ordinary condition, produces no sensible effect, will now produce almost intolerable pain, and a degree of suffering almost beyond endurance: hence the urine of its usual acrimony and natural saline impregnation, produces such intense pain, and sometimes lasting for a long time, by which all inflammatory symptoms are much aggravated. We must therefore endeavour to render the urine as mild as possible. Nothing contributes more to this object than dilution. The saline and consequently the stimulating principles are, if not absolutely, at least relatively reduced, and persons in the most severe forms of gonorrhœa will pass diluted urine of specific gravity 1001 to 1005, with ease, who could not pass it of specific gravity 1010 without excruciating pain. The choice of the diluent, provided it be mild and bland, is an object of less moment, perhaps, than it would at first sight appear. Pure water, that is, without any saline impregnation, is the most effectual diluent, for the virtues of all essentially depend upon the proportion of watery fluid. But as, perhaps, it would be difficult to persuade many persons to swallow the quantity required to prove beneficial, it is usual to medicate it in some way or other. Thus boiled water in which toasted bread has been soaked, or in which linseed has been infused, or acacia dissolved, will be taken to the requisite extent, when mere water would be refused. The practitioner, of course, when he finds his patient refractory, will solicit him by varying the medication, and substituting barley-water, milk, and such like, when the patient cloy of the others.

While we thus endeavour to diminish the acrimony of the urine by plentiful dilution, we must also attempt to reduce the irritability of the urinary organs. This is best done by sedatives, as muriate of morphia, hyoseyamus, or hydrocyanic acid. When morphia agrees, it is the most effectual sedative. The sedative may be given in solution, as in the almond emulsion, which, perhaps, is the pleasantest vehicle. The narcotic should be given in sufficient doses, and until it produce the required effect. At this period, also, especially after the requisite depletion, I have found colchicum act as a urinary sedative, and, indeed, produce the most beneficial effects*.

* I have found the acetic extract of colchicum, given with the compound powder of ipecacuanha,

If we find that, notwithstanding our endeavours to promote and dilute the secretion of urine, our attempts fail, we may then give some mild diuretic, such as juniper with nitric ether*, which will usually have the effect without over-stimulating.

It has been already observed that the irritation of the urethra and bladder is often extended to the rectum, producing a troublesome tenesmus, and various other kinds of uneasiness. In such cases anodyne and emollient enemata†, with the warm bath, give the most effectual relief. To reduce the heat, swelling, and external inflammation of the penis, it should be enveloped in a single rag of linen kept constantly moist and cool by means of a solution of acetate of lead in which a lump of ice may be kept constantly floating.

From very extensive trials, I can pronounce the above the most effectual as well as the safest mode of treatment. Under it I have known the discharge entirely cease without any of the severe consequences which frequently supervene on the stimulant and astringent treatment. If, however, the discharge should not cease, or that any thing like gleet succeed, which, however, hardly ever happens except in those who have suffered severely from repeated attacks of gonorrhœa, then we may give the copaiba with nitrous ether. If, after all, the discharge prove obstinate, we may have recourse to the means next detailed.

Stimulating and astringent treatment.—The next mode is that which may be named the stimulating and astringent. It consists in administering urinary stimulants internally, and astringent injections externally. Perhaps there are but few, who, if the inflammatory symptoms ran high, would adopt this plan immediately at the beginning. Still I have known some who maintain that these stimulants not only arrest the discharge, but completely subdue the inflammatory action. That anomalies of this description may occasionally occur in physis, as in all other circum-

or hydrochlorate of morphia and ipecacuanha, as mentioned in a former lecture, in the form of pill, a very effectual preparation.

* R. Infus. Junip. dr. x.; Spir. ejusdem C. dr. j.; Tinct. Opil. min. x. M. ft. haustus bis terve in die sumendus, ad urinam promovendum.

The infusion of pareira, or of buchu, with some of the extract of pareira, may be added occasionally with advantage to any of these.

† R. Decoct. Amyli, oz. x.—xij.; Tinct. Opil, dr. j.; Ext. Hyoseyami, gr. x. Misce intime ut fiat enema tepidum intra rectum injiciendum.

stances, no one can deny; but that they form the rule instead of the exception, is a conclusion no way warranted, but on the contrary directly at variance with the facts.

The first treatment consists in clearing out the bowels, by sulphate of magnesia in sufficient doses. Some give the sulphate in two or three drachm doses, adding to each dose a few grains of nitrate of potass. Some select balsam of copaiba, immediately after; and give it very often in nauseous doses, even to excite vomiting. Camphor mixture and nitrous ether render it more agreeable to the stomach. But the most celebrated of these remedies are the berries of the piper cubeba, or cubeb, as it is more commonly called. Of this, very large doses, two or three drachms for instance, or even more, of the powdered berries, are given two, three, or four times a day. The powder is given in water and in milk, which, according to some, is the best vehicle. Such is the reputation of cubeb for curing gonorrhœa, that many when attacked with this affection take cubeb in very large doses upon their own sole responsibility. The effects are said to be the immediate, almost the instantaneous cure of the disease. But such should be reminded that the suppression of the discharge is not the radical cure of the disease. I have seen many who have seriously injured their health, not only through the means often necessary to relieve the excitement thus induced, but the irritation often lays the foundation of severe urinary affections, to break out at some future, though perhaps remote period.

The external local means consist in the injection of stimulating or astringent solutions into the urethra in the male, and the vagina in the female. The metallic salts are usually selected for this purpose, and those in most repute are the sulphate and acetate of zinc, acetate of lead, sulphate of copper, and nitrate of silver. The strength varies from one to three grains to the ounce, and distilled water should always be chosen for their solution. If an injection be required at all, I myself should prefer either the acetate of zinc or the nitrate of silver. The acetate of zinc is readily formed, by decomposing sulphate of zinc by acetate of lead, in the proportions of about 30 parts of the former to 47 of the latter. These, if previously dissolved separately in the requisite quantity of distilled water, and filtered* will give

* When the solutions of these two salts are mixed together double decomposition ensues, and a soluble acetate of zinc remains in solution, while the sulphate of lead being insoluble precipitates, which is separated by the filtration. Pearson, however, thought that the efficacy of the injection as thus formed depended upon the stimulant action of the insoluble sulphate of lead

as a solution at once fit for use. With respect to the solutions of sulphate of copper, and the acetates of lead, I must confess that I should never use them except as last resources, after the failure of all other methods; and I must confess I should not be very sanguine in my expectations as to their beneficial effects. The most effectual, the least irritating, and in general the most innocent of all the metallic injections in my judgment is the nitrate of silver, and where I found an injection necessary, I should decidedly give the preference to this. From one to two grains of this salt dissolved in an ounce or ounce and a half of distilled water will form a very suitable injection. From two drachms to half an ounce, the latter quantity, perhaps, more suited for women, should be injected into the urethra or vagina, two, three, or four times a day. It is also recommended to prevent the injection passing beyond the neck of the glans, (which is the limit of the disease,) by compressing the penis at this part between the finger and thumb. But we certainly have evidences of a much greater extent. The scalding often is felt at the bulb of the urethra, at the membranous, and even as far down as the prostatic portion. Often too, the inflammatory action extends to the neck of the bladder, and to the mucous lining of the same viscus. The site of strictures too, which mostly result from the inflammation of gonorrhœa, prove that the consequences at least extend much farther than the glandular portion of the urethra. But still perhaps it is not necessary that the injection should be pushed farther than the glandular portions, and no precautions are necessary to secure such limits, for unless special measures be adopted to push the injection farther, it will seldom pass these limits under the ordinary modes of injecting.

When in spite of all these means the discharge continues obstinate, other plans have been recommended—such are, the introduction of a bougie two or three times. This may or may not be medicated; thus, it may be smeared with mercurial ointment, or with the unguentum hydrargyri nitratis. When perfect gleet has been established, tonics, with sea-bathing, &c. added to the above, are the means best adapted for its removal.

upon the lining membrane of the urethra. If such were the case, it would be better to use sulphate of lead mechanically suspended in distilled water. I have tried both salts, the soluble and the insoluble, separately, and the result has been decidedly in favour of the former.

VELPEAU'S CLINICAL LECTURES ON OPHTHALMIA.

By J. HENRY BENNET, B.L. & B.S.
Sorbou.

INFLAMMATORY AFFECTIONS OF THE CORNEA.

Treatment of acute keratitis—continued. —Purgatives: iodine, sulphur, tartar emetic. —Local treatment. Chronic keratitis. —Symptoms, causes, duration, and prognosis. —Treatment.

Purgatives.—Purgatives are much employed in the treatment of keratitis, and are classed among internal irritants; improperly so, in my opinion, as it is by no means certain that they act by irritating the intestines. It is much more probable that they act on the system in general, by the quantity of fluid which the mucous membrane of the intestines secretes under their influence. The purgatives which appear to be most frequently used are castor oil, jalap, scammony, aloes, colocynth &c.: I am, however, at a loss to decide whether theory or experience has induced practitioners to prefer them. I have myself given all these purgatives a fair trial, either alone or combined, and not only am I unable to say whether one merits the preference over another, but I have even some doubts respecting the value of purgatives in general in this affection. They appear to be useful as adjuvants, when combined with blood-letting, but given alone their efficacy is certainly but slight. In all cases, however, in which the tongue is foul, the breath bad, the abdomen distended, they are extremely beneficial. Indeed, purgatives ought, I think, to be considered more as medicinal agents, to be employed against the disordered state of the digestive organs, than as general remedies likely to act on the inflammatory diseases of the eye.

Among the various purgatives which are used, there are two which have attracted great attention—the tincture of colchicum and calomel. The tincture of colchicum has been principally employed in England, in the rheumatic and arthritic forms of ophthalmia; that is, in keratitis and in iritis. I have often tried it, in doses varying from fifteen or twenty drops to a drachm and a half or two drachms daily. The tincture acts as an irritating purgative, but its purgative effects are exceedingly variable. Sometimes a patient is purged with twenty drops, sometimes a drachm produces no effect whatsoever. Generally

speaking, the tincture does not act in doses under a drachm. I now never give less, often more. I believe that it exerts a beneficial influence over the course of the disease, but I have never seen a marked improvement take place from day to day, as some authors assert they have done; and as we have other purgatives the action of which is preferable, I now seldom employ it.

As regards calomel—the panacea of some ophthalmologists for diseases of the eye—I have given it in every possible manner, in doses of six, eight, or ten grains daily, in doses of twenty four or thirty six grains every twenty four hours, divided into fractional doses of two or three grains every hour, combined with opium or with sulphur. In some cases I have administered it so as to produce salivation in the course of three or four days, in others so as only to produce this effect in twelve or fifteen days. The result of all these essays is, that I cannot allow calomel to be as efficacious a remedy as English practitioners represent it to be; I have seldom seen keratitis rapidly modified by its action, and in some cases, although considerable salivation had taken place, the progress of the disease was not arrested. In the greater number of patients to whom I have given calomel, it seemed to produce no effect whatever on the ophthalmia; with some there was slight amelioration, but that amelioration did not seem to me greater than that which the tincture of colchicum and other purgatives generally produce. The efficacy of this remedy has, in my opinion, been much exaggerated; it is in reality much less beneficial in keratitis, and, indeed, in ophthalmia in general, than is generally asserted. I, therefore, only employ it when the disease resists the action of other therapeutical agents, or when the constitution of the patient, or the state of weakness in which he is, from previous loss of blood, will not allow us to have recourse to depletion. I am also cautious in administering it, as, under whatever form mercury is given, its introduction into the system is often attended with disagreeable consequences. It may produce a mercurial stomatitis, or an affection of the mucous membrane of the intestinal canal, which swells, and becomes of a greyish colour; and this affection is rather difficult to cure.

The remedies which are used as alteratives in the treatment of keratitis, are iodine, sulphur, and tartarized antimony.

Tartarized antimony has been much praised in England by Mr. Lawrence and Dr. Mackenzie; they give it according to the method of Rasori, in doses of eight, ten, or twenty grains, in the twenty-four hours. Some practitioners combine it

with sulphur or opium. To form an opinion of this, or indeed of any other therapeutical agent, there are two kinds of data to consult—the facts published by others, and those which our own experience furnishes. When the facts which are brought forward to prove the efficacy of a remedy are carefully examined, it is, in some degree, possible to foresee what will be the result of any essays undertaken to prove how far the assertions made in its favour are correct. In some instances the facts are so striking, that it is impossible not to allow that the remedy is possessed of some efficacy; in others we cannot but question the influence it has had over the course of the disease, when we find, as in the cases published in favour of tartarized antimony, that it had already existed several days before the remedy in question was employed, and that general and local blood-letting, blisters, and setons, were resorted to at the same time. I have myself often tried tartarized antimony, in doses of from four or six to ten or fifteen grains, but do not believe that it exercises any specific action whatever over the disease. It either acts as an irritant on the intestinal canal, or on the system in general, by giving rise to a copious secretion from the surface of the mucous membrane. I think it is as efficacious a remedy as the tincture of colchicum, or purgatives in general, but not more so; and as it occasions continued nausea, which distresses the patient, I now scarcely ever employ it.

With regard to the tincture of iodine, and sulphur, I have not often had recourse to them, and then only when all other means had failed. The results I have obtained are of a very unsatisfactory nature. Sometimes the patients were better, sometimes they were worse; but it would be difficult to say whether the change was to be attributed to time or the remedy. I must say I place very little confidence in their action.

In conclusion, the general treatment of this disease only offers one really efficacious therapeutical agent, and that is, general blood-letting, unless we consider blisters applied over the eyelids as forming part of the general medication. All the other remedies are merely to be looked upon as adjuvants.

Local treatment.—However successful the general treatment of acute keratitis may be, it seldom entirely subdues the inflammation. In most cases, although the intensity of the symptoms may be mitigated, they do not entirely disappear, and it becomes necessary to have recourse to remedies which act directly on the tissue which is affected. Local treatment is not,

however, equally serviceable in every form of keratitis; it is indeed more especially on examining the action of topical applications that you will perceive the utility of the division I adopted when describing the disease. When the deeper layers of the cornea are inflamed, their influence must necessarily be very limited, as they do not remain in contact with the cornea sufficiently long to reach the seat of the affection, either by imbibition, or by endosmosis. Some ophthalmologists have been so much influenced by these considerations as entirely to reject local remedies in the treatment of keratitis. This rejection, however, is not warranted by experience, as even in diffuse interstitial keratitis the application of local remedies is not unfrequently followed by favourable results. In superficial keratitis they are extremely useful, especially when the conjunctiva is inflamed—and you well know that this is nearly always the case—by dissipating the inflammation of the conjunctiva. They also act on the affection of the cornea; this you will at once understand, if you recollect the nature of the vascular communication which exists between the interior and the exterior of the eye. When ulcerations of the cornea exist, more benefit is to be derived from topical applications than any other class of remedies.

Before we commence the examination of the various topical applications which are used in the treatment of keratitis, I must call your attention to a certain number of therapeutical agents which do not, in reality, deserve the name of local remedies, as they are generally applied round the eye or above the orbits; I mean the mercurial and belladonna ointments, the tincture of digitalis, &c. Mercurial ointment has been praised as an external application by those who thought they derived benefit from mercurials used internally. The cutaneous surface of the eyelids, and the integuments which surround the orbit, are rubbed night and morning with a small quantity of the ointment. Thus applied it is often productive of benefit, but it is not, certainly, as efficacious as most authors have asserted. It is now seldom used alone, being generally associated with some preparation of belladonna, digitalis, or opium. These substances are combined with the mercurial ointment, principally with a view to modify the photophobia and epiphora, which form such prominent symptoms in keratitis. It was supposed that these symptoms originated in retinitis, or in the inflammation of the ciliary circle, and by employing belladonna—a substance which acts principally on the nervous system—it was thought that they might be mitigated.

These theoretical ideas are, you well know, erroneous, photophobia and epiphora being generally caused by ulceration of the cornea, consequently the influence of these medicinal agents cannot be very great. The combination of these substances with mercurial ointment is, nevertheless, advantageous when the pain is intense, as is often the case in deep-seated keratitis. The tincture of digitalis may be employed in the same manner, and with the same results.

The most simple topical remedies are emollients, such as linen steeped in cold or warm water, and poultices. The more important are the various collyria and ointments.

In the first stage of keratitis, if the inflammation is very slight, it may possibly be subdued by bathing the eye continually with cold water; but when that period is passed, a compress steeped in warm water, or a light poultice placed between two folds of linen, is more beneficial. Poultices are useful, as emollients, in deep-seated or interstitial keratitis, unattended with ulceration; but in the superficial form of inflammation, or when there is an ulcer, they appear rather to irritate than to do good. It is probable because this remark has not been made, that many practitioners disapprove of them in every case. Ointments are scarcely applicable to keratitis, unless it be to the superficial form when accompanied by conjunctivitis. Owing to the convex form and smooth surface which the cornea presents, they are swept off by the eyelids before they have had time to act on the disease. They are even injurious when the cornea is ulcerated, as they often remain on the ulcerated surface, and, acting as foreign bodies, increase the inflammation. This last remark will also apply to the different dry collyria which are employed, such as calomel, the oxide of bismuth, &c.; they are equally injurious when any ulceration exists. Dry collyria may, however, prove useful in superficial keratitis, if the cornea is entire; in deep-seated keratitis, on the contrary, they can be of little or of no use.

The liquid collyria employed in the treatment of keratitis are nearly the same as those which are used in conjunctivitis. They are, as we have already seen, extremely numerous, but not more than three or four are worth preserving. The nitrate of silver collyrium deserves here, as in the treatment of conjunctivitis, the preference over all others; it is an exceedingly useful remedy in superficial keratitis, and is even still more beneficial when the inflammation is accompanied by ulceration of the cornea. You must not, however, expect its effects to be as rapid as in that affec-

tion; the vitality of the cornea is not as energetic as that of the conjunctiva, and this physiological condition necessarily exercises more or less influence over the affections of which it may become the seat. I shall not enter into any details respecting the composition and the manner of using this collyrium, as I have already spoken at length on the subject when I gave the treatment of conjunctivitis.

The collyria containing the sulphate of zinc*, and the deuto-chloride† of mercury, belong to the same class. They are both useful remedies, but inferior, I think, to the nitrate of silver collyrium. In some cases of chronic ulceration I have, however, known the solution of the sulphate of zinc succeed, when the nitrate of silver collyrium had failed. These preparations are therefore worth retaining, as one may succeed when the other fails. Narcotics constitute another class of topical agents, among which you will find the tincture of belladonna, the concentrated aqueous solution of opium, Rousseau's and Sydenham's tincture of opium. I have repeatedly applied these preparations pure to the eye in acute keratitis, and have found that in five cases out of six the inflammation was exasperated; I therefore look upon them as topics of a very irritating nature, and not at all adapted to the acute stage of the disease. Although I disapprove of them when pure in acute keratitis, they may, I think, be serviceable if more or less diluted. Thus, in some cases of ulcerated keratitis accompanied by intense photophobia and neuralgic pain, I have derived considerable benefit from a collyrium containing fifteen or twenty drops of Sydenham's laudanum to four ounces of rose water, to which I sometimes add four or six grains of acetate of lead, or twenty grains of extract of belladonna.

Such is the treatment of acute keratitis. We have yet to study the chronic form of this disease, and its various complications, which we will do in our next lectures; you will then, I hope, have acquired a full and comprehensive knowledge of the pathology and treatment of the inflammatory affections of the cornea.

Chronic Keratitis.

Chronic keratitis, though generally confounded by authors with other diseases, and but little known or studied before the publication of M. Mirault's interesting essay (*Archiv. Gén. de Méd.* 1834), is, nevertheless, an extremely common disease. In most instances it is merely the consequence

* R. Sulph. Zinc, gr. iv.; Aquæ, oz. i.; Mucil. dr. i. M. ft. collyrium.

† R. Hydrar. Deuto-chlor. gr. $\frac{1}{2}$ ad $\frac{1}{2}$; Aquæ, oz. i. M. ft. collyrium.

of acute inflammation of the cornea, but is not unfrequently met with as a primitive affection.

The anatomical characters of chronic keratitis not being the same when it commences at the centre of the cornea as when it commences at the circumference of that organ, it will be necessary for us to examine them briefly in both forms of the disease.

The instances in which chronic keratitis first manifests itself in the centre of the cornea are not so rare as is generally supposed. Whenever it is occasioned by external injury, this region is nearly always the first affected; and you must be well aware that it sometimes occurs spontaneously in the same part of the cornea, as we have lately had several cases of this nature in our wards. When the inflammation is diffuse, the following are the characters which the cornea presents: its usual transparency gradually diminishes, and it assumes a palish tint, as if it were obscured by a slight mist. Its surface when examined with a lens appears to have lost its polish, and to be covered with small, half opaque specks; but no vessels can be traced in its tissue. This my own experience enables me to advance with certitude, although many observers, and among others M. Mirault, have maintained the contrary opinion. M. Mirault, who, in his thesis, stated that minute vessels might be observed in the cornea in this the first period of chronic keratitis, has, however, since then retracted his assertion. Sometimes these symptoms succeed each other with rapidity; sometimes, on the contrary—and this is more frequently the case—they are slow in manifesting themselves. There is no shedding of tears, and the patient feels little or no pain; but the sight is always more or less disordered—a fact which the nature of the lesion at once explains. The disordered state of the visual functions is, indeed, sometimes the only symptom which informs the patient of the existence of the disease. The suffusion of the cornea, slight at first, gradually increases as the affection advances; and, unless its progress be arrested, the cornea becomes lactescent, or of a deep opaline colour; and flakes of coagulable lymph are deposited between the lamellæ of its tissue. This change in the transparency and texture of the cornea is generally less apparent as we approach the sclerótica. The friction of the eyes against the palpebræ causes pain; and photophobia, as also a certain degree of epiphora, soon declare themselves. When the affection has advanced thus far, the circumference of the cornea, and that part of the sclerótica immediately adjoining,

becoming vascular, it is then impossible to distinguish this form of chronic keratitis from the form which we have yet to examine.

When chronic keratitis commences, as it generally does, at the circumference of the cornea, the principal characters are to be found in the peculiar vascularity of the conjunctiva, the sclerótica, and the cornea. The vascular zone of which I spoke when treating of acute keratitis—and which, as you well know, is formed by the vessels of the conjunctiva, and by those of the sclerótica—exists, but is less regular and less apparent. The conjunctival vessels are superficial, small in number, and irregularly distributed, many of them terminating in the superficial lamellæ of the cornea. Those of the sclerótica, which are given off by the ciliary branches, are deep seated, numerous, run nearly parallel to one another, and, converging as they approach the cornea, are lost in its tissue. Although the cornea thus becomes injected, its transparency is not necessarily impaired; for the small red filaments, which give rise to the vascular appearance it presents, may exist without the slightest effusion of lymph being observed along their course. Mr. Travers says that he has never seen them unaccompanied by slight effusion; but if you observe attentively the patients who enter our wards, you will soon find that the cornea may remain perfectly transparent, though vascular. At a later period, however, coagulable lymph is effused on each side of these vessels; and the opaline streaks, which are thus formed, may, by uniting, entirely obscure the cornea.

You must not, however, suppose that the vascularity is always such as I have just described it. The modifications it presents are extremely numerous, and can with difficulty be accurately described. It is only by attentively studying the disease at the bedside of the patient that you can become familiar with the various forms under which it is observed. Thus the vascularity may occupy a portion of the cornea. When this is the case it assumes a semilunar form, and is either situated at the angles of the eye, where the long ciliary arteries terminate, or at the extremities of the vertical diameter of the cornea, where the short ciliary arteries are distributed. In some cases it is superficial, and is then evidently formed by the anterior ciliary arteries, which anastomose with branches of the muscular and palpebral. Sometimes it is deep-seated and general, and as manifest at the centre as at the circumference.

When the vascularity is circumscribed—and this is principally observed after acute keratitis with ulceration—that

part of the cornea which is affected may either remain transparent, or assume a whitish or greyish colour. It may also be covered with small granulations, or there may be a thickening of the conjunctiva. This thickening of the conjunctiva differs from pterygium by its irregular termination, and especially by its adherence to the cornea underneath, which is also more or less vascular.

When the vascularity is superficial, the entire cornea becomes covered with small granulations. Examined with a lens, it appears as if it had been strewn with sand. The vessels which appear on the surface interlace as they arrive at the centre, and form a network, which gives the cornea the appearance of a mucous membrane. It is to this form of the disease, when carried to its greatest height, that authors have given the name of pannus, from the fancied resemblance which there exists between the cornea and a piece of red cloth. It seems as if a soft, thin, red, fungous veil had been applied over the anterior surface of the eye. The cornea, however, still retains some degree of transparency between the principal vascular divisions, so that the patients continue to distinguish large objects, although they are not able to discern with precision their form.

When the vascularity is diffuse, general, deep-seated, and interstitial, the cornea retains, during a longer period, its characteristic properties. The vessels being less interlaced do not so soon modify its transparency, and the granulations of its surface are much longer before they become so developed as to impede the passage of light into the eye. The cornea resembles a mirror, crossed in various directions by small vascular filaments, the volume of which seems rather to increase than to diminish as they recede from the conjunctiva. It is before they disseminate in the tissue of the cornea that the vessels of the conjunctiva and those of the sclerótica anastomose. Between the ramifications of these vessels may be seen streaks, or patches of coagulable lymph, which give the cornea a singular appearance. The pupil always remains clear.

This form of chronic keratitis is nearly always combined with the superficial form. It is impossible to assign a limit to its duration, such is the tenacity with which it resists every plan of treatment.

If in addition to these characters, you bear in mind, that in all cases of chronic keratitis vision is more or less impaired, you will be able at once to recognise the disease, whenever it presents itself to your notice.

Causes.—The causes of chronic keratitis

being the same as those of acute keratitis, acting either with less intensity, or on less irritable subjects, it would be useless for me again to enumerate them. Among these causes, however, there is one which I cannot pass over, as little attention has been paid to it by surgical writers; I allude to chronic granular blepharitis. I have, in several instances, seen the affection of the cornea gradually developed under the influence of this cause—a fact which the contact of the membrane with the diseased eyelid easily explains. In one case, in which the granular state of the palpebræ had existed for three months, the keratitis corresponded perfectly with the diseased portion of the inner surface of the eyelids, diminishing and increasing, as the granular blepharitis diminished or increased. In another case the relation between cause and effect was still more evident. The patient, when he entered my ward, had granular blepharitis of the temporal half of both eyelids; before long he was attacked with keratitis, but on the temporal half of the cornea only.

Duration and prognosis.—It is altogether impossible to assign a limit to the duration of this disease. It is one of those affections in which the hopes of the medical attendant, as well of those of his patient, are repeatedly raised and repeatedly disappointed. The symptoms often appear to give way for a few days, when suddenly, in the course of a night, the disease regains the ground it has lost. Even when the treatment employed has proved successful, and the inflammation appears subdued, a relapse is of exceedingly frequent occurrence. Abandoned to its own course, the duration of chronic keratitis is indefinite; it often remains many months in the same state, and may at last terminate by entirely disorganizing the cornea. Suppuration of the whole eyeball, or even of the cornea, seldom, however, takes place. That form of inflammation which commences by the centre of the cornea is the mildest; yet it often gives rise to specks which impair the sight of the patient more or less, according to the situation which they occupy. In the order of their importance, I may next name partial keratitis, and then the superficial form of the disease. When the circumference of the cornea only is vascularized, the inflammation often gives way, but when the vascularity is general, deep-seated, and accompanied by the white streaks I have already described, little or no hope of effecting a cure can be entertained.

Treatment.—Chronic keratitis, when it has existed for a considerable length of time, and has invaded the entire cornea, is one of those diseases against which all the

therapeutical agents we can employ are powerless, and when it does give way, the cure ought sooner to be attributed to nature than to art. It is in vain that you employ the powders, the ointments, the solutions, the collyria, which are often successful in the acute form of the disease—they appear to make no impression. Blisters over the eyelids, which one would suppose likely to prove beneficial, seem to have lost their efficacy. Blood-letting, purgatives, and mercurials, are not more successful agents, and annular cauterization with the nitrate of silver, lauded by some practitioners, has been as ineffective, in my hands, as all other remedies.

Some surgeons, seeing how difficult it is to overcome the inflammation, have proposed the excision of that portion of the conjunctiva which surrounds the cornea, with a view to prevent the afflux of blood to the diseased membrane. If, however, you call to mind what I have said respecting the distribution of the vessels of the eye, you will perceive at once that the operation is not calculated to accomplish the end proposed. By excising the conjunctival vessels which ramify on the superficial lamellæ of the cornea only, you destroy but one of the sources from which that membrane is supplied with blood; the ciliary arteries, which furnish the ramifications seen in the tissue of the cornea, remaining intact. As might, therefore, be easily anticipated, the result of the operation is, generally speaking, far from favourable. I have tried it in many instances, but without success. Among other cases I remember that of a man who was in my wards some few years ago. I tried purgatives, mercurials, cauteries on the temples, blisters over the eyelids, and every topical application that can be thought of, yet he left me nearly in the same state as when he entered the hospital. Some time after, the circular incision of the conjunctiva was resorted to in another hospital, and the case was published in the medical journals as successful. A month after this, however, he was again in my wards, exactly in the same state as when he left me.

Fortunately, the cases we are called upon to treat are not all of this nature. They may be recent, and then often yield to proper treatment. If the tissue of the cornea itself is inflamed, general measures are indicated. In such cases I generally proceed in the following manner:—I begin by bleeding from the arm, regulating the quantity of blood abstracted by the intensity of the inflammation, and the constitution of the subject; the following day I give a purgative; the fourth day I cup the patient on both temples, and on the sixth day I recommence the same

course of treatment, modifying it as circumstances may direct. Cauteries on the temples, so often employed by Mr. Lawrence, and mercurial frictions, may also be employed. By a treatment thus directed, I have often succeeded, when local measures had proved altogether ineffectual. Collyria are, generally speaking, of little or no use in this form of the disease.

When the inflammation lies principally, or entirely, in the superficial layers of the cornea, the treatment is different, topical remedies being then most likely to prove beneficial. Calomel, bismuth, laudanum, and the various resolute collyria, may be employed alternately. The solution of the nitrate of silver, prepared according to the formula which I have given you, more especially deserves the notice of practitioners. It has often been of great service to me when other remedies have failed to produce any effect. Excision of the conjunctiva is likely to prove successful in this form of the disease, unless, indeed, the inflammation also occupy the deeper seated lamellæ of the cornea; the superficial vascularity of the inflamed membrane being supplied, as you well know, by the vessels of the conjunctiva.

It is generally considered necessary in keratitis, and indeed in nearly all other ocular inflammations, to keep the eyes covered, and to place the patient in a room from which light is more or less excluded. These precepts are, however, founded on erroneous views, and are, I am convinced, more calculated to do harm than good. I do not mean to say that, when the eyes are inflamed, they should be exposed to the open air, or to a strong light without any protection, for this would be falling into the other extreme; but that a middle course may be, and ought to be, adopted. When a portion of the conjunctiva has been excised, the measures which I now condemn must be resorted to, with a view to prevent, if possible, the inflammation and suppuration of the wound that has been made. I would here mention, that the loss of substance which follows the circular excision of a portion of the conjunctiva is sometimes attended with disagreeable consequences. In one case, in which the operation had been performed, the formation of the cicatrix drew down the palpebral conjunctiva, giving rise to ectropium of the eyelid. In another case in which the inflammation of the cornea appeared to be kept up principally by the vessels of the conjunctiva, excision of a portion of that membrane was followed by suppuration of the cornea, and the total loss of the eye; it would seem as if the nourishment of the cornea had been supplied by the conjunctival vessels alone.

CLINICAL REPORTS
OF
DIFFICULT CASES IN MIDWIFERY.

By ROBERT LEE, M.D., F.R.S.

Physician to the British Lying-in Hospital, and
Lecturer on Midwifery at St. George's
Hospital.

[Continued from p. 877.]

FOURTH REPORT—concluded.

*Forty two Cases of Difficult Labour, in
which the Forceps was applied.*

CASE CI.—On the 20th October, 1832, I was called to a patient in the lying-in ward of the St. Marylebone Infirmary, who had been in labour with her first child upwards of thirty hours, and it was reported that the head had made little progress for twenty hours. The occiput was to the right ischium, and the left ear was immediately behind the symphysis pubis. The other ear could not be felt. After dilating the external parts, the blades of the forceps were easily applied and locked, and the head extracted without much force. The child was alive, and had sustained no injury.

CASE CII.—Mr. Jorden, of Lower Belgrave Street, Surgeon-Accoucheur to the St. George's Lying-in Institution, on the 10th April, 1838, at 11 P.M. requested me to see a private patient, who had been unusually long in labour, in consequence of the face of the child presenting. The head had not advanced for eight or ten hours. The face was much swollen. There was not the slightest probability that the labour would ever be completed without artificial assistance. I applied the forceps, and soon extracted the child alive and uninjured. The mother recovered favourably.

It is impossible for a case to occur, in which the employment of the forceps could be attended with more satisfactory results than this. Without the forceps, the life of the child must have been destroyed before labour was completed.

CASE CIII.—On the 29th August, 1824, 2 P.M. I was called to a patient residing at 7, Harford Place, Drury Lane, who had been in labour more than twenty-four hours. The os uteri was rigid, and little more than half dilated; the membranes were ruptured; the head had not passed into the cavity of the

pelvis. Pulse strong and frequent; tongue loaded; much thirst; abdomen tender. The pains were regular, but had little effect upon the head. Twelve ounces of blood were drawn from the arm, and an opiate clyster administered.

At 9 P.M. the os uteri fully dilated, and the head so low in the pelvis that the ear could be easily felt. As symptoms of exhaustion were beginning to appear, and I thought it probable the head would not be expelled without assistance, I applied the forceps with great care, and completed the delivery in half an hour. The child was alive, and the mother recovered very well.

CASE CIV.—On the 18th July, 1835, was called to a case of protracted labour, by Mr. Harding, in which the head of the child had been in the cavity of the pelvis for six or eight hours without advancing. The os uteri was fully dilated. The pains were strong and regular; the left ear was behind the symphysis pubis. The blades were easily passed and locked, and with very little force the head was extracted without any mark or injury: it was alive. Hæmorrhage of a formidable character soon took place, but it was checked, and the patient recovered favourably.

CASE CV.—On the 22d July, 1839, at 3 A.M. I was requested by Mr. Webster, of Connaught Terrace, to see Mrs. H. who had been in labour thirty hours with her second child. A great part of the head was in the cavity of the pelvis, and an ear could be readily felt behind the symphysis pubis. The head had not advanced for many hours, and the pains, which had been declining in strength, had no effect in pressing it forward. The bones overlapped one another, and there was a large tumor of the scalp formed. The meconium of the child was passing in considerable quantity. It was evident the head would never be expelled by the natural efforts, and we determined to employ the forceps, the blades of which were introduced and locked without much difficulty, and the head easily extracted. The child was alive, and the mother recovered in the most favourable manner. It was impossible for a case to end in a more satisfactory manner than this did, or for greater benefit to be derived from the forceps.

This patient, after being long in labour with her first child, and threatened

with convulsions, was delivered by craniotomy. The head of the child was jammed in the brim of the pelvis, and an attempt to apply the forceps having failed, it was opened, and extracted with the crotchet.

CASE CVI.—Mrs. P. æt. 26, April 1835. First pregnancy, full period. Returned home after midnight from a large dinner party, at which she had partaken of a variety of dishes and wines, and had been seated near a large fire. Labour came on at 4 A.M. and soon after she became incoherent, and said she felt her teeth falling out of her head. On attempting to drink some warm tea, she bit a large piece from the edge of the china cup, and crushed it between her teeth. Violent convulsions immediately followed. Copious venesection and an enema gave no relief. In an hour and a half the head of the child was within reach of the forceps, and it was applied, and the child was soon extracted alive. By feeling with the finger the umbilical cord round the neck of the child pulsating, it was known to be alive when the forceps was applied. Although every precaution was taken to prevent any injury being inflicted on the mother during the time the head was being extracted, the perineum was extensively lacerated, from the impossibility of retaining her for an instant in the same position. She died at 11 A.M. The child has been reared.

CASE CVII.—On the 27th August, 1833, I was called to a patient of the St. Marylebone Infirmary, residing in Cleveland Street, Grafton Street, who had been forty hours in labour with her fourth child. The head was at the outlet of the pelvis, and, as the pains were still strong and regular, there was a great probability that it would in time have been expelled without artificial assistance. I thought, however, that it would sustain less injury if extracted with the forceps than if left to suffer further from the pressure, as it was much swollen. The instrument was easily applied, and the head extracted with little force. The child was alive and did well, and the mother sustained no injury.

CASE CVIII.—Several years ago I was called to a case of protracted labour from rigidity of the parts at the outlet of the pelvis. The patient was advanced in life before she married, and

it was her first child. The os uteri was fully dilated, and the head advanced so low into the pelvis, that an ear could readily be felt. The head was much swollen and all the soft parts. The pains were feeble, and had no effect. I had no difficulty in passing the blades of the forceps over the sides of the head; but I could not without much, indeed by any degree, of force get them to lock. The medical friend who consulted me made several attempts to lock the blades, but could not succeed, and he determined, contrary to my advice, to endeavour to extract the head with the blades unlocked, which he succeeded in doing to my surprise, and thereby saving the life of the child. The perineum was, however, torn, and I have not since felt justified in operating with the blades of the forceps unlocked.

CASE CIX.—Mr. Walker, of Marylebone Street, called me on the 11th August, 1838, to deliver a woman who had been thirty-six hours in labour. It was the first. She was a small woman, without being distorted. She had previously born a dead child at the seventh month. The os uteri fully dilated; vagina not rigid. The head was in the pelvis. The head was lying transversely, and an ear felt in the usual situation. I found no difficulty in applying and locking the blades of the forceps, and extracting the head; but in doing this the perineum was slightly torn. The child was alive, and the mother recovered, and suffered no great inconvenience from the injury she had sustained.

The head had made no progress for a considerable time. The pulse was remarkably slow, and she was at times incoherent; and between the pains she lay in a state approaching to insensibility. These were the reasons which induced me to deliver artificially.

CASE CX.—January 3d, 1834, at 11 o'clock at night, I was requested to see Mrs. G., æt. 40, who had been upwards of thirty-six hours in her first labour. The membranes had been ruptured twenty-four hours. In the morning a dose of laudanum had been given, and about mid-day three doses of the ergot of rye. The pains had nearly gone off. The head was so low that an ear could be touched behind the symphysis pubis; and the anterior lip of the os uteri, puffy and tender, was pressed down between

them during each pain. The vagina was hot, tender, and excessively rigid, as was the perineum. The labia were swollen to twice the natural size. Fourteen ounces of blood were drawn from the arm, a stimulating clyster thrown up, the bladder relieved by the catheter, and warm fomentations applied to the external parts. When the pains came on, the anterior lip of the os uteri was pressed up with two fingers. The pains returned with greater force and regularity, and for a time I hoped that the head would be expelled; but at four o'clock on the following morning the contractions of the uterus entirely ceased, and she fell into a state of the most alarming exhaustion. The head was sufficiently low for the application of the forceps; but the soft parts were so swollen and tender, that it was impossible to introduce the blades, and the head was opened. Although I extracted the head very slowly, so rigid was the perineum, that it gave way in a slight degree in spite of the most careful support.

Inflammation and sloughing of the vagina followed, but she ultimately recovered without any injury to the bladder or rectum; and I have since delivered her of a living child, at the full period, with the forceps. The cicatrix in the vagina was extensively lacerated during the extraction of the head, without any serious mischief resulting from it. Blood-letting and all other means were had recourse to in the second labour, and the forceps was not applied till she was completely exhausted. The cicatrix of the vagina was too thick and extensive to admit of any relief from its division with the scalpel.

The child could not possibly have been preserved in this instance without the forceps.

In none of the forty-two forceps cases now related, did any thing but mischief result from the use of the instrument before the greater part of the head of the child had passed through the brim of the pelvis, and the orifice of the uterus was fully dilated. In no case was the employment of the forceps advantageous where the blades were applied and locked with great difficulty, and great force required to extract the head of the child. The lives of eleven children were saved, which otherwise must have been sacrificed, out of the forty-two, by the forceps; and the death of

only three of the mothers can be referred to its injudicious use. Sixteen, however, suffered more or less severely from laceration and sloughing of the perineum, vagina, bladder, and rectum. By a little more caution most of these had consequences might, I think, have been altogether obviated.

In more than twenty cases of protracted labour, where it had been proposed to deliver with the forceps—the histories of which it would be tedious to relate—I recommended delay, and they all terminated favourably without artificial assistance.

OBSERVATIONS

ON

COMPLICATED SURGICAL INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with the Auxiliaries in Portugal and Spain.

(As delivered in his Lectures at Sydenham College School of Medicine.)

[Continued from page 887.]

II.—INJURIES OF THE CHEST—concluded.

5. *Pain a devious indication of site or nature of injury. — Cases in illustration. — 6. Varieties in the suppurative action. — Much purulent expectoration not always a sign of extensive pulmonic disease; neither is its absence to be taken as a proof to the contrary. — Occasional sudden evacuation of contents of an abscess of the lungs by the mouth. 7. Hemorrhage on receipt of wound—how occasionally arrested. — Internal hemorrhage ushered in by rigors. 8. Intermission of chest symptoms. 9. Foreign bodies not always giving rise to disease when lodged in lungs. — Treatment of severe injuries of chest. 10. Wound of heart.*

5. It will be seen, from the case of West, that pain is a very devious indication of the site of injury, or its extent, the pain and inconvenience being sometimes referred to the uninjured side or part.

These injuries also give rise not unfrequently to an order of sympathetic pains difficult to understand, particularly pains of abdomen and stomach, where no alteration of structure can be found to account for them in those organs.

Case where chief pain was referred to abdomen, and the ball fancied to be lodged there by patient.

George Parker, penetrating gun-shot wound of thorax: recovered.

Ball entered the right side of chest above the tenth rib, near its neck, fracturing one of them. Considerable hæmorrhage recurring twice; checked by wet compress and full bleeding. States that he immediately expectorated blood.

On admission anxiety of breathing; pain of abdomen, tense and tender on pressure, particularly near to umbilicus, where he says that he feels the ball is lodged.

V.S. ad. §xvj.

Next day easier; respiration also; no return of hæmorrhage; very little bloody expectoration; still pain at point above indicated; pulse about 100, contracted and wiry; tongue furred; much thirst.

Hirud. xxx. V.S. ad §xvij.

3d day.—Slept a little last night; is at present comparatively easy; chief pain at the one point; also of right shoulders, near lower angle of scapula; aggravated on moving the arm; pulse 96, soft; respiration natural; skin ditto; tongue clean and moist.

4th.—Slept a little towards morning; complains more to-day of pain of right side of chest near wound, increased on respiration, but has no cough nor spitting of blood; troubled with painful flatulence of abdomen; relieved by enema and free evacuations.

5th.—Relieved by cupping right side; abdomen more relaxed; fancies he feels the ball moving as he changes posture; breathing pretty easy; pain in abdomen, and on side, in full inspiration.

6th.—Slept well; pulse 81, softer; tongue clean and moist; a little soreness only in abdomen on pressure; respiration tranquil; suffers little when quiet.

7th.—Bullet discovered below the integuments of the axilla, and extracted, followed by immediate relief of severe pain shooting down the side from axilla, under which labouring all night; pulse 80; respiration tranquil; still considerable pain of right and posterior part of chest round the wound.

36th.—Improved gradually; the ball a good deal jagged, and grooved deeply; a little scraped and flattened. Judging

from this appearance, in connection with the symptoms, it seems probable that after striking the ribs sharply, and fracturing them, it glanced upwards, and exterior to the cavity of the chest, instead of passing through it. The ribs seem to have united again. Two small portions of bone came way, under the arm-pit. Incapable of any exertion. Pulse is very remarkable, so small and fine that scarcely can the finger note the beat, barely 60 per minute; appetite good, and in all other respects his health seems not much affected; no previous disease of chest to his knowledge; respiration confined; he has severe pain, on attempting to draw a full breath, in a perpendicular line from about the sixth rib to axilla.

78th day.—Discharged cured.

Wound of thorax giving rise to anomalous pains in epigastric region—in chest—not at the site of injury—in the groin and knee.

J. West, of middle age, wounded on the 25th of July, 1833, by a musket-ball, which entered on the left side between the 5th and 6th ribs, and ascending obliquely to the point of its exit on the right side, where it fractured the scapula a little above the inferior angle.

On his admission he had not lost much blood, but was suffering severely from pain and difficulty of breathing. Air was forced out from the wounds; his pulse was full and quick; pain referred to his right side *below and anterior* to the course of the ball; he was bled to twenty ounces, and a blister was applied to the seat of pain. He passed a tranquil night, apparently much relieved by the treatment adopted.

2d day, not much pain; respiration easy; pulse pretty good; tongue white; bowels rather confined in spite of aperient medicine.

Rep. Haust. Purg. Haust. Salin. 4tis horis.

3d day I examined him at greater leisure than the influx of wounded and press of duties had previously permitted. I found his breathing short and hurried; he complained of a hacking and irritating cough. There was pain when he breathed, but not as might have been anticipated, *in the course of the wound, but in the epigastric region and across the lower and anterior part of the chest*; pulse accelerated, and a little sharp; tongue moist and clean; skin cool.

Ordered a mixture with Digitalis.

15th day.—Little in the interval to be remarked; the cough was troublesome; and on the 6th day suppuration was established in the wounds, and soon discharged freely; the general health tolerably good; bowels open; pulse soft; though patient often sleepless at night from cough. On the 14th day he complained of *pain in the groin*, without any obvious cause, unattended by either swelling or redness; and on the 15th he complained of suffering much, *not only from pain in the groin, but in the knees also*.

20th day.—The wound had continued discharging freely, and seemed healthy; added to which, he slept pretty well at night, but during the preceding night hæmorrhage had supervened to a considerable extent; cold was applied, and a bandage and compress, which retained it externally: circumstances, however, led to the belief that it continued internally; he lay in considerable pain, groaning frequently.

21st day.—I found him lying perfectly unconscious of surrounding objects; breathing difficult and laboured; groaning continually as though suffering great pain; countenance anxious; surface of the body cold; pulse 100, small and feeble; the symptoms leaving little doubt that effusion or extravasation had taken place to a considerable extent. During the afternoon he died.

Bleeding, digitalis, colchicum, and free discharge from the bowels, seemed in the latter stages altogether ineffective.

Inspectio Cadaveris.—An incision was carried across the back, from the left side, where the ball entered, to the opposite side, a little beyond and above the inferior angle of the scapula, where the ball had been extracted on the field. On the left, as far as the spine, this incision exposed the course of the ball, and for a considerable space below there was effusion of blood between the layers of muscles, attended with some disorganization of substance; at the spine all trace of the ball seemed lost; it was found to have passed over the arch of the spine, striking off at its root the spinous process of the 6th dorsal vertebra, laying bare the theca of the spinal cord, without further injuring it. Beyond this some portions of red cloth were found, and the ball had then wheeled round the ribs, between the layers of muscles, until it came in con-

tact with the external edge of the inferior costa of the scapula, which it fractured with such violence as to drive a spicula of some size through the intercostal space, wounding the pleura, and probably the lungs. The latter effect, however, could not be distinctly ascertained, for although the piece was found projecting into the cavity of the chest, the lungs were so adherent with the effused fibrin, that no trifling lesion could have been demonstrated.

On opening the chest a quantity of dark-coloured serum and semi-coagulated blood required removal, when extensive adhesions of both lungs over the whole surface, except on the left side, where the effused blood had separated the lung from the walls, were found; the vessel wounded could not be seen. Perhaps much, or the whole of the hæmorrhage, might have arisen from the sharp spicula penetrating the substance of the lung.

This is a highly interesting and instructive case in many points of view; perhaps had the true nature of the injury been ascertained during life, the removal of the projecting spicula might have led to different results—at least the chances of recovery would have been materially increased, although it is very probable from the appearance of adhesions of old standing, and his poor state of health, that he still would have ultimately sunk. In this case we find all the mischief to be produced by a fractured rib, effected by a spicula of scapula forced in a very unusual manner to project inwards through the intercostal muscles. It shows the necessity of a careful, dexterous, and scientific examination of all such wounds when first received; when alone free examination in many instances is possible.

The pain, referred to the epigastric region, and even below and anterior to the wound rather than to the seat of injury, which was of a nature eminently calculated to induce inconvenience and suffering at the very point where the cavity was penetrated, cannot fail to impress upon you the importance of looking upon the site of pain as an expression or indication of the point injured with becoming caution. A similar feature, you will find, marks a case I shall have shortly to allude to in reference to other effects.

Finally, what is to be said of the pains of groin and knees: have they

reference to the injury of the chest, or the injury of the spinal column? Looking at the entire absence of all other symptoms indicating spinal injury, and the point implicated—being so far above the lumbar plexus—it seems doubtful. Not the least extraordinary part of this complicated case lies in the fact, that although the theca was laid bare, the spine suffering great violence, yet during life nothing drew the attention of either patient or surgeon to this part of the injury.

Indeed, it will often happen that the symptoms are only concentrated on the real site of injury towards the termination of the case—even on the last day only. Of this the following gives a remarkable example. It will be seen that the first and most prominent symptoms pointed to the opposite cavity, where probably some effusion of soft lymph dulled the sound on percussion, while great effusion came on subsequently in the other; and only on the last day were the most urgent symptoms referred to the true site of very extensive injury.

Case of penetrating wound, with lesion of right lung; the most prominent symptoms, until the last day, referring to the left.

John Jackson, æt. 21. A musket-ball entered between the third and fourth ribs, carrying with it a long spicula of rib into the middle lobe, and traversing through the apex of the lower lobe: it was found after death lying loosely on the left side of the spine, near the last dorsal vertebra.

1st day.—Hæmoptysis; hurried and painful breathing; sharp and bounding pulse, 120; skin hot and dry; cough.

3 P.M.—Relieved by the abstraction of twenty ounces of blood. Dull sound from the left side on percussion.

4th.—Pulse feeble; hæmoptysis diminished; sleepless; feels easier sitting up; thirst; bowels opened for the first time since injury. This day no expectation of blood.

5th.—Increased arterial action and pyrexia; return of hæmoptysis; pulse 100, hard and bounding.

V.S. ad 3xx.

6th.—Hæmoptysis again has disappeared; pulse feeble; patient unable to lie down.

7th.—Sense of weight in the left side

of chest most urgent; been hitherto able occasionally to lie on both sides; wound not suppurating; hacking cough, with severe pain, which latter symptom is chiefly referred to the diaphragm; bowels freely opened; pulse 128, neither full nor hard.

8th.—Lies upon the right side, and has lost in a slight degree the sense of weight and pain in the left.

9th.—Slightly improved; pulse 120, full, not hard. Feverish night sweats.

19th.—Unable to lie down; cough constant; pain excessive down right side, and to the middle of the back; pulse exceedingly feeble and indistinct, 128; no perspiration last night; suffered, on the contrary, from cold. Died.

Post-mortem.—A quantity of fœtid air escaped from the thorax when opened. Two quarts of mingled blood and serum, with large portions of lymph and parenchymatous structure floating in it, were found in the right cavity of the chest. The lungs shrunk to the spine, occupying a very small compass. The superior lobe was healthy. The ball had penetrated the middle lobe, and passed out at the apex of the lower. The lung was gorged with blood in the track. The structure of the lung was not otherwise affected. The pleura costalis and pulmonalis, especially of the middle and lower lobe, was thickly coated with lymph, and its structure thickened to the extent of nearly a line, as may be observed in the preparation on the table. Lymph and evident symptoms of inflammation were found on the left side, but no adhesions; and the whole of the lung was healthy. Liver enlarged, but apparently not diseased in structure; gall-bladder nearly empty; rest of the viscera normal.

The symptoms sufficiently indicated effusion; and from his being relieved by lying on the right side, it was of course to be presumed that the effusion was chiefly on that side. The sense of pressure or weight on the left side, of the lung, which it afterwards seemed had entirely carried on the respiration, gave similar diagnosis. Thus although, as I have stated, the left side until the last day was the site of the symptoms, yet they indicated effusion on the right. *They did not, however, indicate lesion or other mischief; on the contrary, they would rather have led to the belief that any such injury was on the opposite side—that is, the left—where the lungs*

were not only uninjured, but healthy. The absence of suppuration in the wound is worthy of remark, in connection with the internal effusion.

Continuing the description of the more remarkable effects of these injuries, and the prominent features which occasionally give the leading character to the case, and form the basis of diagnosis and treatment, we shall find that there are many singular varieties not yet touched upon, and none more important and necessary to be understood than those of the suppurative stage.

6. Sometimes there is not great discharge from the wound, but apparently in lieu there is copious purulent expectoration, which the patient describes to come from the injured part. This view is the more important, inasmuch as it establishes a fact not generally understood, that the abundance of purulent expectoration does not in these cases indicate more extensive disease of the lungs; for, on the contrary, this discharge gradually abates, as it does when occurring from the wound, and the patient recovers. It seems, in fact, to be only an internal instead of an external secretion, and discharge of matter.

Case of penetrating wound and injury of lungs, with moderate suppuration, but long-continued expectoration of matter.

Peter O'Brien, æt. 24. Ball entered two inches below tendon of pectoralis major, at anterior axilla, fractured sixth rib, and entered the chest. Countenance pale and fallen; cold perspiration; difficult and painful respiration; pulse slow, compressed, and laboured; and soon became weaker, and thread-like. Refers all his pain to the diaphragm, particularly to one point over tip of liver, at right side. Disposition to cough, but says diaphragm rises in lumps on making the attempt.—C.C.

Pulse fell so low from the cupping, that bleeding was not resorted to.

Evening.—Greatly relieved.

2d day.—A little bloody expectoration; some cough; pulse risen to 82, hard and wiry.

3d day.—Pulse 102, hard and bounding; not able to cough; expectoration of mucus and blood; bowels not yet opened.

V.S. 3xvj.

4th.—Pulse intermittent; *râle muqueux* and *bruit de soufflet* of right lung.

C.C. Croton oil, mij .

5th.—Pulse stronger and fuller; skin excessively hot; pain on breathing; increased cough and spitting of blood continue; unable to strain to pass his fæces; complains of spasmodic pains and "lumps," as he describes it, about the diaphragm. Cupping-glasses to the chest; breathing thereby relieved. The abstraction of four ounces of blood produced a great change in the pulse, reducing its volume, but increasing the number of pulsations. Pain in breast.

6th day, relieved; pulse full and more even; bowels not yet opened; pain in chest, and cough, less.

7th.—Sharp and severe general febrile attack; bloody expectoration, in a few days changing to puriform flakes; inspiration inaudible on left side; countenance languid and lowered; eyes sunk; lips pallid; breath fœtid; bowels at last opened.

8th.—Sense of weight in left lung, and on coughing he forces from the wound a quantity of white milky fluid mixed with air.

Hirudines, xxx. Tr. Digitalis, mxx . every three hours.

9th.—Greatly relieved.

13th.—Expectorates a quantity of thick pus. He states that he feels the matter when he coughs and attempts to spit, coming from the wound into his throat. The air which he expels as he coughs has a fœtid odour; no blood is mingled with the expectoration.

24th day.—Cough and expectoration continue; but chest symptoms are otherwise much mitigated.

44th.—Cough continues, with night sweats and diarrhœa, and air escapes from the wound when he coughs. The expectoration gradually diminished, and by the end of the second month the wound was healed up, and the breathing became freer.

In the 4th month, he was invalidated home, incapable of active exertion, and complaining of pain under the left nipple; could not lie on the wounded side; very little expectoration or cough remained; no night sweats; appetite good, and for some time previous had been recovering his strength.

In this case we see the suppuration from the wound unusually moderate,

while the expectoration of matter was both copious and long-continued.

Case of penetrating wound of thorax, without lesion of lung or suppurative disease in its structure, attended with copious expectoration of pus.

Benjamin Cresswell, æt. 27, struck by a musket-ball on the 16th of March, 1837, which entered near the middle of the spine of the right scapula, and passed in a transverse direction from shoulder to shoulder, on the left side fracturing the clavicle, the scapula slightly. It traversed the cavity of the thorax at its superior posterior portion, without injuring the lungs.

Progress.—First day expectorated blood; complained of no difficulty of breathing; pulse hurried, but soft.

3d day.—Oppression on breathing.

10th day.—Expectoration of blood only recurred once slightly; suffered from nearly constant pain and difficulty of breathing, the former referred occasionally to the back, but generally “*to the centre of the chest.*” Pulse varying from 100 to 116. Discharge from wounds considerable, fetid; matter also collected over left clavicle.

15th.—Pulse 120, full; tongue pale, moist, and coated; bowels open; cough distressing; *expectoration of pus and mucus abundant*; discharge excessive; arterial action violent, and observable over face and neck at a considerable distance; pain neither great nor constant.

21st.—Little variation until the previous night, when delirium supervened; pulse 160, fluttering; does not complain of much pain; tongue dry and rough; some diarrhœa; great thirst.

22d.—Died.

Treatment.—Repeated bleedings; digitalis and salines.

Post-mortem.—Injury as described; right lung and its cavity did not seem implicated. On removing the lung of left side considerable adhesions were found on its posterior surface; about six ounces of sanio-purulent matter was found in the cavity, and a coagulum of blood at its upper surface. In the upper lobe a large tubercle was found, and in the lower lobe several smaller, and one large; also in the middle lobe, the posterior surface of which was gorged and hepatized. The right lung seemed healthy, with the exception of

some little effusion and adhesion at its posterior surface. The liver and other viscera of the abdomen were healthy; the gall-bladder nearly empty.

From a consideration of the symptoms of this case, with the actual changes, we see that a copious purulent expectoration existed, without any suppurative disease in the lungs, although there might have been some connection established with the collection referred to. Here also pain is referred, not to the true site of injury or subsequent mischief, but to the *centre of chest*, confirming the observation already made on this point.

The irregular manifestation of suppurative action in these cases is thus clearly enough established. I have watched the progress of cases in which there was a purulent expectoration, and yet on examination after death the lungs have been found only more or less tuberculated, but presenting no trace of vomice or abscesses. In other cases we find that abscesses and vomice may exist in great number in the substance of one or both lungs, and yet not the slightest admixture of matter be detected in the expectoration. In Longson's case, an abstract of which I gave in a previous lecture, this state of things existed.

Or again, the walls of an abscess will perceptibly give way in the chest; much matter will be ejected by the mouth, and the rest in a continued discharge from the wound. This occurred, and was well marked, in the following case:—

Thos. Smith, æt. 18, wounded on the 16th of May, 1837, by a musket-ball, which entered at the back, and passed through the superior portion of the scapula, making its exit in front, through the clavicle.

On receiving the wound a quantity of blood gushed from his mouth, and continued in smaller quantity for several days. On the eighteenth day after his removal from Iruu to San Sebastian he had great pain when he coughed, and occasional sense of suffocation. Respiration hurried; pulse quick and tremulous; discharge from wounds profuse. He continued in much the same state, expectorating pus, until the 70th day, when he felt something give way internally during the night, and immediately

coughed up a large quantity of pus, and pus escaped from the wound at the back.

The case was long protracted, and most probably either ended fatally in the country or soon after his return: the last portion of the notes seem, however, to have been mislaid.

While speaking of the suppurative action, it is further necessary to remark that a relative action is sometimes established between the discharge from the wound and the quantity of expectorated matter; these alternations, generally attended with well-marked constitutional effects, giving indications for treatment which may not be disregarded with safety to the patient. The following case puts these various points in a strong light. Time will not permit me to give more than very short abstracts, confining the attention as exclusively as possible to the features establishing certain principles. You will so understand these curtailed sketches of cases; viz. that many details are omitted, not that they are devoid of interest, or unfitted for instruction, but that they do not bear upon the particular point in question.

Case of alternating suppurative action between the lung and the wound.

Benjamin Britton, æt. 27; a blacksmith by trade; sanguineo-lymphatic temperament: wounded Oct. 1, 1836, by a musket-ball, which passed through the scapula above its spine, between the third and fourth ribs, and entered the cavity of the chest. A large portion of the scapula was comminuted, and removed. There was some difficulty of breathing, but he chiefly complained of severe pain about the stomach, unattended by sickness.

V.S. 3xvj. Haust. Purg.

2d day.—Pain of stomach continued.

7th day.—Wound was granulating, and discharged.

9th.—Had a bad night. Pulse small and soft; wounds healthy. Complained of pain about right breast. Expectorated in small quantity sputa tinged with blood. Cough troublesome. Blister applied, and a mixture of oxymel scillæ. Mucilag. acaciæ and hyoseyamus ordered.

10th.—Much relieved; bloody sputa disappeared; breathing easy.

14th.—An incision made into a tumor, above the wound, of emphysematous character, yesterday, from which no pus escaped. To-day purulent matter discharged forcibly with air on every attempt to cough.

32d day.—The discharge ceased; the wound granulating. In the interval the matter had been most abundant, and the case had been complicated by an attack of erysipelas.

33d day.—He complained of wind in the bowels, which inconvenienced him, and on the succeeding day of great difficulty of breathing. Pulse full and quick; bowels open; cough severe. He was bled, blistered, &c.

34th day.—Relieved in some degree of his more violent symptoms. Breathing easier. Copious expectoration of purulent matter, which continued the two succeeding days; the febrile action subsiding.

39th day.—Patient felt better. Pulse more natural; tongue clean; cough diminished; expectoration less; breathing easy.

41st day.—An abscess presented internal to the wound on the back, and an opening made from which pus and air escaped. The wound recommenced discharging on the 43d day, and on the same it is noted that there was no expectoration.

45th day.—The opened abscess discharged freely; the wound scarcely at all.

49th day.—There was again diminution of discharge from the wounds, which were healing; the cough and expectoration returned. These two latter symptoms continued for a period. On the 57th day night sweats, and very profuse, supervened. Discharge, expectoration, and cough, diminished.

In the 5th month he was invalidated, and the following note made:—"Has cough at night, and copious expectoration. Can only lie on the wounded side. No night sweats. Has occasional attacks of diarrhœa. Can make a deep inspiration without pain. Appetite good, and general health seems to be but slightly impaired."

This is about the best case of recovery I have witnessed from so serious an injury in the first instance, and attended by so many complicating circumstances.

The case of Smith leads us to another

class, viz. hæmorrhagic effects. A gush of hæmorrhage following the infliction of the wound, and continuing in lesser degree for many days, is not unusual. The case of Smith furnishes an example. A dangerous hæmorrhage of this kind may frequently be arrested by venesection, producing a rapid syncope. An example of this will be found in the case of Wolfe.

Internal hæmorrhage or extravasation of blood, occurring during the progress of the case, I have known give the rigors which generally mark the formation of matter.

Case of rigors, connected with internal hæmorrhage.

Richard Vincent, æt. 28. Wounded by a musket-ball, which entered immediately over the right clavicle, partially fracturing it, and subsequently the second and sixth ribs, in the latter of which it lay imbedded. Admitted with great difficulty in breathing, and complaining of much pain, particularly in the arm and fingers.

3d day.—He had passed a good night, felt easy, and had no symptoms indicating injury to the lungs or chest. From that day to the 12th, febrile action considerable, and difficulty of breathing. In the afternoon severe rigors supervened, and a presentiment that he would die. Pulse small and frequent. In a few hours death occurred.

Post-mortem.—On opening the thorax adhesions were found between the pleura costalis and pleura pulmonalis, particularly towards the sternum, on the detachment of which a large quantity of blood was found filling the right cavity. The axillary vessels were found injured by the passage of the ball, and the parietes of the thorax, with the pleura costalis, appeared of a dark livid colour—in a state approaching to mortification. The posterior lobe of the right lung was found lacerated; the substance of the whole collapsed, and of dark livid hue.

This case further shows a remarkable intermission of chest symptoms; alternate improvement and deterioration.

8.—An intermitting pulse is frequent in all these injuries. It is prominently marked in the case already given of O'Brien.

With respect to the intermission of chest symptoms, I have observed that

they not only intermit in all urgent symptoms of injury to the chest, for twenty-four or forty-eight hours subsiding, but attacks of local inflammation will intermit with general febrile action, which is well shown also in the case just quoted.

9. Foreign bodies are more frequently lodged in the lungs than any other important viscus, and although great mischief generally ensues in the passage of the body as well as where it lodges, yet the exceptions to this are sufficiently numerous to deserve attention. The following case proves very indisputably that mischief does not necessarily ensue in the immediate neighbourhood of a foreign body even in 159 days.

Case of ball lodged in lungs for 159 days, producing no alteration of structure in its immediate neighbourhood.

David Cashin, æt. 42, was wounded Oct. 1 by a ball which entered about half an inch above the scapular end of the clavicle, and lodged. After death it was found to have passed near the angle of the first rib, fracturing it.

It is unnecessary to enter into any details of the symptoms for the present object: it was a protracted case, and the notes are proportionably voluminous. During the first three months he had all the usual chest symptoms: at that period diarrhœa supervened; vomiting occasionally; loose pieces of bone exfoliated; frequent pain of head and stomach; constant purging; great thirst; were the chief symptoms during the last two months. He died in the sixth month.

The post-mortem examination showed that the principal disease had been in the upper and lower lobes of the left lung; the whole of the lower was strongly adherent, and between it and the pleura a chain of continuous abscesses, containing about a quart of pus, had burrowed as far as and between the attachments of the diaphragm to the ribs. The superior and lower lobes were much disorganized, containing numerous vomice, and perfectly useless as far as the function of respiration was concerned. The ball was found in the base of the middle lobe of the left lung, not encysted, and the portion of lung immediately surrounding it showed no

trace of disease, but appeared perfectly healthy.

Under these different heads or classes may most of the varieties of effects and symptoms resulting from chest injuries be arranged; and it is important that they should be classed and borne in mind, if the surgeon would avoid errors in diagnosis and treatment of a most mischievous tendency.

The treatment of these injuries assumes nearly as many varieties as the injuries it is meant to remedy. Although a case quoted, where the man was shot in his bed in the hospital, the medical officer in charge of the division within a few feet of him, and where the most instant measures were adopted in vain to prevent fatal consequences, show how inadequate are all our means in many of these cases, yet many other examples of recovery here cited prove not less satisfactorily that much is in the surgeon's power, and that a great number of severe cases may ultimately be saved, when the treatment is judiciously modified and adapted to the peculiar states of the patient. These cases afford indications of the modes I have found beneficial. I have merely to add, that attention to easy position, very vigorous depletion when a hard and bounding pulse, or local pain, indicate febrile reaction or inflammation in the chest, cannot be too early adopted. On this often depends the result of the case.

But on this alone we must not depend; powerful adjuvantia are to be found in the treatment of these cases, as in complicated injuries of the head, by the proper use of which you are enabled to abstain from repeated general blood-letting, and husband the resources of your patient for the exhausting suppurative stage, an almost invariable sequence. These consist in a copious secretion from the mucous membrane of the intestinal canal, to be obtained by various means, but in which there is always some difficulty during the first six days; repeated purgatives and enemata being required. I think the best means of effecting this object seems to be one or two brisk doses of calomel and jalap, grs. v. and xx. On the second day repeated, and followed by a dose of castor oil. If no effect, grt. ij. of ol. tlg. on the third day, with alternating injections of castor oil and salts and senna in gruel.

In the second order as to value I hold digitalis, and minute doses of tartarized antimony, which, combined, both tend to lower the heart's action, and act upon the skin.

In the subsequent stages, when occasional attacks of inflammatory character set in on the chest, blisters, or local blood-letting, in combination with the above medicines, generally suffice. And even in the earlier stages, after venesection has been freely resorted to, it is often advisable to employ local blood-letting; and it will be found that occasionally four or six ounces drawn by the cupping-glasses, from the precise situation of the pain, will afford both a greater amount, and a more permanent degree of relief, than twice the quantity abstracted from the arm, and, of course, at half the expense to the system generally.

In the long-protracted and subsequent stages, when an abundant discharge—one or two pints of purulent matter—may be daily poured from the wounds, the patient must be carefully supported; nourishing diet, tonics, and even the stimulus of a few ounces of mellow wine, may be required. In this part of the treatment great judgment is required, not, on the one hand, to allow the patient to sink from exhaustion, nor, on the other, by food or stimulus, to induce frequent or severe attacks of inflammation.

I have preferred endeavouring to fix the chief varieties of these injuries—in their nature, progress, and symptoms—rather by a series of cases drawn from my own observations, than by mere definitions and directions; it has seemed to me that the more important facts would be less likely to escape the memory.

I have spoken only of injuries as affecting the lungs. I have met with but one case of injury to the heart not immediately fatal. A portion of the apex was carried away, and the liver also injured. He lived two days, protesting to the last, although educated as a medical man, that it was not a penetrating wound, clearly proving how little the evidence of the patient's impressions are worth as to the nature or extent of such injuries.

NOTES

OF A

DISSECTION OF A HUNCHBACK.

By ROBERT HUNTER, M.D.

Andersonian Professor of Anatomy, Glasgow.

[For the London Medical Gazette.]

As the female, the subject of the following case, was casually brought into the dissecting room, little of her history could be learned. We ascertained from those who had lived in her neighbourhood that she was about 80 years of age, and seemed to enjoy to the period of her death uninterrupted health. From the extraordinary deformity of the subject, and the rarity of such subjects in the dissecting room, I made a particular inspection, the details of which may not prove uninteresting or useless.

When laid upon the table the subject measured four feet six inches in length; the anterior part of the thorax projected more than usual, and somewhat more upon the left than right side; and the lower extremity of the ensiform cartilage was turned forwards and upwards so as to form a kind of hook, that still remained soft and cartilaginous*.

The hunch, which was confined to the right side of the back, evidently involved the ribs of that side; and from its size and the great deformity it imparted to the trunk generally, seemed to produce an elevation of the shoulders, and consequent apparent shortening of the neck. The chest was short, turned inwards at its lower margin, and its circumference at the inferior angles of the scapulae was thirty inches. No cicatrix could be found on any part of the back or chest. After noting the particulars connected with the external aspect of the body, I then opened the thoracic and abdominal cavities in the usual manner, and obtained a view of the thoracic and abdominal viscera: next I dissected the muscles, blood-vessels, and nerves of the whole subject, and more particularly those in immediate relationship with the spine; and lastly, I exposed completely the skeleton, and had thus an opportunity of ascertaining the condition of the skeleton gene-

rally, as well as of the individual bones. In the description I am now about to give I shall reverse this order, and describe the condition—1st, of the bones; 2d, of the muscles; 3d, of the blood-vessels; 4th, of the nerves; 5th, of the viscera.

1st. Of the Bones.—The most cursory inspection of the skeleton leads to the conclusion that the *origo mali* existed in the bones. The whole skeleton is obviously affected. The osseous texture is lighter, more transparent, and more brittle than in the natural state—circumstances dependent partly on a deficiency of the phosphate of lime, and partly upon the defective organization of the osseous texture; but all the bones are not affected to an equal degree. The bones of the head are least affected; next those of the limbs; and those of the trunk have undergone the greatest change. Of the last, the bones of the spine appear to have been primarily affected, and by their change of relative position necessarily imparted corresponding changes in the ribs and sternum. I shall therefore notice, in the first place, the state of the spine; and, secondly, that of the ribs.

In a well-formed spine the natural curvatures are the antero-posterior; no lateral deflection exists, or only in a very slight degree. In the spine to which we refer, however, three remarkable peculiarities exist—1st, the antero-posterior curvatures are much greater than natural; 2d, two lateral curvatures exist, one in the costal region, and another in the opposite direction, in the lumbar; and 3d, a twisted state of the spine, arising from a change in the relative position of the vertebrae.

The most remarkable peculiarities are the lateral curvatures. The deflection from the mesial line commences at the first dorsal vertebra, and proceeds directly to the right side through the 2d, 3d, 4th, 5th, 6th, 7th, and 8th vertebrae. It then turns at a very acute angle, and proceeds almost as directly to the left side, through the 9th, 10th, 11th, and 12th dorsal, and 1st, 2d, 3d, 4th, and 5th lumbar, where it again turns, and by the medium of a 6th lumbar vertebra, reaches the mesial line at the top of the sacrum.

Besides the great extent of the lateral curvatures which the spine thus presents, an extraordinary twisted or spiral state of the spine exists, which is

* In the skeleton which has been preserved this does not appear, as the cartilaginous part of the ensiform appendix has dropped off, from the maceration and cleaning to which the bone has been subjected.

worthy of particular observation. This seems to arise from the relative change of position which the vertebræ have undergone, by which the anterior aspect of the bodies of the vertebræ has been made, in succession, to veer from the mesial line till they face fairly to the right side, almost to the back, and then as gradually veer in the opposite direction till they face the left side. From the rotation of the vertebræ thus upon their axes, the ribs are necessarily much displaced, as well as changed in form, and the displacement and deformity are different on the two sides of the body. On the right side, the ribs, generally speaking, are more curved than natural, and some of them are made to bend round the bodies of those vertebræ that form the principal part of the hunch. The ribs on the left side are straighter and more slender than natural, and as they are connected to the spine at the concavity of the lateral curvature, they appear to be huddled together; and, what is more remarkable still, from the heads to their angles they are bent backwards, or in the opposite direction from the natural state, and from their angles to the cartilaginous extremities

they are curved greatly from above downwards. The pelvis is also deformed, but not to any great degree. The horizontal ramus of the pubes, on the left side, is straighter or less arched than usual, and the two opposite sides of the brim or inlet are consequently unequal; but the deformity is so small that it attracted no attention till the bones were fairly exposed. The sacrum was then found to be broad and flat, and to form a slight angular projection at the junction of the fourth and fifth sacral vertebræ; the salient part of the angle being turned backwards. So much, then, for the different parts of the skeleton.

The most remarkable peculiarity appertaining to the whole skeleton is its extreme lightness; it weighs only $4\frac{1}{2}$ lbs. To ascertain how far this falls short of the average weight, I weighed six other adult skeletons in my possession, and by the kindness of Dr. Marshall was enabled to obtain the weights of all those (nine in number) in the Anatomical Museum of the College, the particulars of which are indicated in the following table:—

Table shewing the respective Weights of Fifteen Skeletons.

| Male. | Weight. | Female. | Weight. |
|-------------------------------------|----------------|------------------------------------|----------------------|
| 1. Above ordinary size | 12 lbs. | 1. Above ordinary size | $10\frac{1}{2}$ lbs. |
| 2. Middle size | $9\frac{1}{2}$ | 2. Middle do..... | 8 |
| 3. Do. (all the bones exostosed) 10 | | 3. Do. do..... | 9 |
| 4. Largest size | 15 | 4. Do. do..... | $8\frac{1}{2}$ |
| 5. Do. do. | 14 | 5. Do. do. | 8 |
| 6. Do. do. | 13 | 6. Below middle do..... | $7\frac{1}{2}$ |
| 7. Middle do | 12 | | |
| 8. Do. do. | 11 | | |
| 9. Do. do. | 11 | | |
| Average nearly 13 lbs. | | Average nearly $8\frac{2}{3}$ lbs. | |

The above averages can only be viewed as approximations to the truth*. It is probable that the average for the males is high, and that for the females rather low. Be this as it may, it is obvious that our deformed skeleton is only about half the weight of the ordinary skeleton; and we may presume that a

relationship exists between the cause of this deficiency of weight and the deformity*.

* By the kindness of Mr. James Douglas, lecturer on anatomy, College Street Medical School, I have been enabled to add to the above table the weight of two skeletons in his possession, the one a male, which weighs 12lbs., and the other a female, which weighs 11lbs., which reduces a little our average weight of the males, and increases that of the females.

* By an additional act of liberality and kindness on the part of Dr. Marshall, the able demonstrator of anatomy to the College, and father of practical anatomy in Glasgow, I have been enabled to add to the above list the weight of two hunchback skeletons, and in which a similar state of the osseous system exists to that which forms the subject of the present paper. The one happens fortunately to be that of a male, and the other that of a female. The male skeleton was found by Dr. Marshall to weigh 5lbs., and the female 4lbs., so that the skeletons of the three hunchbacks—one male and two females—weigh $13\frac{1}{2}$ lbs. and the average weight is $4\frac{1}{2}$ lbs.

2d. *Of the Muscles.*—The muscles of the head and limbs were normal. The limbs, indeed, were peculiarly well formed. The muscles of the trunk were differently circumstanced. Those of the back were examined with great care. The superficial and broad muscles of the region, viz. the trapezii, latissimi dorsi, rhomboidei, serrati postici superiores and inferiores, were all unusually massy, resembling, in this respect, the muscles of a male subject. The long muscles that lie in the vertebral groove, immediately under the broad muscles, were variously affected. Those attached to the head were well developed, particularly the splenii, complexi, and trachelo-mastoidei. Those stretching along the lumbar and dorsal vertebræ, viz. the sacro-lumbales, longissimi dorsi, spinales dorsi, and multifidi spinæ, were abnormal. They followed the curvatures of the spine, and uniformly presented an atrophied and degenerated condition where they lay upon a concave part of the curved spine, and a red, fibrous, and natural appearance at every convex part of the deformity. The left intercostal muscles possessed much of their natural structure. The right intercostal muscles in many places had degenerated into a fatty matter—a circumstance peculiarly marked near the angles of the ribs in the 5th and 6th intercostal spaces, where the hunch is most protuberant, and the ribs least moveable.

3d. *Of the Blood-vessels.*—The blood-vessels of the head and limbs were normal in size, course, and distribution; and in the trunk the only remarkable deviation from the natural appearance was found in the aorta: this great vessel followed accurately the lateral curvatures of the spine. From lying upon the left side of the vertebral column in the thorax, and corresponding consequently with the concavity of the spinal curvature, the angle which the vessel forms is more acute than that formed by the spine. It is probable, however, that this deviation from the natural state of the vessel had no material effect upon the circulation of the blood.

4th. *Of the Nerves.*—Notwithstanding the extraordinary curvatures of the spine, neither spinal marrow nor nerves appear to have been in the slightest degree compressed or affected. The foramina conjugalia were of the usual size, even upon the concave side of the lateral

curvature, and a free egress was given consequently to the spinal nerves; and the nerves in the other parts of the body had, as far as observation could reach, the natural structure.

5th. *Of the Viscera.*—The thoracic cavity was much shortened in the longitudinal direction, and increased apparently to a corresponding degree in the antero-posterior and transverse diameters. The heart was large but not hypertrophied, and its valvular apparatus normal. The lungs were sound, crepitating when pressed, at every point: no adhesions, but the left lung considerably larger than the right.

The abdominal viscera were free of disease. The stomach, intestines, and peritoneal appendages, in particular, remarkably free of the least vestige of morbid structure. The glandular organs, particularly the spleen, pancreas, and kidneys, also normal; but the form of the liver was considerably affected. The lower margin of the organ was bent back towards the spine, which imparted a curious rolled-up appearance to the viscus, and which has obviously been produced by the margin of the thorax jutting inwards. The liver otherwise seemed to be of the natural structure. The gall-bladder was filled with well-conditioned bile, and the ducts were patent, and of the usual size. The pressure to which the liver thus appears to have been subjected, does not seem to have affected in the slightest degree its organization.

From the above case the following conclusions may be drawn:—

1st. That the curvatures of the spine, which exist in hunchback, arise without ulceration or solution of continuity in the osseous or cartilaginous parts of the vertebral column.

2d. That in hunchback the bones of the spine are both deflected from the mesial line and rotated on their axes, and the degree of rotation in any vertebra is proportional to the degree of its deflection from the mesial line.

3d. That the deformities in other bones of the trunk arise secondarily, or from the spinal curvatures.

4th. That in hunchback the bones of the skeleton generally are remarkable for lightness and transparency—peculiarities obviously dependent upon a deficiency of calcareous matter; and

5th. That the morbid condition of the

bones on which hunchback depends, is not incompatible with longevity.

It is inconsistent with the scope of the present paper to enter into the treatment of hunchback; suffice it, however, to say, that the principles of treatment ought to have a reference, 1st, to the condition of the system on which the lightness, transparency, and, it may be, other morbid conditions of the bones, depend; and, 2d, to the means, whether mechanical or otherwise, by which any tendency to spinal deformity may be contracted, and the natural form and healthy state of the spine promoted.

Among the constitutional means the following may be mentioned: pure air, nourishing food, particularly a milk diet, from the phosphate of lime which the milk contains, tonic medicines, the cold bath, friction over the whole surface of the body, passive exercise, and active exercise, at first in a moderate degree.

The local means ought to be entirely of a mechanical kind. The mechanical means should simply have a reference to the bearing off the superincumbent weight of the head and upper extremities, when the vertical position requires to be maintained beyond a certain period. Attention ought likewise to be paid to the position of the spine in the recumbent posture, and still more particularly to the regular daily training of the muscles of the spine, and to the training of the muscles equally on both sides of the spine.

33, North Hanover Street, Glasgow.

TWO CASES OF ADHERENT PLACENTA,

FOLLOWED BY PHLEGMASIA DOLENS.

To the Editor of the Medical Gazette.

SIR,

If you think the accompanying cases of sufficient interest, you will oblige me by giving them a place in the GAZETTE.

I am, sir,

Your obedient servant,

JOHN CHATTO.

Leigh Street, Aug. 23, 1839.

CASE I.—*Very tedious labour—Adherent placenta—Irritative fever—Hypercatarrhis—Phlegmasia dolens—Great debility—Recovery.*

Mrs. L., æt. 28, a delicate woman, of a nervous temperament. She has never

had a child, but miscarried about two years ago.

Dec. 2d, 1836.—I was sent for yesterday, when I found she had had pains, of more or less severity, for several hours, and that the os uteri, which was as thin as the thinnest paper, was expanded to the size of a crown-piece, and tightly stretched over the vertex. During the whole of to-day the pains had been of a varying character, and the dilatation hardly at all advanced. My patient being very much fatigued, and very heavy for sleep, which, however, was prevented by the recurrence of the pains, which were yet inefficient for the purposes of parturition, I gave her an opiate.

3d.—Much refreshed and invigorated by sound sleep, and the pains, although coming on at longer intervals, are more effective. After a few hours, however, the pains again relapsed into their former state of inefficiency. In the evening very little additional dilatation had occurred, and so thin was the undilated part of the cervix uteri, that one could with difficulty believe any thing was there interposed between the finger and the child's head.

4th.—After a cessation of many hours the pains came on this forenoon with vigour; a little liquor amnii was now forced down; and the patient soon after becoming sick, complete dilatation followed at no distant period, immediately after which the membranes ruptured. Again the pains became perfectly inefficient for the completion of labour, and I gave her a dose of the ergot, which I had been deterred from administering before by the rigidity of the external parts, (now considerably abated), and by the tight manner in which the presentation was grasped by the very thin os uteri. The pains, though slow, gradually increased in severity, and a live child was delivered, with but little distension of the perineum, on the morning of the 5th, the mother being very much exhausted.

Finding, from external examination, the uterus disposed to contract, and that I could feel the insertion of the funis, I proceeded, shortly after the birth of the child, to the removal of the placenta; but, finding it resist any efforts I deemed it prudent to make, and which caused great pain, I desisted from any attempts for two or three hours, giving her at intervals some ergot, which, however,

excited no pain whatever. On again examining, I found a small portion of placenta in the vagina, but the great bulk retained in the uterus, whence it could not be dislodged. I now passed my hand into the cavity of the uterus, and discovered the great mass of the placenta adhering to the fundus. So firm was its attachment, that I soon found that any thing like pulling at it would only be attended with its partial removal, and I therefore carefully and slowly peeled it from its attachment, causing thereby excessive pain to my unfortunate patient. In some parts it came off very smoothly, in others it left asperities; I believe, however, that I succeeded in detaching the whole, although, in bringing it through the vagina, some portions were broken off, which, however, were easily removed afterwards. Although, prior to the commencement of the operation, I had room enough to move my hand freely in the cavity of the uterus, yet no sooner had I completed the detachment than the uterus contracted powerfully upon my hand, and expelled both it and the placenta which it grasped. No hæmorrhage whatever attended the case. The patient was nearly exhausted, almost senseless at intervals. Her pulse was hardly to be felt; but by the continued use of stimuli she had, in two or three hours, almost entirely recovered from this distressing and alarming state.

6th.—Feels comfortable, although very feeble. No after-pain. Discharge ordinary. Slight uterine tenderness. Slept. Pulse 120.

9th.—Up to this morning, although her pulse continued at 120 (small), and the discharge had become very fetid, yet, upon the whole, she seemed progressing. But this evening I was sent for to her again, and never had I seen, except in puerperal fever, so great a change in the countenance as I found to have taken place in her since the short time I had seen her. It was collapsed, and livid marks surrounded the eyes. Alternating chills and heats, with a wiry pulse running up to 130 or 140. Intense thirst. Tongue streaked with brown, and respiration much hurried. On examination, I found great tenderness of lower part of the abdomen, and especially over the left uterine region.

Hirud. xij. et Cataplasma. Lini.

10th.—Although the leeches did not

bleed much, yet the pain was materially relieved, and the pulse reduced to 120.

Hirud. vj. Cont. Catapl. Lini. Cap. Calomel. gr. ij.; Opii, gr. $\frac{1}{4}$. *itis horis.*

These leeches bled profusely, so that she became very faint. All pain and tenderness effectually relieved.

14th.—She had been going on very well until yesterday. The pain had never recurred. The pulse sometimes was but 110, very small, and both it and other symptoms put on so plainly the marks of true debility, that I ventured to give her a little jelly and beer, for which she had a great craving. Yesterday, however, she was seized with a violent hypercatharsis, and although that has, by the use of opiates, subsided to-day, she is much reduced by it. It probably arose from the calomel, which had been continued until yesterday, although only in one-grain doses, and guarded by opium.

18th.—Had been again improving, and even gaining strength (the pulse, however, never slower than 110, and generally 120), when, after a day passed with an indescribable malaise, she was attacked yesterday evening with excessive pain, occurring at intervals, in different parts of the right lower extremity. When I saw her this morning she had the appearance of one suffering from exhaustion. She was much tormented by paroxysms of heat and sweating, unpreceded by any chills; pulse very rapid; tongue quite clean. On examination I found excessive tenderness in the groin and calf of the leg, so that she shrieked on the slightest touch; nay, sometimes even the sheet touching her was insupportable. The pains, and tenderness especially, were observed in the course of the vessels; the former also striking around the pelvis.

Hirudin. x. inguin. Embroc. Anodyn.

In the evening I found she was so much easier after applying the embrocation, that she had not employed the leeches. Could bear pressure much better in the groin.

Catapl. Lini inguini. Pulv. Ip. C. gr. x. h. s. s.

I should have observed, that with this attack there was no other symptom of direct uterine irritation: thus no bearing down pain, and no increase of the discharge, which had much diminished

in fœtor and quantity for a long time past.

19th. — Very little improvement ; pulse 120, full, and soft ; tenderness yet considerable ; no tumefaction of the limb ; her countenance much dejected.

Hirud. viij. Hydr. c. Cretâ, Pulv. Ipecac. Comp. aa. gr. iij. 4tis horis.

21st.—Dr. Lee favoured me with his opinion of the case. Her countenance still continued bad, and her pulse mounted up to from 120 to 140, although, after another application of leeches, its fulness entirely disappeared, and it resumed the small character it possessed prior to the attack. Now, as throughout the case, except just at the commencement, her tongue is quite clean, and no irritability of stomach has manifested itself. At intervals she still has burning heat and profuse sweating. The tenderness in the groin is still very considerable, extending in the course of the femoral vein, which may be traced as a firm cord, and accompanied by considerable though not excessive tension of the limb. The leeches had been repeated, and the mild mercurials continued. Dr. Lee considered, from the rapidity of the pulse, which had persisted throughout this case (it has seldom been less than 120, often much more), that from the commencement there had been going on a degree of chronic inflammation about the cervix uteri ; that latterly the veins of the uterus had participated in the inflammation, which was now extending by the femoral vein, producing genuine phlegmasia dolens. He recommended a continuation of mild mercurials until the mouth became affected, and the occasional application of leeches ; but observing the very reduced state of the patient, he deemed great caution necessary in the employment of further depletion, and that even before very long tonics or stimuli might be required.

31st.—The case has required from time to time a few leeches, which, although they always increased present suffering, were always attended with ultimate benefit. Pain and tenderness in groin and extremity much relieved, and swelling, which had increased, subsiding. Pulse reduced to 100 ; but it has become so exceedingly feeble that I have latterly urged upon her more nourishment, to which she has a great objection, and ordered her quinine. The

ung. hydr. fort. has been substituted for the hydrarg. c. cretâ, as the latter produced considerable purging. She states she has a discharge identical with the menses when quite natural.

Jan. 2d.—Yesterday and to-day she complained of pains in the left extremity, similar to those which had affected the right ; and on examination of the inguinal region, and course of femoral vessels, tenderness and knotted cords are discovered. Her countenance, which had become cheerful, now assumed the same anxious appearance as heretofore ; the pulse becoming much fuller, rose to 130. Leeches were applied yesterday, but no relief followed ; on the contrary, the pain increased, and the tenderness became diffused over the whole pubic region.

Rep. Hir. ij.

3d.—These leeches by error were permitted to bleed profusely ; pulse reduced to a mere thread ; pain and tenderness, though relieved, still there. I allowed her some wine and beer, continuing the inunction.

6th.—Has suffered much from debility since last report, but had began to rally until yesterday. Tenderness also diminished, but existing ; as also does considerable swelling of the limb. As the inunction produced no effect upon her mouth, I substituted for it gr. iij. calomel, with half a grain of opium, under the use of which she became easier, and her pulse slower (110) ; but she had only taken three doses when, yesterday, a violent hypercatharsis ensued again, reducing her to the last extremity. Yet, so far from the local malady being increased, the pain and tenderness became most remarkably diminished, as did the tumefaction of the limb.

9th.—Her debility is very great ; indeed, from the thready state of her pulse, and her great emaciation, she seems almost sinking, slipping down in the bed like a patient in the last stage of fever. Her disgust for all articles of nourishment is so great, that, although it has been explained her safety in some measure depends upon doing so, she can hardly be persuaded to take wine, &c. The purging has been arrested by laudanum.

Feb. 9th.—Although at first slowly, she has upon the whole continued progressing since last report, so that now her strength is materially improved.

Her limbs, though no longer swollen, are stiff, and often very painful about the joints, requiring anodyne embrocations; still there are hard cords in the course of the veins; pulse nearly 100, and small; the catamenia established.

Jan. 14th, 1839. — Having passed through a pregnancy with very little inconvenience, she was delivered to-day after a very easy labour, the placenta being removed with the greatest facility. Her health has long been firmly re-established.

I have omitted to mention in the above detail, that the secretion of milk, which had at first disappeared, was reproduced in her convalescence, which, indeed, she delayed by a rash attempt to suckle her child. I should also observe, that the most marked relief to immediate suffering was derived by the application to the affected extremity of warm linseed-meal poultices; indeed, whenever the slightest tenderness manifested itself, the part was enveloped in one of these, often with complete relief; and long after all pain subsided, the use of this remedy was attended with great comfort.

CASE II.—*Very tedious labour—Placenta adherent—Extraction delayed—Phlegmasia dolens—Death—Post-mortem appearances.*

Mrs. W., a delicate and nervous woman, with a very sallow complexion, æt. 30; first child. She suffered much from pain during the latter months of her pregnancy.

May 3d, 1839.—She was delivered to-day of a large, dead, putrid child. Her labour has been excessively tedious, having lasted, with intervals of ease, two or three days; it was totally uninfluenced by the secale cornutum. She felt after delivery very faint and exhausted, although no hæmorrhage whatever occurred. On proceeding to pass my hand along the funis, to ascertain the situation of the placenta, it broke off at no great distance from its point of insertion, without the slightest force being employed on my part. Finding there was no hæmorrhage, that there was considerable lessening of the size of the uterus, although the same want of pain continued which had characterized the previous stages of labour, and seeing her state of extreme exhaustion, I deemed it better to allow her

some repose before I attempted the removal of the placenta, which, owing to the absence of the funis, and the possibly diseased state of itself, might probably be attended with more than ordinary difficulty: I could feel a small portion in the vagina. She had then several hours of refreshing sleep, which invigorated her considerably, although her pulse was yet small and quick. I now endeavoured to remove the placenta, but found that, although I could grasp a small portion, the main body of its substance remained *in utero*, and that the cervix firmly grasped it. The attempt at dilating this gave her great pain, as did also the dilatation of the vagina. I succeeded in getting hold of a large portion, but not sufficient to justify attempts at traction by it. She suffered much pain, and was frequently very faint. After a while Dr. Lee saw her, and removed the placenta, which was partially adherent. The operation was attended with agonizing pain, both as regards the dilatation of the cervix and the peeling off the placenta, and was followed by great faintings, requiring the free use of stimuli: this removal was effected about twenty hours after the birth of the child. On examination of the placenta it was found not to be entire, and of a much less firm texture than natural. A day or two after, a remaining large portion was discharged from the vagina.

7th.—Has had little or no fever; no abdominal tenderness, although some considerable after-pain. Her pulse has continued quick and small (120), and her countenance very ghastly. The discharge from the vagina intolerably fætid.

14th.—Altogether has gone on well, although complaining at intervals of severe pains, and of various anomalous and transitory sensations, referrible in part to her nervous temperament, *e. g.* aphonia, dysphagia, &c. Discharge subsiding, and fætor diminishing; pulse yet very quick, and countenance bad.

20th.—Improving in strength and appetite; no abdominal pain; pulse varying between 100 and 120; all fætor of discharge gone; countenance better.

24th.—Had been going on pretty well until yesterday, so that, although her pulse was yet very quick, her appetite, strength, countenance, and spirits, were much improved. But during yesterday she had much pain in the right

lower extremity; and to-day, on examination, I find great tenderness in groin, and in course of the vessels, as far as the ham, while the limb is considerably swollen. Her pulse now mounts up to 130, very small; countenance very sallow and haggard; great heats and sweats; utter want of sleep.

Hirudin. vj. inguin. Cat. Lin. Pil.
Cal. c. Ant. Tart. et Opio, h. s. s.

27th.—By the cautious use of leeches, and continuance of mild doses of calomel and opium, she seems easier to-day. Pulse is slower; swelling less, though the limb is double the size of the other. The tumefaction is chiefly situated between the knee and ankle, where it pits upon pressure; tenderness in groin, though abated, continues, and there is considerable fullness of that part compared with the opposite side, while hard cords can be traced into the thigh, and all the superficial veins of the limb are distended.

Rep. Hirudin.

29th.—Pulse 140; respiration hurried; much sweating; no tenderness now in groin, or pain in limb, which, however, continues still as swollen, and very hot. The calomel and opium has been omitted, as it purges her.

Dr. Lee saw her yesterday, and observing her exhausted state and feeble pulse, he recommended that any further depletion should be had recourse to only in the most cautious manner, and suggested that stimuli might be speedily required.

June 1st.—Pulse, which had a day or two ago much diminished in frequency, yesterday became more rapid than ever (130 to 140.) Her debility is excessive, and sweating profuse; her tongue has continued tolerably clean, and very little irritability of stomach present. There is little pain now in the extremity, and the swelling is diminished considerably. The left leg has now, however, become a little swollen towards the ankle, and there is slight tenderness of the groin. The last day or two she has taken beer and wine.

3d. — With very little increase of swelling in the left extremity, and hardly any tenderness in the groin, she gradually became weaker and weaker, and sank to-day completely exhausted, having refused nourishment or stimuli for some time past in any but inefficient quantities.

Examination of the body fifteen hours after death.—This being made under the surveillance of some relations, the removal of the parts for leisurely and complete examination could not be effected. The time being fully occupied in examining the state of the uterus, and the abdominal venous system, much attention was not paid to the condition of the other organs, which, however, were inordinately pale. The liver and spleen softened in texture, and the latter much increased in size. No marks of peritoneal inflammation existed. On tracing up the vena cava inferior from the brim of the pelvis, I found its cavity contained some coagula, which, however, only partially filled it, were not at all firm, and were easily removed. On examining the renal vein of the left side, it was found in a very diseased state; its coats much thickened; its cavity blocked up with firm coagula, upon the removal of which the inner membrane was found abraded; the cellular tissue in which it lay imbedded was also much thickened; and behind it was a considerable collection of purulent matter, which infiltrated down towards the pelvis, among the cellular tissue behind the vena cava, and in front of the psoas muscle. The right renal vein was also firmly blocked up; but on removing the coagula, the appearance of the vein was nearly natural. On cutting into the kidneys they were found excessively pale, and containing a serous fluid. Tracing the vena cava backwards towards the cavity of the pelvis and the thigh, I found the pelvic and femoral veins completely plugged in the same manner as the renal, observing here, also, that the coagula were much firmer, and the lining membrane of the veins seen to be much more disorganized on the left than on the right side; indeed, on the latter, after the coagula were removed, if we except some distension, the veins were natural enough; so, too, in regard to the uterine veins, while they were simply plugged on the right side, they were thickened in texture, and their lining membrane discoloured and abraded on the left. The uterus was at least double its natural size, and very flabby in its texture. On opening into its cavity, I found the marks where the placenta had adhered at the fundus, slight dark shreds still remaining, which seemed identified with the mucous membrane,

or rather not to be removed without tearing it. Over a circular space, more than equal to a crown-piece, around the site of the adhesion, the mucous membrane was discoloured of a very deep tint; but on gently scraping this with the back of the scalpel, the colour disappeared, and the mucous membrane, of a natural appearance, remained; and so it continued to within half an inch of the os uteri; but the whole circumference of the os was almost of a black colour, irregularly ulcerated, and in some parts seemed almost gangrenous. Here (*i. e.* for half an inch in breadth around the whole circumference of the os) the black colour was not removeable, and the mucous membrane was ragged and disorganized.

I perceive Dr. Lee refers to this case (LVI.) in his valuable summary of cases of retained placenta, *MEDICAL GAZETTE*, page 751. Although, at the time, I believed the state of the patient permitted, or rather required, delay, yet I now think it would have been much better to have endeavoured to remove the placenta shortly after the birth of the child.

It may reasonably be supposed that the inflammatory action which produced the ulceration of the cervix uteri (which I may observe was attended with no local symptom referrible to the uterus, although the persisting quickness of the pulse throughout the case led to the suspicion of its existence), may have been induced by the reiterated attempts to dilate the cervix.

IDIOPATHIC TETANUS.

To the Editor of the Medical Gazette.

SIR,

SHOULD you deem this case worthy a place in your valuable journal, it is very much at your service, and its insertion will oblige

Your obedient servant,

HENRY BULLOCK.

Uxbridge, Sept. 9, 1839.

James Clements, aged 26, a man of good general health, although addicted to spirit-drinking, states that a fortnight since, while engaged in his ordinary avocation, that of a brick-maker, he fell over a wheel-barrow, and injured his back, which was somewhat inflexible

during the two subsequent days; but this he attributed rather to the alternations of heat and cold to which he was exposed than to the accident. For the last two days, having followed his occupation as usual, he has had difficulty in swallowing, and stiffness of the neck and limbs. He is now, August 3d, labouring under the most unequivocal symptoms of tetanus, for the countenance is strongly indicative of the disease; he has great difficulty in deglutition, his jaw being nearly fixed; intense rigidity of the whole muscular system, except of the arms, which are only thus affected during the existence of the paroxysms, which recur with more or less intensity every two minutes, and often more frequently, continuing about half that period. There is complete opisthotonos, the body resting upon the occiput and heels. He complains of a constant and severe pain, extending from the ensiform cartilage to the spine opposite; the perspiration profuse; nights restless, sleeping occasionally for five minutes at the utmost; pulse about 84, and irregular. The bowels had been relieved the previous day by an aperient. There is no pain upon pressure over any part of the spinal column. I now prescribed—

Hydrarg. Chlorid., Pulv. Scammon. aa.
gr. v. statim sum. Enema Tabaci
(3ss. ad Oss.) statim injiciend.

The usual depressing effects of this last remedy were produced in twenty minutes, and lasted two hours. The prostration was excessive, for his pulse could scarcely be detected; even respiration at one time was hardly perceptible; nausea and vomiting distressing. Ammonia and other stimuli were resorted to until he began to rally. By these means the bowels were unloaded of an immense quantity of dark scybulous fæces. During the first six hours after the employment of the tobacco, the spasm was very materially abated both in severity and frequency.

Enema Tabaci nocte manequere repetant.
Emp. Cantharid. reg. spin. lumb. et dors. Extract. Colocynth. Co. gr. x.
ft. pil. ij. o. m.

R Quinæ Disulph. gr. ij.; Acid. Sulph. dil. ℥ij. Sp. Æth. Sulph. Co. 3ss.;
Mist. Camph. 3iss. 2da q. hora. Brandy, arrow-root, and strong beef-tea.

Without burdening the case with the prolixity of a daily report, it may be

sufficient to state, that the amendment, though progressive, was almost imperceptible at each visit, the original treatment being adhered to with slight variation as the circumstances of the case seemed to demand: the same formidable collapse followed the administration of the tobacco, and a similar degree of relief. At the expiration of the fifth day his condition was so far improved that the paroxysms supervened at intervals of twenty minutes, but not with that severity and regularity of accession as formerly. There was less general rigidity, the trismus, however, remaining much the same. The aspect of his countenance was considerably better; the perspirations mitigated; and during the night he frequently slept for two hours without waking; deglutition performed more easily. The tobacco enemata to be discontinued; otherwise the same treatment as before, with the daily administration of aperients consisting of calomel and colocynth. (Emp. Cantharid. nuchæ, as he complained of headache.)

By the 13th day he was so far convalescent that he experienced a paroxysm only about once an hour, which was very slight and transitory: his jaw could now be separated nearly an inch, there being very little rigidity of muscle, with the exception of those of the abdomen, and he expressed himself as being much better. The quinine, &c. continued at more distant intervals, with brandy, meat, and beer.

20th day. — Declares himself quite well, not having been conscious of a spasm for some days, and on the 25th day from the time I first saw him he walked a distance of upwards of six miles.

I have been induced to trouble you with a narration of this case, as attended by my partner, Mr. James, and myself, because it serves to establish, as far as a single case can, at least, the efficacy of a plan of treatment recently recommended by a very high authority, Mr. Travers*. I have styled it *idiopathic* tetanus only because its immediate cause was unknown. I am disposed, however, to conjecture that the medulla spinalis or its membranes contracted some lesion in the fall, and that the disease arose from that injury. I think so, especially from the lapse of time be-

tween the accident and the appearance of the tetanic symptoms. Under this impression I blistered the spinal column, yet without any marked benefit fairly referable to this remedy.

ANOMALOUS ERUPTIVE DISEASE.

To the Editor of the Medical Gazette.

SIR,

DURING the months of July and August there has been prevalent in this neighbourhood, and in the present month a few cases remain, of an eruptive disease presenting some remarkable features, for which it appears to me to be worthy of the attention of your readers, among whom some may perchance be able to contribute respecting it additional facts. Its peculiarity consists in its combining the forms of three diseases, which we are accustomed to regard as specifically different and distinct, namely, scarlatina, variola, and varicella, and the symptoms of each have occurred in different cases, in various order and severity.

In many children it has first shewn itself as scarlatina, the tonsils being inflamed, the papilla or the tongue enlarged, and the red blush on the skin having fairly that character; but after two days, more or less, the efflorescence has disappeared, and vesicles, of various sizes, some precisely similar to varicella, and in many cases the crop has been very abundant; in other cases larger vesicles more thinly scattered.

Immediately these have ceased to arise, a new efflorescence, of a purplish hue, in irregular patches, slightly elevated, with irregular edges, has arisen, so extremely like measles that any one seeing the patient under it, for the first time, would certainly pronounce it at a glance to be that disease. When these symptoms have been successive, as I have described them, the case has appeared as if the three diseases had occurred together, and each had struggled into existence in spite of the others; this order has been most frequent, but the period occupied by the three successive forms has been various; in some three days have shewn them all, in others it has occupied six, in others nine days. In other cases a different arrangement, and a more perplexing admixture of the three forms have rendered it impossible to give a satisfactory diagnosis.

* On Constitutional Irritation, vol. II.

In several instances, it is worthy of remark, the children had before gone through at distinct times both measles and scarlatina.

In the matter of treatment I have nothing to say, save that I have seen no fatal cases. The sequelæ have in different instances looked like the results of different diseases, some children having had the pains in the wrists and ankles, with a dropsical tendency; others troublesome mucous discharges and remittent fever.

But I cannot say that these have followed, with the regularity I expected, any severity or prominence of the forms of disease, to which they are usually linked.—I am, sir,

Your obedient servant,
JOHN GARDNER.

49, Great Portland Street,
Sept. 9, 1839.

ON THE EFFECTS
OF
COLOURED EMETINE.

BY DR DOMEIER.

[For the London Medical Gazette.]

I BELIEVE that emetine, whether coloured or pure, has not been very frequently administered in this country. Of the few trials which may have been made with it, hardly any appear to have been registered; indeed, I do not recollect reading a single one, either in medical journals, or elsewhere. Perhaps this may be a sufficient excuse for publishing the following scanty notes of seven cases, where I gave coloured emetine, a few years ago, when I was physician to the Westminster General Dispensary. To the best of my recollection, I saw the medicine taken in every instance. This is a point of consequence, as it must be confessed that among the many uncertainties of the practice of physic, we must number the doubt whether the medicine which is prescribed is swallowed.

CASE I.—Feb. 22d, 1836. Charles Healing, æt. 40, has long laboured under cough, for which he has taken a variety of remedies with little benefit. Gave him half a grain of coloured emetine.

Feb. 24th.—No vomiting has been produced by the emetine.

29th.—I gave him two grains of coloured emetine, as he was feverish, and complained of general pains.

March 1st.—Very slight vomiting from the emetine. Feels considerable nausea to-day.

CASE II.—Feb. 23d, 1836. Mrs. Magarvie, of 11, Little White Lion Street, has long laboured under ascites and cough, but is better. She was much benefited a short time ago by an emetic composed of tartarized antimony and ipecacuanha. I gave her a grain of coloured emetine.

Feb. 24th.—The emetine produced three fits of vomiting, in which bile, &c. were brought up; and she is better.

CASE III.—Feb. 24th, 1836. Mrs. Hubbard, æt. 19, feels a cynanche tonsillaris coming on, to which she is subject. I gave her a grain of coloured emetine.

Feb. 25th.—The medicine produced one fit of vomiting, and the patient is better.

27th.—As she felt as ill as ever, I gave her another grain.

28th.—No vomiting from emetine.

CASE IV.—Feb. 24th, 1836. Mrs. Pratt, æt. 74, complains of cough, occasional sickness, and rising of bile. Gave her a grain of coloured emetine.

Feb. 26th.—Coughs less, and is better in other respects. Had several fits of vomiting. Gave her another grain.

29th.—Reports that she vomited a little.

CASE V.—Feb. 25th, 1836. Louisa Symes, æt. 16, complains of rheumatism. Is much confined to the house, and seems of a plethoric habit. Gave her a grain of coloured emetine.

26th.—The medicine produced neither vomiting nor nausea, but the patient feels better. Gave her two grains of tartarized antimony.

27th.—The antimony produced several fits of vomiting. The tongue is still furred, but the patient calls herself well.

CASE VI.—March 4th, 1836. Mrs. Malone, æt. 50, who confesses that she sometimes takes spirits, is suffering from a chronic cough. I gave her two grains of coloured emetine.

9th.—The emetine had its full effect.

CASE VII.—March 23d, 1836. Mrs. Waterman is suffering from spinal irri-

tation, with great nervousness and a foul stomach; emetics operate upon her but feebly. I gave her two grains of coloured emetine.

March 25th.—The emetic produced nausea, but no vomiting.

Magendie says, that two grains of coloured emetine given to a healthy man, fasting, cause prolonged vomiting, followed by considerable sleepiness. But he adds, that a quarter of a grain is sometimes sufficient to produce nausea and vomiting. Its effect upon the sick is the same, namely, it causes vomiting and purging; but it is likewise beneficial in catarrhal affections, particularly when chronic*.

Though Magendie speaks of the purgative effect of the emetine, when given to the sick, as showing the identity of its action with that which it has upon the healthy, this property is not mentioned by him in the latter case, nor do I find it recorded in my notes.

It is probable that emetics, once so much used, and now so undeservedly neglected, may again come into fashion, in which case emetine will merit more frequent trials, as the list of established emetics is certainly very short. Dr. Holland, in his "Medical Notes and Reflections," has a judicious chapter on the use of emetics, in which he repeatedly expresses a wish for their more frequent employment, and observes that "if ipecacuanha were invariably of good quality, which unfortunately it is not, it might be sufficient in almost every instance."—(P. 299).

Now, emetine has the advantage of saving the patient from the nauseous earthy taste of ipecacuanha, besides being of less variable quality.

In the cases above narrated the dose was sometimes too small, but I thought it right to keep on the safe side. It is scarcely necessary to caution the practitioner against giving equally large doses of the pure, as of the coloured emetine—the mistake might be fatal.

LETTER FROM DR. HOPE

ON

DR. C. J. B. WILLIAMS'S LATE STATEMENT.

To the Editor of the Medical Gazette.

SIR,

IN your number for August 31, 1839, is an attack upon me by Dr. C. J. B. Williams. I feel the strongest repugnance to obtrude any private disagreement on public notice; and for this reason, but still more from forbearance towards that gentleman, I have refrained from noticing various similar attacks during the last four years. I am advised, however, now to state, that on the occasion of his late attempt to supplant me at St. George's Hospital, I offered him, through the Rev. W. Niven, an arbitration by five gentlemen, equally selected, on the subject at issue between us: namely, which of the two had violated an arbitration by Sir B. Brodie, broken a final agreement by Dr. Macleod, and unjustly appropriated certain experiments. Having first acceded to this offer, he, after six weeks of deliberation, finally declined it, on seeing, at page 30 of the third edition of my Treatise on Diseases of the Heart, my tardily and reluctantly extorted defence against his reiterated impeachment of my integrity.

Now a gentleman conscious of the justice of his cause, and feeling the confidence which justice inspires, would have preferred defending his character by entrusting his case to the fair and honourable tribunal proposed by me, rather than by resorting to personal abuse and unsupported assertion in a public journal. As Dr. Williams has chosen the latter course, it is unnecessary for me to notice him, beyond distinctly contradicting the whole of his statements, and expressing my readiness to furnish his "friends" with irrefragable documentary evidence in substantiation of all that I have alleged at page 30 of my work.—I am, sir,

Your most obedient servant,
J. HOPE.

13, Lower Seymour Street,
Sept. 10, 1839.

* Formulaire pour la préparation et l'emploi de plusieurs nouveaux médicaments. 8e édit. p. 96.

MEDICAL GAZETTE.

"Licet omnibus, licet etiam mihi, digulatam
Arta Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recuso."

CICERO.

THE NEW EDINBURGH PHARMACOPŒIA.

IN the number of the Edinburgh Medical and Surgical Journal for July, 1839, is to be found a review of the London Pharmacopœia of 1836, and the one published by the Edinburgh College this year. On the whole the critique is a solid and judicious one; and even if there were some slight leaning to the Codex published in their own city, we would not venture to censure it. It does not go against the grain, says Aristotle, to praise the Athenians at Athens. Our contemporary, like ourselves, would have preferred to see one Pharmacopœia take the place of the three now used in these islands, and is disappointed that the project has miscarried. There are great difficulties, no doubt, in the way of such a union. To carry on the compilation of a British Pharmacopœia by correspondence would be as long and wearisome as the matches at chess which are sometimes conducted in this manner, and would be barely possible if Dublin was to be included in the scheme. If the articles of the treaty were to be arranged by personal discussion, some of the principal members of the profession must leave their homes and their practice for a very thankless office. The Edinburgh Journal, however, thinks that if there had been sufficient zeal on both sides, the difficulty regarding distance might have been got over, as far as respected England and Scotland. We think so too, for to genuine zeal difficulties hardly seem to exist—*impossible, n'est pas français*, said Napoleon. Minute details could

not well be given, nor small differences arranged by written correspondence, but the greater features of the work might have been laid down in this manner, leaving the more delicate touches for verbal discussion. A meeting of ten days, or a fortnight, would have been sufficient to complete the negotiation had the parties been thoroughly in earnest; and, at any rate, the two ends of this island might have agreed to make up their medicines in the same way. Two commissioners on each side would have been sufficient, who might have met at that dull season of the year when metropolitan practitioners can leave, without much danger, the scene of their duties; nor would it have been very onerous to recompense them sufficiently for their expenditure of time and talent.

We can easily conceive, however, that, supposing these preliminaries to be adjusted, a great difficulty might still remain; the difficulty, on both sides, of knowing how much or how little to concede. Ought the commissioners to be considered as representing the number of medical practitioners in their respective countries, which would be a tangible, though perhaps invidious way of estimating their votes; or ought they to represent the medical and pharmaceutical merits of London and Edinburgh, which would be almost as invidious, and could not fall into the domain of calculation?

In a united Pharmacopœia of this kind, it would perhaps be necessary to include many formulæ which, being favourites on one side of the Tweed only, need not be made compulsory on both; taking care to avoid having more than one formula for the same remedy. Thus the Parisian Codex contains numerous preparations, which are not compulsory, but which afford the advantage, that when the physician prescribes them, their name alone is suffi-

cient; and he need not torture his memory or his invention to combine the ingredients, well knowing that the mere title, like some magic form of words in a tale of wonder, will unlock all that he can desire. Jeremy Taylor somewhere expresses a wish that those religious teachers, whose zeal is far greater than their knowledge, should be restrained from preaching sermons of their own composition, and be confined to homilies; and we think it would not be a little comforting to the druggist, and not a little advantageous to the public, if ordinary practitioners could crib and cabin their prescriptions more nearly within the limits of official formulæ.

Our contemporary observes that physicians would be much aided in the composition of a pharmacopœia, if they could receive suggestions from those who are to make up its formulæ; and he draws a melancholy picture of the state of chemists and druggists in this country. A man may set up in this trade, with the most scanty smattering of the sciences which bear upon his occupation, and however small may be his acquaintance with the language and meaning of physicians' prescriptions. This is true enough, but yet there is no deficiency in London, and we presume none in Edinburgh, of druggists well qualified to give excellent hints to the compilers of the code by which they are to be governed; for here, as elsewhere, the legislative is very frequently and very properly guided by the executive power. We must acknowledge, however, that the want of a systematic education among our druggists necessarily lessens the number of such skilful advisers, and is perhaps the reason why we have to "search in vain among our pharmacutists for names as distinguished in science as those of Sertner, Buchner, Robiquet, Pelletier, Guibourt," &c. The remedy proposed by the Edinburgh Journal is an improved

education to be forced upon the druggists by law; it allows, indeed, that in these times interference with free trade is not popular, but thinks that the interest of the public and the profession should cause this unpopularity to be disregarded. We doubt whether any scheme for the regulation of druggists would meet with favour in parliament, unless it made part of a more general bill for the new-modelling of the whole medical profession. And who is there capable of drawing such a bill? Or who of sufficient influence to get such a bill passed, if it were drawn? On the other hand, it is clear that if the strange verdict stands, which was given the other day at Liverpool, in the case of the Apothecaries' Company *v.* Greenough, the famous act of 1815 is virtually repealed in favour of the uneducated druggist; so that a new statute will be required either to improve the dealer in drugs, or to prevent his competing with the apothecary. But we should imagine that the verdict will not be held good in the Court of Queen's Bench.

The Edinburgh reviewer turns with gratification to the tests, the introduction of which into the Pharmacopœia was proposed by the Northern to the Southern College. Their application is not confined to chemical articles, but extends to many vegetable substances. Thus, when gamboge is pure, "a decoction of its powder cooled is not rendered green by tincture of iodine, but merely somewhat tawny" (*Ed. Pharm.* p. 13), showing that it has not been adulterated with starch. The best catechu yields to sulphuric ether 53 per cent. of tannin dried at 280°, and the worst affords 28 per cent.

The powder of conium, when triturated with a solution of potash, exhales a powerful odour of conia; and the outer surface of cusparia is not turned dark-green, nor its transverse fracture red, by nitric acid. This test distin-

guishes the true from the false angustura bark, as the reviewer observes; or, in other words, cusparia bark from that of the *Brucea antidysenterica*; the latter, as it contains brucine, is reddened by nitric acid.

Of olive oil, the College says, "when carefully mixed with a twelfth of its volume of nitrate of mercury prepared as *Unguentum Citrinum*, it becomes in three or four hours like a firm fat, without any separation of liquid oil"; by which the presence of inferior oils may be detected. The oil of cinnamon is known from oil of cassia by its cherry-red colour, purely "cinnamomic" odour, and its being changed by nitric acid into a nearly uniform crystalline mass. *Copaiba*, among other characters, dissolves a fourth of its weight of carbonate of magnesia, with the aid of gentle heat, and continues transparent.

A decoction of powdered scammony, when filtered and cooled, is not rendered blue by tincture of iodine; thus showing that it is free from starch.

Such are a few of the applications of tests by the College, which, with the commentaries of the reviewer, of which we have made use, will be of service to the practitioner.

We ought not to omit to mention that there is a chapter of tests in the *Edinburgh Pharmacopœia*, giving directions for preparing oxalate of ammonia, nitrate of barytes, solution of the nitrate silver (12 grains to the ounce), solution of ammoniated silver, solution of nitrate of barytes (24 grains to the ounce), and solution of phosphate of soda.

Here is an instructive instance of the difficulty of reconciling theory and practice. In the list of articles of the *Materia Medica* the College says "*Aqua—Spring Water*. For pharmaceutical use spring water must be so far at least free of saline matter as not to possess

the quality of hardness, or contain above a 6000th of solid matter."

Theoretically, distilled water should be used in pharmacy, at least in a great number of its operations, but then this is expensive. Dr. A. T. Thomson suggests the use of filtered rain-water alone; but this, too, we apprehend, would be somewhat troublesome; that is to say, it would not be easy to procure such water in large quantities, at a small expense. And, lastly, springs so pure as the passage just quoted indicates, are not, we believe, very common.

We shall not regret our repeated examinations of the excellent work, of which we now take leave, if they induce our younger readers to impress their memories, while yet receptive of new facts, with an accurate knowledge of drugs and their best preparations.

MEMOIR OF DR. PHYSICK.

THE number of the *American Journal of the Medical Sciences* for May, 1839, contains an interesting biography of the late amiable and accomplished Dr. Physick, one of the most distinguished ornaments of our profession among our brethren in the west. We subjoin a short extract, which derives additional interest from its also relating to John Hunter:—

Fortunately for Dr. Physick, his father's connections in London were such, that he was enabled to introduce his son to some of the most learned and polished society of that great metropolis. An intercourse of this kind created for him an influence and gave him opportunities by means of which his cherished views were considerably promoted. All who ever saw Dr. Physick must have been struck with the exceeding dignity and courteousness of his manner. For this no doubt he was principally indebted to nature, though it must have been improved and confirmed by this association with the elevated society which he enjoyed whilst abroad. By means of this same influ-

ence Mr. Physick succeeded in securing the consent of Mr. John Hunter, then one of the most celebrated anatomists and surgeons of the age, to receive the subject of our memoir under his immediate care and tuition.

Dr. Physick considered this as the most important era in his professional life. He early became convinced of the extraordinary advantages which he might derive from this connection with Mr. Hunter, and proceeded accordingly to devote himself with the most ardent zeal to the study of practical anatomy and surgery. By dint of constant and unwearied application to his studies, aided also by a course of unceasing and untiring dissections, he soon made rapid advancement in the attainment of his objects, and what was also of much consequence, secured to himself the approbation and esteem of his great master. Mr. Hunter, in fact, was so well pleased with the zeal, industry and correct deportment, of Dr. Physick, that he took pleasure in acknowledging him as a favourite pupil, and bestowed upon him, with the most unreserved confidence, the full benefit of his advice and experience. During this period Dr. Physick attended regularly the lectures delivered by Mr. John Clark and Dr. Wm. Osborne, on Midwifery.

Dr. Physick continued to prosecute his studies with the most exemplary perseverance and industry, under the immediate superintendence of Mr. Hunter, throughout the year 1789. On the first of January, 1790, he was appointed House Surgeon to St. George's Hospital for one year, the usual period of that service in the institution. This appointment he owed exclusively to the patronage and influence of Mr. Hunter. The advantages of such a situation to the student of medicine, in facilitating his acquisition of practical knowledge and skill, were of the most important character; and were so well known as to cause the place to be sought after by numerous applicants, most of whom, from the circumstance of their English birth alone, it might be supposed, could have had an influence which would have rendered them successful competitors against a foreigner for the place. Here were exemplified in the most happy manner the important advantages which Dr. Physick derived from the favourable impressions which Mr. Hunter

had imbibed respecting his general worth, his talents, and his acquirements. These considerations induced Mr. Hunter unhesitatingly to exert the whole of his influence in behalf of Dr. Physick, with what effect has been stated.

A few months after this period, Dr. Physick had so severe an indisposition, that Mr. Hunter became alarmed about him, and was on the eve of insisting upon his return to America. This attack, no doubt, was principally owing to the laborious life which he led, and the close confinement to which he subjected himself. Providence, however, for its own wise and beneficent purposes, thought proper to restore him to health, to the great delight and gratitude of his parents and friends.

It was during the period of his remaining at St. George's Hospital, that Dr. Physick acquired a vast deal of that surgical skill and dexterity which laid the foundation of his subsequent greatness. Having his whole time occupied in administering to the wants of such unhappy objects as were suffering from the effects of accidents or disease—being constantly engaged in applying the necessary bandages and dressings to fractured bones, dislocations, wounds, and injuries of every description, and seizing hold, as was his invariable custom, of every such opportunity of making himself minutely acquainted with the most perfect manner of performing these services—he soon became remarkably expert in all his manipulations, and acquired a degree of experience which increased greatly his stock of practical knowledge. He indeed exhibited a degree of neatness and dexterity in the application of bandages and dressings never excelled probably by any other surgeon.

During the period of his services in this institution, he learned also the manner of constructing and contriving several kinds of instruments and apparatus, which he subsequently was the first to introduce into this country, to the great benefit of our art.

An anecdote frequently related to me by Dr. Physick, connected with his early appointment to St. George's Hospital, I may be pardoned for mentioning here, notwithstanding it has already been promulgated from another source. His success in obtaining this situation caused some slight degree of dissatisfac-

tion on the part of some of the disappointed applicants, who conceived that their claims for the situation were stronger than his. In consequence of this, Dr. Physick perceived that they evinced uncommon curiosity respecting his manner of discharging his duties, and were disposed to scrutinise his actions with the greatest strictness. A short period after commencing his services, a patient was admitted into the hospital with dislocation of his shoulder; the head of the humerus being lodged in the axilla. Fortunately the accident was quite recent. It so happened that at the time the man was admitted, the whole class were in attendance at the house. They, of course, were exceedingly anxious to witness the manner in which the reduction would be effected, and Dr. Physick was well aware that his method of restoring the bone to its natural situation would be severely criticized. He directed the patient to be seated upon a high chair, and then proceeded to examine the injured shoulder, questioning the man as to the manner in which the accident had occurred. Whilst making these inquiries, he placed his left hand in the axilla, and taking hold of the lower end of the humerus with his right hand, he made all the extension in his power; then suddenly depressing the elbow of the patient, he dislodged the head of the bone, which glided instantaneously into the glenoid cavity.

In relating this incident, Dr. Physick never assumed to himself much merit for his success, but rather ascribed it, in a great degree at least, to the favourable nature of the case. His characteristic modesty, however, induced him to underrate his services; his success was doubtless principally owing to that unrivalled address and dexterity of which he subsequently proved himself to be so complete a master. The treatment of this case produced the most happy influence in promoting the interest and comfort of the doctor during the remainder of his stay in the hospital. He stated that from that time forward he always enjoyed the uninterrupted regard and respect of the medical class.

In January, 1791, the period for which he had been elected to St. George's Hospital having expired, he quitted the institution, carrying with him the warmest testimonials, from its proper authorities, of his medical qualifications,

and also of his general good conduct. They went so far as to declare, that instead of considering him to lie under any obligations to the institution, they considered the institution indebted to him for the many benefits he had conferred upon its unhappy inmates, and for the useful results which had been produced by his singular zeal and abilities. He now received his diploma from the Royal College of Surgeons in London.

Soon after leaving St. George's Hospital, Dr. Physick received from Mr. Hunter a mark of respect and esteem which was in the highest degree gratifying to him, and more particularly so as it furnished conclusive evidence of Mr. Hunter's entire confidence in his professional skill and attainments. Mr. Hunter invited him to take up his residence with him, to become an inmate of his house, and to assist him in his professional business; he also held out inducements to him to establish himself permanently in London.

Notwithstanding the tempting nature of these offers, and the great advantages which Dr. Physick might have derived from accepting them, it did not comport with either his own desigus, or those of his father, that he should exile himself from his native country. In accordance with the plan previously laid down for the completion of his medical education, he was to visit Edinburgh, in order to graduate in medicine in the University of that city. He, however, gratefully accepted Mr. Hunter's invitation to reside with him until this period should arrive; and accordingly he remained with Mr. Hunter, and assisted him, not only in his professional business, but also in the prosecution of his physiological experiments, and the making of anatomical preparations, until May, 1791, when he took his final leave of London. I may notice that his father had, previously to this period, returned to America.

The parting between Mr. Hunter and Dr. Physick was painful to the latter to an extreme degree, and certainly the most distressing event which occurred to him during his stay in London. The ties which bound him to Mr. Hunter were of no ordinary description. Mr. Hunter had not only extended towards him the warmest friendship and regard, but had also conferred invaluable benefits upon him, by giving him the advantages of his powerful aid and in-

fluence, and by promoting, by all the means in his power, his medical researches. These obligations could only be acknowledged on the part of Dr. Physick by the most sincere and ardent devotion to his beloved preceptor; and in fact the admiration felt for Mr. John Hunter by Dr. Physick amounted to a species of veneration; he never ceased to consider him as the greatest man that ever adorned the medical profession. Could his honoured master have been permitted to witness the closing career of his pupil, he would have felt himself amply recompensed by the rich harvest of fame and usefulness which the latter had gathered, in consequence of his valuable aid and instructions.

SCIENTIFIC MEETING IN GERMANY.

To the Editor of the Medical Gazette.

SIR,

It seems worth announcing to the practitioners and friends of the medical and physical sciences of England, that the Annual General Meeting of German Naturalists, Chemists, and Physicians, will be held this year at Pymont, the most ancient and celebrated mineral watering-place of Northern Germany, a medical sketch of which is to be found in Nos. 23 and 24 of the *Lancet*, vol. ii. 1837-38. Foreign visitors devoted to these branches of knowledge will find there not only the kindest reception from their scientific brethren, but also convenient lodgings, gratuitously offered to them by the sovereign, and by the principal citizens of the place. The first public sitting is fixed for the 18th September, the last for the 26th of the same month.

Without any other claim than that of scientific fellowship, I venture to beg you, sir, to allow the few lines above to find their way into the next number of the highly esteemed periodical published under your careful direction, and to accept on this occasion the most sincere respects of

Yours,

R. HARNIER, M.D.

Pymont, Sept. 1, 1839.

[We have great pleasure in granting Dr. Harnier's request, though it has reached us so late, that our readers must not lose much time if they wish to reach Pymont by the 18th. He will see that we have taken the liberty to correct a few foreign expressions in his communication. —ED. GAZ.]

VARICOSE CAPILLARIES.

To the Editor of the Medical Gazette.

SIR,

IN Dr. Hake's statement which appeared in the *MEDICAL GAZETTE* of August 24th, he refers to a letter which was written by me to Mr. Kiernan in answer to one I received from that gentleman, requesting me to state what I remembered of a conversation that took place between him and Dr. Hake during the inspection of an anatomical preparation, under the microscope, on an evening that I passed at his house. I could do no other than comply with Mr. K.'s request, and I can conscientiously assert that what I stated was as nearly as possible what passed on that occasion. In vindication of my own character I feel compelled publicly to state this, as Dr. Hake has to my surprise and regret denied the correctness of my statement. The dispute between these two gentlemen has taken a very serious turn, and has excited much attention; I therefore feel myself bound to be not less cautious in what I say than if I were placed in a witness box in a court of justice; nor would I on any account say one word inconsistent with the strictest truth, in favour of or against either of these gentlemen, and it is very painful for me to be obliged to make my present statement, as up to the night in question, Dr. Hake had acted with much kindness to me. When I saw Mr. Kiernan after having written the letter which appeared in your journal, he told me that he was very sorry he had been obliged to ask me to state what I knew of this business. I answered that, had he used Dr. Hake as Dr. H. had used him, I should have written a precisely similar letter to Dr. Hake, and it was my intention to have told this to Dr. Hake, if I had seen him.

I now proceed to make some remarks on Dr. Hake's statement. Dr. Hake says that he looked at the preparation "for some minutes;" I stated that he examined it for "about an hour and a half," and to that statement I adhere; and it certainly does occur to me that Dr. Hake was so deeply interested in the subject under his inspection as to be quite unconscious of the time he was occupied with it. Dr. Hake also says that he looked at the circulation in an aquatic plant "for a much longer time" than at the preparation; but Dr. Hake must certainly remember the following circumstance. After I had been examining the plant for some time I requested him to come and view the beauty of the circulation; his reply was "no, I can see that any time, I have some-

thing to look at here (meaning the preparation) that is much more interesting."

Dr. Hake also said, as I have stated in my former letter, that "he could sit and look at it all night." Dr. Hake says that Mr. Kiernan was "obstinately taciturn, and whatever remarks were made came from me (Dr. Hake)." I confess I am much astonished at this assertion, and the following observation addressed to me by Mr. Kiernan, by way of apology, in a great degree proves its incorrectness, and at the same time shews the interest they took in the subject of their conversation, and the time occupied in it. Mr. Kiernan said he was sorry, after inviting me to see him, to leave me to amuse myself, while they were looking at the preparation, and talking on a subject which did not interest me.

Dr. Hake states, that after examining the preparation in question, he asked Mr. Kiernan to show him some other preparations. I must state that no request of this kind was made by Dr. Hake; that the examination of that one preparation, and the conversation upon it, occupied nearly the whole of the evening, and that Dr. Hake's own words, that "he would be as silent as the grave," referred to the preparation he had seen, and not to any others which he had not seen; and that Mr. Kiernan did not use any words even like the following, "that no one living could find out what he had done"—"it was utterly impossible." Every one will admit that, had Mr. Kiernan used these words, it is not likely I should have forgotten them.

In my former letter, I said, "during the time—which was about an hour and a half—that Dr. Hake was examining it with the microscope, you (Mr. Kiernan) pointed out several different parts to him, one of which you said was disease in its most incipient state." On this part of my letter, Dr. Hake remarks, "but Mr. Kiernan did not point out 'different parts,' one of which was illustrative of disease in its 'incipient state,' as Mr. Powell intends to imply; he only made the preparation to shew the parts which were injected." To this I answer, that mine is a plain statement; that I did not intend to imply either more or less than I stated; and that Dr. Hake himself confirms what I stated, viz. that Mr. Kiernan moved the preparation to point out to him the "diseased parts," that is, the "injected parts."

I now repeat what I said in my former letter, viz. that Dr. Hake wondered Mr. Kiernan had not published it—that Mr. Kiernan was too careless about it—and that some one would certainly publish an ac-

count of the same subject before Mr. Kiernan. The word "it" twice repeated, and the words "same subject," obviously refer to the preparation examined by Dr. Hake, and cannot be applied to preparations which Dr. Hake says he asked Mr. Kiernan to shew him, and of which I never heard until I saw Dr. Hake's statement; and I shall never be able to understand how Dr. Hake could urge Mr. Kiernan to publish discoveries as his own, which Dr. Hake now says he himself made ten months ago in Paris. Nor shall I ever be able to understand how Dr. Hake could express such unqualified admiration of what Mr. Kiernan showed him, saying, that it was "the most important anatomical fact that had ever come to his knowledge," without giving the slightest hint that he had ever seen any thing of the same kind before. If he even had seen any thing of the same kind before, Dr. H. admits that, as we walked home together from Mr. K.'s, he expressed his fear that Mr. K. would be anticipated if he did not publish his discoveries soon—and by his discoveries, I understood Dr. Hake to mean the discoveries Mr. Kiernan had that night communicated to him; and he did not even then give me the slightest idea that he had ever seen, or even heard of, such things before; and when Mr. Kiernan told me that Dr. Hake intended to make public those discoveries as his own, I could not at first believe it, for I thought that Mr. Kiernan had misunderstood Dr. Hake, and I said "it must be a mistake." I may here add that Dr. Hake expressed so much admiration of the anatomical preparation he had seen, and so impressed was I with the effect produced on him by it, and by the anxiety he expressed that Mr. K. should shortly published his discoveries, that I told my family the next morning how delighted Dr. Hake had been with what Mr. Kiernan had shewn him.

I am fully aware how disagreeable this statement will be to Dr. Hake, and no one regrets it more than I do, but I feel myself bound in justice to the public, to Mr. Kiernan, and to my own character, to make it, and I am sorry that some medical friend of Mr. Kiernan's, who would have been much more competent to the task, was not present, and who would have been able to do that full justice to that gentleman which I am incapable of doing.

I remain, sir,
Your humble servant,
H. POWELL.

24, Clarendon Street, Somers Town,
September 11th, 1839.

RESEARCHES IN EMBRYOLOGY.

REPLY TO T. WHARTON JONES'S

REJOINDER,

By DR. MARTIN BARRY.

[For the London Medical Gazette.]

T. WHARTON JONES, in a spirit more controversial than courteous, accuses me of "a pure invention" in alleging* that he had claimed priority of discovery as to the germinal vesicle and germinal spot in the mammiferous ovum. Let us see whether the facts of the case justify him in the use of such an imputation.

In the answer which T. Wharton Jones attempted to my former article, *MED. GAZ.* Aug. 24, 1839, he quotes the words of the Editor of that periodical, and adopts them as part of his own statement, not disclaiming or qualifying any thing therein alleged. Now the Editor, arguing on behalf of T. Wharton Jones, and speaking of the discovery of the germinal vesicle and spot, says as follows:—

"Hence, it appears that, like many other discoveries in science, the germinal vesicle of the mammiferous ovum was discovered about the same time in this country and on the continent. But it will be seen from Mr. Jones's memoir, that he had investigated the subject so fully and successfully as to be able to give such a description of it as is only to be drawn from the united labours of Coste, Valentin, and Wagner†."

He goes on to say, "*A comparison of dates will determine the mere matter of priority.*" Priority for whom? Not for Valentin—not for Wagner; but for T. Wharton Jones. How is this shown? The writer immediately tells us, that "Mr. Wharton Jones's observations were made in the beginning of September 1834, and his memoir read before the Royal Society, 18th June, 1835." Why are these dates given at all? To prove that which the writer said a comparison of dates would determine—the *matter of priority*: to prove, in fact, that T. Wharton Jones was not the last, but the first in the field,—and thus was the priority of discovery set up for T. Wharton Jones. This gentleman adopted, as I have said, the very words in which that claim was preferred, by republishing them as part of his own statement: and yet, in the face of all this, he now says, "This is a pure invention on the part of Dr. Barry"—and then adds, "I am not aware that any thing I ever wrote or said can be construed into such a meaning; and I do not perceive that you, Mr. Editor, in the remarks reprinted in the last number

but one of the *MEDICAL GAZETTE*, advanced any claim of priority in my behalf."—So much for T. Wharton Jones's denial of having advanced a claim of prior discovery—and so much for my "pure invention."

What I stated in answer to this claim of priority set up for T. Wharton Jones, was as follows: "Valentin and Bernhardt having published an account of the germinal vesicle in October 1834, and R. Wagner having sent to Müller's '*Archiv*' an account of the germinal spot in the same year, the discovery of both the vesicle, and the spot on the *inside* of it, was made known to the world previously to T. Wharton Jones's publication of his discovery of the germinal vesicle, and (the object he now supposes to have been) the germinal spot, in June 1835*."

As to observations made previously to publication, they must, of course, have been made previously in every case. T. Wharton Jones says he made his in September 1834: at what distance of time the observations of Valentin and Wagner preceded their respective publications, I know not; but I take it that the date of publication in each case is an authentic and correct criterion as to the question of priority: it is the public evidence of the fact: but as to the private transactions to which T. Wharton Jones alludes connected with his observations, I have now heard of them for the first time. Since, however, T. Wharton Jones now disclaims priority of discovery, I shall not dwell upon that part of the subject any longer.

But T. Wharton Jones states that this matter of the germinal vesicle and spot is only an episode to the original question, and then proceeds to say, "the main point in dispute, I beg it to be remembered, is contained in my communication of the 20th of July, the object of which was to disprove the assertion, that the study of embryology is 'one to which the attention of physiologists in this country has scarcely begun to be directed,' and to expose the unfounded pretensions to novelty, originality, and correctness, which Dr. Barry has introduced into both series of his '*Researches*.'" Here T. Wharton Jones has only repeated his first unwarranted construction of a passage of mine, which I explained in a manner that showed it did not bear the meaning he had chosen to put upon it. When he thought fit to repeat his attack, it would have been only candid in him to have accompanied it with my explanation. As he has not thought proper to do so, I here subjoin it:—

"I think it is obvious from the context of the passage cited, when taken in con-

* *MEDICAL GAZETTE*, Aug. 31, 1839, p. 848.† *Ibid.* for Aug. 24, 1839.* *MED. GAZ.* Aug. 31, 1839, p. 847.† *Phil. Trans.* for 1838 and 1859.

junction with what had preceded it—and which T. Wharton Jones has not quoted—that I meant to make no invidious allusion whatever to the labours of English physiologists on the subject of embryology in general, but that the remark objected to in that passage has a reference only to that portion of the science of embryology which regards the existence of the microscopic ovum in the ovary of mammals, as discovered by Baer, and upon which so little had been observed or written in this country, as compared with German research, that I thought—and still think—myself perfectly justified in stating, that the attention of physiologists in England had scarcely begun to be directed to it.*

Had T. Wharton Jones extracted more than a sentence isolated from the context, it would have shown that I had no intention of making a sweeping attack on British physiologists in reference to embryological science in general. I certainly never suspected, until I saw how my words had been misconstrued, that the most perverted ingenuity could have attributed to them a meaning so different from the true one.

As to the invidious allusion to what he is pleased to designate my “pretensions to novelty, originality, and correctness,” I shall only repeat what I before said†, that they “are before a tribunal on whose intelligence and impartiality I can rely, and from whose decision I will not shrink.”

ON POISONING BY ARSENIC.

ORFILA'S LATE DISCOVERIES.

THE subject of poisoning by arsenic, which is so important both in forensic and practical medicine, has just been re-examined and thoroughly solved—at least in its medico-legal relations—in some memoirs communicated to the Royal Academy of Medicine.

For this we are indebted to M. Orfila. No one doubts the immense importance of the medico-legal applications of these new researches; but the same cannot be said of their therapeutic value, for this has been contested.

As we are disinterested witnesses of the discussion, and have conscientiously studied all the details of the question, we shall examine it successively under its two aspects. We must observe, however, that in these new inquiries of M. Orfila, the therapeutic question is subordinate to the medico-legal one. We shall, therefore, touch but slightly on the first; but we shall go at length into the method by which arsenic is detected to a certainty, in

the bodies of those poisoned by it, and which, by the extension of which it is capable, will effect a fortunate revolution in toxicology, by ensuring the discovery of the greater number of poisons in the bodies of their victims; and this at every period of their crime, however advanced decomposition may have been, and in whatever manner the poison may have entered the living organs. Such, by anticipation, is the general enunciation of the results of these inquiries.

Hitherto, medico-legal examination in cases of poisoning has consisted chiefly in analysing the matters found in the stomach and intestines after death. Investigation was not pushed any farther.

But it often happens, however little the judicial inquiry may have been delayed, particularly when the dose of the poison has not been very large, that the most careful analysis does not detect the slightest trace of any poisonous substance, although poisoning has really taken place. This is particularly the case with arsenic, the special object of the late investigations, and must be so also with a great number of other poisons.

The cause of this failure is obvious enough; the poison has been removed by absorption from the alimentary canal. Whether the arsenic is swallowed, or applied to any other part of the system, the explanation is the same; unless the dose is very large, it disappears sooner or later, being carried by the absorbents into the depths of the system. This being granted, it is plain that if we confine ourselves to testing for arsenic according to the established methods, a skilful poisoner may escape the just punishment of his crime; for the jury is rarely satisfied except by the absolute detection of the arsenic.

Now, M. Orfila's method pursues the poison through every tissue of the frame, and detects it in the liver, the lungs, the brain, nay, in the last wrecks of organic matter. Here follows a proof; we select it from many others, first, because it is decisive, and also because it has been the starting point from which all the details of the question have proceeded.

On the 22d of December, 1838, a man died with all the symptoms of poisoning; but these are no more than probable evidence, as many natural diseases may be attended by the same symptoms. The body, therefore, was buried. A fortnight afterwards the public loudly demanded that the circumstances attending this death should be judicially investigated. The body was disinterred, and on examining the digestive organs, those anatomical lesions were discovered which usually follow poisoning by arsenic. It remained to be seen if chemical analysis would con-

* MED. GAZ. for Aug 17, 1839.

† Ibid.

firm the triple testimony borne by the symptoms of the disease, the organic lesions, and public opinion. Skilful experimenters tested and tested again, according to all the rules of science, but in vain; not an atom of arsenic was detected, and the corpse was again buried.

Meantime, the moral proofs of poisoning became stronger every day. M. Orfila was officially consulted, and, by his advice, the body was again disinterred, in April, about four months after it had been originally buried. The remains of the corpse were sent to Paris to be again examined. It is easy to imagine the state of the internal organs in a subject which had rapidly sunk under its symptoms, even if it did not perish by a violent death; which had been buried and disinterred twice in the space of four months; which had undergone all the minute trials of a judicial inquiry, as well at the hands of the chemists as of the physicians; and which, in conclusion, was exposed to the continual joltings of a post-chaise during a journey of eighty leagues. In fact, the stomach and intestines no longer bore any trace of organic structure, and all the other parts were more or less disfigured. It was to this mass of flesh, almost shapeless, and half decomposed, that M. Orfila had to apply his new method. This memorable experiment was performed in the presence of MM. Devergie and Lesueur, and with their assistance. The result did not disappoint the celebrated forensic physician; he demonstrated the presence of arsenic in the liver and the limbs of the victim; and it was even detected in the cask which had been used to preserve the remains. Let us now mention in what this method consists, how it is practised, and on what its success depends.

Arsenious acid, when introduced into the stomach, or enclosed in the subcutaneous cellular tissues, is absorbed, and mixing with the blood, enters every organ. When it is finely powdered, and placed on the subcutaneous cellular tissue, only one or two grains are absorbed, whatever may be the quantity used; and this small quantity is sufficient to kill dogs of different sizes. More of it is absorbed when it is introduced into the digestive cavity.

The cases of poisoning which have hitherto occurred in man show that arsenic acts in the same manner that experiment shows it does upon dogs, except that a greater quantity is required to produce death in man. The mode of action of arsenic being thus determined, in reference to the parts to which it is applied, to the passages through which it makes its way, and the quantity which is required for poisoning, M. Orfila meets the question of the extraction of the poisonous substance, in his

ordinary way, by experiments and facts. He first shows that it is possible to obtain metallic arsenic from the portion which has been absorbed; and next, that it is indispensable to have recourse to this extraction when the poison has not been found in the alimentary canal, nor in the matters vomited, nor in the other parts to which it may have been applied; for if we confine ourselves, as has been done hitherto, to looking for arsenic in the matters coming from the stomach and intestines, we run the risk of finding none, either because none remains in the digestive tube, or because the matters vomited have been removed; while the metal may always be obtained from the portion of the arsenious acid which has been absorbed, as facts and experiments continue to show. This poison, adds M. Orfila, may be detected by properly treating a certain number of muscles, or a single viscus, previously dried, particularly if the viscus is very vascular; but it is better to act upon the whole corpse, or at least on half of it, as the quantity of arsenious acid which has been fatal is too small for us to hope to detect it beyond the reach of doubt, if we treat only a single viscus, or an inconsiderable portion of the muscles and bones.

Moreover, arsenious acid can be detected in the blood obtained by bleeding the patient, provided there are several ounces to examine. In this point of view, at any rate, bleeding would be highly useful, by facilitating the inquiries of justice. We shall afterwards say what we think of its utility as a therapeutic agent.

We have just seen, on the one hand, how arsenious acid may be introduced into the system, and on the other, what becomes of it and by what line of proceeding it is to be detected; it remains only to show the method of extracting it. M. Orfila proves by the accumulated results of cases and experiments, that the best method of obtaining the metal consists in boiling the whole body in distilled water for six hours, in precipitating the impregnated fluid with sulphuric acid, then removing the arsenic from the sulphur which is deposited, mixing the decanted and filtered liquid with solid azotate of potash (nitre), evaporating the mixture to dryness, and then incinerating the product: this is first to be treated with water, and afterwards with concentrated sulphuric acid, and then to be put into Marsh's apparatus, not in its usual form—for this is inadequate to the purpose—but as modified by M. Orfila. It would be disadvantageous to omit throwing down the precipitate with sulphuric acid, and to mix the liquid at first with the nitrate of potash, because, whatever we do, we always lose a portion of the arsenious acid while burning the

collected matter with the nitre. The loss will be evidently much smaller if we begin by removing from the fluid all that sulphuric acid can precipitate, and only treat with nitre the liquid which covers the precipitate.

It is proper to add that we lose but little arsenic if we burn the organic matter after having diligently mixed it with the dissolved nitre; while much less is obtained if the mixture of the animal matter and the nitre has been made in a mortar. The loss is still more sensible, if incineration has been performed after Rapp's method.

The body is to be cut into pieces, and may be conveniently boiled in large cast-iron cauldrons, or in copper ones, if the verdigris is carefully removed; and a very clean iron pan, or a Hessian crucible, may be used for the decomposition of the animal matter by the nitre.

In places where, for want of utensils, the examiners do not undertake all these investigations, it will always be possible, and, indeed, indispensable, to boil the body in a large cast-iron or copper cauldron, for six hours, with distilled water and ten or twelve grains of solid potash prepared by alcohol; and then evaporate the fluid to dryness, after having passed it through fine linen, while still lukewarm. The solid product may afterwards be conveniently submitted to the necessary tests. Lastly, the presence of arsenious acid in a human body with which it has not been placed in contact, provided its existence has been demonstrated by boiling the corpse cut into pieces, in distilled water, for six hours, without the addition of an acid, incontestably proves that the poison has been taken during life; for numerous experiments have shown that the bodies of those who have not been poisoned with arsenic, when treated in the same manner, furnish no trace of it.

The chief object of the investigations which we have just analysed is to detect the presence of arsenic, either during the illness of the patient, or after his death; and we are compelled to conclude that M. Orfila's new method of investigation, joined to his improvements of the old ones, makes it impossible henceforth to miss the tangible proof of arsenical poisoning; so that those who have committed such a crime can never again escape the vengeance of the law.

But there is another duty, of which the medical jurist must not lose sight; it consists in preventing the judges from committing an irreparable error, by showing beyond all doubt, that the poisonous substance discovered in the living or dead body has been really introduced by a criminal hand, and that it can neither have

been naturally produced in the human frame, nor artificially developed by the action or reaction of the numerous agents employed in testing.

M. Orfila has not overlooked the importance of this task. He first inquired whether the human body contained arsenic among its chemical principles; under what form it appeared; and whether it was possible to distinguish it from arsenic introduced from without. These points having been cleared up, he examined the conditions of the purity of the tests used, and fixed rules by which we may be assured that the arsenic obtained is neither derived from the reagent, nor the vessel, nor from the earth where the corpse may have been long deposited.

M. Orfila has ascertained the existence of an arsenical compound in the human body. This compound, which he believes to be arseniate of lime, is found in a small proportion in the bones, and perhaps in other tissues. This important fact might make one fear that the occurrence of a natural salt of arsenic would affect the results of our analysis, and thus condemn us to a lamentable state of doubt as to the perpetration of the crime. It is fortunate, however, that the experiments of our great medical jurist have cleared up this fearful dilemma; for they have proved that the natural arsenical compound is not soluble in boiling distilled water kept neutral; while, on the contrary, poison introduced into the system is dissolved and consequently disengaged by this menstruum. The reagents employed in these inquiries are the sulphuric and azotic (nitric) acids, potash prepared by alcohol, azotate of potash (nitre), water, iron, and zinc. M. Orfila shows that the sulphuric acid of commerce sometimes contains arsenic in the state of arsenious and of arsenical acid, which might lead to error; but he also teaches the means of purifying it. The same may be said of nitric acid, if it has not been distilled over nitrate of silver. The potash used in these examinations never contains any; the iron and zinc may contain some, but it is easy to test them beforehand, and free them from it.

The instruments used in these investigations are cast iron boilers, porcelain capsules, Hessian crucibles, flasks, and test tubes. The boilers will never yield any arsenic to the fluid that they contain, provided it is kept neutral by the addition of potash prepared with alcohol. The porcelain capsules, the flasks, and the tubes, never yield arsenic; but it is necessary to rinse them with an alkaline solution when they have contained arsenical substances.

Lastly, some earths contain arsenic, and may thus make medico-legal examinations

more complicated. However it is easy to test them, and to distinguish the particles of arsenic which they afford from those furnished by the body.

To sum up: the important inquiries of which we have given a short abstract, authorize us to conclude that poisoning by arsenious acid will in future be recognised under all circumstances; and that it will be ascertained without the chance of being confounded either with the presence of arsenical salts naturally existing in the human body, or with the accidental occurrence of arsenical compounds in the tests or instruments used, or in the soil where the body has been buried. In other words, in the memoirs that we have just analyzed, poisoning by arsenious acid is examined under every aspect, and illustrated by such an apparatus of cases and experiments that the irresistible authority of the best demonstrated truths is stamped on the method of which a particular application is described.

To complete this analysis we will add a few words on the employment of venesection in the treatment of poisoning by arsenic. In the first place, is bleeding indicated? It is not long since antiphlogistics were thought to be universally indicated; while, at present, another extreme prevails, and they are rejected almost every where. This is so much the case, that after having formerly combated the absurdity of treating every disease by this method alone, we have now frequently to contend in favour of these powerful agents. Arsenical poisoning is a striking instance in point, yet discrimination is necessary in this as in every other case. If it is meant that in this kind of poisoning bleeding is indicated in every patient, in all circumstances, and in all the phases of its course, the answer is obvious; but no one, we believe, goes so far as this. On the other hand, if any one denies that bleeding is a means of lessening the consequences of this poison, and asserts that it necessarily hastens the catastrophe, and that we ought instead to use stimulants at every stage of the case, he commits a palpable error, which is every moment refuted by facts.

The length to which this article has extended does not allow us to enter into the details of the treatment, which too often is useless.

Before we discuss the different points of this important question, we shall wait till the new experiments projected by the committee of the Academy have thrown some light on the difficulties by which it is still surrounded.—*Gazette Médicale*, Aug. 17th, 1839.

RHEUMATISM OF THE UTERUS

IN PREGNANCY AND PARTURITION.

THE three following cases, which afford some evidence in favour of the existence of this affection, are from a memoir by M. Dezcimeris, in a late number of "*L'Expérience*."

J. D. aged 33, during her fourth pregnancy, had in consequence of a chill four weeks before the end of her time, a tense lancinating pain in the uterus, with fever. Diaphoretics diminished this pain, but it was replaced by others, which fixed some times in the upper, and sometimes in the lower extremities. During delivery, the uterine contractions were extremely painful, and from the first day they drew shrieks from the patient without producing the least dilatation of the orifice. The uterus could not be touched without causing most acute suffering; but bleeding and fomentations soothed these pains, and brought on true labour pains, and the accouchement was completed in a short time.

After three days the rheumatismal pain of the uterus reappeared, and required bleeding, ammoniacum, and calomel. Suddenly the pain ceased, and the disease established itself in the muscles of both fore-arms, preventing the patient from holding her infant; and they then disappeared from those parts and fixed on the left knee. All indisposition then ceased in the rest of the body, but the knee swelled and was intolerably painful. Numerous bleedings, calomel, and other means, only gradually diminished these symptoms; but weakness and stiffness of the joint remained for some time, and required the use of crutches.

Q. R. aged 24, of a strong constitution, was received pregnant with her first child in the Maison d'Accouchement of Trèves; during the greater part of her gestation she had had to wash linen in a very cold room, with damp clothes on, and her feet in the wet.

Soon after her admission, (on the 26th of October) she felt pains, which seemed the preludes of labour, succeeding each other at unequal intervals, but producing only slight dilatation of the uterus, though they were very severe. On the 27th, the pains sometimes ceased for a whole hour. On the 28th, the os uteri was more than an inch in diameter, and the membranes were distended like a bladder within it; the pains were strong and frequent, at the same time that the movements of the fœtus were active and painful; in the afternoon the pains became weaker, and the orifice was a little contracted. On the 29th, the orifice was completely contracted, and the patient complained of a

severe pain in the right iliac region, and a sensation of weakness in the whole body. On the 31st, the abdominal pain continued, with head ache; the pulse, which from the commencement had always been frequent, was still so; there was not the least vestige of uterine contractions. The urine was red, and discharged with a kind of tenesmus of the bladder. The rheumatismal nature of the case was no longer doubted, and an infusion of calomel and valerian, with Hoffman's anodyne, was administered as a diaphoretic. On the 1st of November, the febrile heat and the sweat had rendered the night very restless; the headache continued, but all the abdominal pain had ceased, and the pulse had lost its frequency. On the 2d, the patient felt quite well. On the 26th and 27th the same pains of the abdomen returned again, but soon ceased, and on the 16th of December the case was terminated by a natural delivery.

D. K. aged 24, had been exposed to a great deal of cold and moisture. In the 6th month of her pregnancy she caught cold, and had rheumatic fever with cough, and tearing pain in almost every part of the body, and especially in the sacral and pubic regions. After eight days she came to the hospital with the following symptoms: stiffness in the back; lancinating pains in the chest; dry and painful cough; sense of tension in the sacrum, abdomen, and pubic region; loss of appetite; frequent febrile and small pulse. The fundus of the uterus was two fingers' breadths below the pit of the stomach; the abdomen was very sensitive on pressure. Infusion of calomel and acetate of ammonia, with hot fomentations to the abdomen, were ordered; after a copious sweat the patient was relieved, and in a few days was completely restored to health.

About a month afterwards she was delivered with the forceps. The pains in the abdomen and other parts returned after the accouchement, and continued for ten days, when they were replaced by pain and tension in the left shoulder; after three days these diminished, and the abdominal pains returned, but they were now promptly removed by antispasmodics.—*Gazette Médicale*, Août 24.

[We do not think the rheumatic nature of these cases quite so certain as M. Dezeimeris does; but the first and third are sufficiently remarkable to render the existence of rheumatism of the uterus a subject well worthy of consideration. Its tissue is certainly one in which this disease might be expected for a time to establish itself; but other evidence is necessary than that of the alternation of its pains with those of other parts.]

THE HOSPITALS OF PARIS.

As the Hôtel-Dieu at Paris, or at least a part of it, is now rebuilding, a large number of beds have been added to the other hospitals, to supply the temporary deficiency. A French journal having asserted, however, that there was a want of beds, the *Conseil-général des Hospices* has published an answer, which we find in the *Gazette Médicale* of the 31st of August. It appears that before depriving the Hôtel-Dieu of 5 or 600 beds, an adjoining house was prepared to receive 300 patients. They have been attended there since the early part of this year, and at present there are 125 additional beds at the Hôtel-Dieu itself, in the St. Charles's gallery, which is now completed.

New buildings have been added to the Necker, and to the Beaujon hospital. The Necker hospital used to contain only 140 beds, but now has 220, making an addition of 80, of which 30 are vacant.

The three new buildings (*pavillons*) at the Beaujon hospital contain 168 beds; two of these additional buildings have been occupied for a long time, and the third for several days. The foundation of a fourth will be laid.

Thus to make up for the temporary loss at the Hôtel-Dieu, we have
House adjoining the Hôtel-Dieu 300 beds.
Necker Hospital..... 80
Beaujon Hospital 168
(besides 56, which are to be in
the 4th pavillon.)

Ward re-opened at the Hôtel-Dieu 125

673

Moreover, a new hospital, containing not less than 600 beds, is to be built somewhere in the northern part of Paris; and was voted by the municipal council at their last meeting. Every question of art, of hygiene, and of convenience, is studied, so as to make it as perfect as possible; and next year, probably, this hospital, which is rendered very desirable by the increase of population, will bear witness that misfortune is not forgotten in the distribution of the funds destined for public benefit.

[We are glad to find that the number of beds is now so great, but it is plain that there may have been a deficiency at the time the complaint was made.—*Translator*.]

THE ALDERSGATE GENERAL DISPENSARY.

To the Editor of the Medical Gazette.

SIR,

I TAKE the liberty of sending you a copy of a letter which I published in the Times

of Saturday, and which I shall feel obliged by your inserting in the next number of your journal.

Yours obediently,
JOHN H. HOUGHTON.

To the Governors of the Aldersgate General Dispensary.

My Lords, Ladies, and Gentlemen,
I and other candidates for the office of Apothecary to your Institution having received a letter from your Collector, of which the following is a copy, I take the liberty of submitting it to your notice:—

85, Aldersgate Street,
Aug. 28, 1839.

Sir,—I shall remain at home this evening till nine o'clock, for the receipt of subscriptions.—I am, sir,

Yours obediently,
H. PIPER.

As I cannot conscientiously become a party to the means therein implied for obtaining the office, I beg to withdraw from the contest, and to return my best thanks to those governors who have kindly honoured me with their support.—I remain, my Lords, Ladies, and Gentlemen,

Your very obedient servant,
JOHN HYDE HOUGHTON.

14, Carthusian Street.
Aug. 30, 1839.

COLLEGE OF SURGEONS.

To the Editor of the Medical Gazette.

SIR,

As I know you are at all times willing to use your interest in removing any real grievances in our medical corporations, I venture to address you on the subject of the early hour at which the Library and Museum at the College of Surgeons are closed at present. As they are mostly frequented by young practitioners who are engaged at their own homes in the morning, and at the various hospitals generally till two o'clock or past, the present hour (four) of closing is so early that by the time they can reach the College so very little time is left, that a great many are on this account deterred from making use of these most valuable acquisitions. If they were to remain open till five o'clock, many would, I am sure, benefit by them. If the officers were to come an hour later, it would not be demanding more of their time than at present. Trusting that your noticing it may induce the Council to make such an arrangement.

I am, sir, &c.

A MEMBER.

Treatment of Gonorrhœa—continued.

THERE is a third mode of treating gonorrhœa, consisting of a combination of the two last; that is, a moderately antiphlogistic regimen at the commencement, and until the violence of the inflammatory action has been subdued. The antiphlogistic measures consist essentially in the exhibition of laxatives and diluents of a mucilaginous nature. When the pain and irritation of the urethra have been subdued or greatly abated, recourse is to be had to stimulating diuretics and astringents, to suppress the discharge, and probably this last method is that most in use; the details it is wholly unnecessary to reconsider.

It may now, perhaps, be asked what is the relative value of the different methods. With respect to the purely antiphlogistic treatment, I know of no bad consequences likely to arise from it. In the first place chordee can hardly occur under this plan, neither will there be much chance of inflamed absorbents, nor of sympathetic bubo. The chance of future organic stricture, too, evidently must be greatly diminished, because the active treatment prevents all those effects of inflammation in which those several consequences originate. The constant envelopment of the penis in the cold lotion will prevent painful erection; the blood-letting will prevent the

effusions of lymph and thickening which give rise to chordee and stricture, and will at the same time so reduce the inflammatory action, as to prevent the extension of it to the glands and absorbents. As the inflammation subsides, the discharge invariably abates; and I have known instances in which vigorous antiphlogistic measures at the very commencement had effectually prevented the disease from completely developing itself.

Now let us examine the consequences of the stimulating and astringent plan. One of the most frequent consequences is a total suppression of the purulent discharge without any reduction or abatement of the inflammation—on the contrary, more frequently there is a great aggravation of the inflammatory symptoms. These are immediately followed by strangury, hernia humoralis, inflammation of the absorbents, or chordee, one or more of which affections speedily ensue. Undoubtedly these immediate consequences do not succeed in every case, but unquestionably sufficiently often to render the practice generally objectionable. Nor are the local consequences confined solely to the urethra and penis; it often happens that the bladder, ureters, and even kidneys, become involved, and I have known instances of bloody urine after large doses of cubebs in an excited state of the urethra in an irritable habit.

With respect to the mixed mode of treatment, even here, if the adoption of the astringent plan be too early, severe consequences ensue, if not directly, ultimately, and at a remote period. Hence, we may have a renewal of the inflammatory symptoms, with suppression or retention of urine. As remote consequences of either the purely stimulant plan, or the moderate antiphlogistic, followed by the astringent mode of treatment, we may have chronic inflammation of the mucous lining of the bladder, in advanced life terminating in

catarrhus vesicæ, organic stricture of the urethra, and indeed almost all the serious consequences which we have already detailed as arising from unnatural irritations of the urinary organs in general.

But a question of less moment certainly than the ultimate consequences upon the health, presents itself here:—Which is the most expeditious method of cure? To this I would reply, that the stimulant and astringent method frequently suddenly suppresses the gonorrhœal discharges, but this is also attended with symptoms so violent, that we are often glad to restore it by poultices to the glans, and by the adoption of every other means calculated to effect this, and we have reason to be well satisfied if they prove successful. The antiphlogistic method is never attended by such consequences, and, therefore, so far will prove the speedier method. With respect to the mixed treatments described above, I was desirous of examining their relative effects, and, therefore, some years since, when in charge of a military hospital, where the facilities for such were great, I selected the first twenty cases of gonorrhœa, and taking them alternately I treated one half on the purely antiphlogistic mode, and the other half by the mixed method. The average duration of the symptoms in the first set was from seven to nine days; in the second it extended to twenty, and many had a purulent discharge for even thirty days or more*. From these facts, and others which I could readily adduce, I am inclined to believe that stimulants and astringent injections, independent of their ultimate effects, are calculated, after a certain period, to excite, or at all events to keep up, a purulent discharge from the urethra; for I have frequently found that a gleet, generated or occurring during the use of an astringent injection, often disappeared spontaneously on discontinuing its use. Upon the whole, therefore, I should recommend the purely antiphlogistic plan as at least the most innocent, but also, in my judgment, the most speedy and effectual. In all cases, whatever plan of treatment you may choose to adopt, examine the urine, and if you find this unnatural, or in any way seriously deranged, you may depend upon it that the antiphlogistic and sedative plan of treatment is the only safe one in such cases.

With respect to certain adventitious or consequential symptoms, I do not think it necessary to consider farther either their nature or treatment here; and indeed I have dwelt perhaps longer on gonorrhœa than may seem consistent with the legitimate subject of these lectures. But I

have seen so many serious urinary affections which could be distinctly traced to former though remote gonorrhœal affections, and the irritating treatment, that I considered I should have left the subject imperfect and incomplete if I had omitted to bring it under review.

Of the removal of calculi from the bladder.—This subject, though one of very great importance, yet perhaps is not of such interest to the present subject as to render its consideration at any length necessary. The question, in a medical point of view, resolves itself into whether a removal should be effected. If so, when? and lastly, by what means? The operation of lithotomy should, generally speaking, be performed immediately, if the calculus—no matter what the kind—occur before puberty. It should also be performed if there be a calculus, and the phosphatic diathesis be distinctly present, or if the urine be loaded with pale or white-coloured lithate of ammonia.

In cases of calculus before puberty—no matter what the variety—its removal from the bladder appears to be not only judicious but absolutely necessary, as much and long suffering will be thus prevented, and also the risk at this period is much less* than at a more advanced age. But if the lithic acid diathesis be steadily present, the calculus small, the suffering moderate, and the general health good, then perhaps the operation may be delayed till puberty, because after this period changes frequently take place in the system which rather militate against a return of the disease. But where the phosphatic is the diathesis present, and firmly established, the removal of the calculus appears to be the only alternative.

We have in another part examined the possibility of reducing calculi, and it then appeared that all we could hope for was to prevent the further increase, and there would be great risk in leaving a patient under the above circumstances with a calculus in the bladder. And this observation applies to those cases in which the urine is loaded with pale-coloured lithate of ammonia, which appears to be the indication of the transition to the phosphatic diathesis, under which circumstances the re-establishment of the lithic diathesis is totally hopeless, while a calculus actually exists in the bladder.

There are two modes or methods of removing calculi: the one consists in cutting into the bladder, seizing the calculus,

* The foot note which should have been here was by mistake inserted at p. 898 of last No.

* The tables estimating the mortality from the operation of lithotomy in various situations, and at the different ages, may be consulted in either Marcel's or Prout's works, to which the reader is referred as furnishing the data from which the above inferences are deduced.

and then removing it with the forceps. This operation is now named lithotomy. There is another mode of extracting stone, and which may be said to have been lately revived under a new name — lithotripsy*. The relative value or the preference to be given to these two operations depends upon a variety of circumstances, which do not appear to me to be subjects proper for discussion in this place. It now remains that I briefly point out the apparatus necessary for examining the urine, the mode of conducting it, and the inferences to be deduced from the peculiar properties.

Apparatus and chemicals necessary for examining the urine.—The properties of matter may be divided into three distinct series or orders; namely, sensible, mechanical, and chemical. The sensible are those which are determined by the operation of one or more of the five external senses, and consist in the colour, transparency, opacity, odour, taste, tangible properties, &c. The mechanical properties in relation to the urine may be considered as comprehending merely quantity and density. The estimation of quantity may, generally speaking, be left to the patients themselves or their attendants; but the density is determined relatively by what is termed taking the “specific gravity.” The specific gravity, therefore, is nothing more than the measure of comparison of the density of a body in relation to some other whose density has been arbitrarily fixed and made the standard of comparison. Distilled water has been considered as the most convenient standard, and has been named unity or 1.000†. There are several ways of determining the specific gravity of fluids. If we could always determine the absolute weights of equal bulks, the specific gravities would be expressed. In fluids this is always easy enough. Thus if we fill a flask with distilled water, and find that the absolute weight of this measure or bulk of water, is exactly, subtracting the weight of the flask, 1000 grains, for instance, and that the same flask filled with mercury, weighs, making the same subtraction, 13500 grains, the specific gravity of mercury,

is to that of water as 13500 : 1000, or :: 135 to 1.000. For the specific gravity of urine, however, you may use these glass “hydrometers,” as they are called, and which are constructed upon the principle of Dr. Prout’s instrument which I present, and which you have seen so often used. All that is necessary is to immerse it carefully and perfectly clean, and free from any air-globules adhering to it: the number on the portion of the stem above the fluid will give you tolerably accurately the specific gravity compared with that of distilled water.

To observe the changes which occur spontaneously in the urine a few phials are necessary, in which portions of the different specimens should be placed, and allowed to stand for the necessary periods, from twenty-four hours to three days, and then we should observe whether it becomes turbid, or evolves carbonic acid, and such other phenomena. The odour, too, ought to be examined after standing, and compared with that evolved on being first passed.

For the purpose of chemical examination we require litmus paper, both of the natural blue colour, and reddened by a very weak acid, with turmeric paper. By these the acidity and alkalinity of the urine may be immediately determined. We further want the following chemicals:—

Nitric acid, to determine the proportion of urea, and also to determine or identify lithic acid.

Hydrochloric acid, to precipitate the lithic acid.

Oxalic acid, to precipitate lime.

Acetic acid, to identify the oxalate of lime, as formerly pointed out, and to acidulate when we wish to precipitate albumen.

Carbonate of potass, to fuse siliceous matters.

Solution of potass, to precipitate the ammonio and earthy phosphates.

Solution of ammonia, for the same purpose.

Solution of ferro-cyanide of potassium, to precipitate fibrin and albumen.

With the above are required one or two watch-glasses, or a platinum capsule; a microscope, or a Coddington lens, will answer the purpose of examining globules; a blow-pipe, and forceps with platinum points; a spirit-lamp, piece of charcoal, ether, and about half a dozen test tubes. These, with a tall jar for taking the specific gravity by the hydrometer, comprise almost all the apparatus essential for the purposes of a general or hasty examination, and may be readily packed up in a small portable case or pocket-book, so that a great deal may be determined at once.

The first question is, which of the uri-

* Si quando autem is major non videtur, nisi rupta cervice, extrahi posse, findendus est; cuius repertor Ammonius, οβιλιθοτόμος cognominatus est. Id hoc modo fit. Uncus injectur calculo ut facile eum concussum quoque teneat, ne is retro revolvatur, tum ferramentum adhibetur crassitudinis modicæ, prima parte tenui, sed reclusa, quod admotum calculo, et ex altera parte ictum, eum findit; magna cura adhibita, ne aut ad ipsam vesicam ferramentum perveniat, aut calculi fractura ne quid incidat.—*Cels. de Med. lib. vii. cap. 26.*

† For fuller details the reader is referred to the author’s Manual of Chemistry, where the subject is treated of more at length.

nary organs is the seat of the disease. If we wish to determine the operation of the the kidneys, we should select the urine first passed in the morning. That passed after a meal is often influenced by the state of the digestion; and where we wish to examine into the state of this function, such urine will often throw considerable light upon it. We have already pointed out that if the urine be diseased, but contain neither mucus, pus, nor blood, that we may conclude that the kidneys are the seat of the affection. If the urine contain mucus or pus, but be otherwise natural, then we may look upon the bladder as exclusively the seat. When the urine is unnatural, and contains mucus or pus, then both the kidneys and bladder are affected.

We next come to consider the inferences to be deduced from the sensible properties, and first—

Yellowish urine, such as this, almost invariably denotes jaundice. This colour, however, as well as the next, is best observed in a thin stratum and in an opaque vessel, such as a porcelain evaporating dish. If the stratum be deep, or the body of urine great, the whole presents a dark appearance, which completely obscures the yellow and pink tints.

Copper-coloured urine, and becoming remarkable transparent after cooling, is generally not only acid, but also indicates a strong tendency in such urine to deposit lithic acid in the crystallized form, as a *gravel*: this condition should not be neglected.

Cliron-coloured or *yellowish* urine remarkably transparent, and having an *acidulous* reaction, denotes a tendency to, if not actually the existence of, the *oxalate of lime* diathesis, and the deposition of this principle. When such exists great care and attention should be paid in observing the symptoms.

Pale straw-coloured, or of a *bluish green* tint, transparent when first passed and remaining so after, and having a smell of new mown hay, indicates the presence of sugar, and denotes the disease diabetes. *Opale-cent*, oily looking urine, having a peculiar animal odour intermixed with that of the sweet or wild briar, indicates almost unequivocally the *cystic oxide* diathesis. *Pale-coloured wheyish* looking urine, somewhat opaque even when passed, and with a strong urinous smell, is mostly *neutral*, but speedily becomes *alkaline*. These properties indicate a very strong tendency to deposit the *phosphates*.

Urine perfectly transparent when passed, but becoming cloudy on cooling, and precipitating a sediment, or becoming clear after filtration, shews an excess of lithate of ammonia. Urine cloudy when passed, or continuing so after filtration, but after

boiling becoming clear, and depositing a sediment, indicates the presence of mucus, pus, or blood, separately or altogether.

Quantity—By itself can hardly be said to indicate any peculiarity of disease; it is only in connection with other circumstances that it can be made subservient to any useful purposes; and enough has been already advanced upon this subject, which need not now be recapitulated.

Specific Gravity.—This is one of the most important characters of the urine, and is of itself almost sufficient to determine many points of great moment. A diminished or increased specific gravity must depend upon the proportion which the saline principles bear to the watery portion of the urine. Urine of a low specific gravity, as 1.010, if of the ordinary colour and transparent, and at the same time abundant, indicates a nervous or hysterical constitution of body, with a tendency to spasm. If of the same gravity, or even lower, and opaline or of a wheyish colour—such as you see here—there is a strong predisposition to phosphatic depositions, and such urine speedily becomes alkaline. Urine, however, of a phosphatic character, has often a much higher specific gravity, 1.020 or 1.025, and then it contains urea in excess, which, undergoing decomposition, becomes converted into carbonate of ammonia, thus increasing the phosphatic deposition. When the specific gravity is much above 1.017, and the colour deepened, inclining to red, or high coloured, as it is termed, it indicates a feverish tendency, with indigestion and derangement of the functions of the liver. Urine of a specific gravity, varying between 1.025 and 1.030, of a colour somewhat like ale, with a diuresis and frequent micturition, mostly indicates an excess of urea, and a strong tendency to diabetes. A specific gravity of 1.030 and above, transparent, and of a pale straw or of a bluish green colour, is an almost certain characteristic of diabetes. This urine will be found to have the peculiar smell of diabetic urine. If the specific gravity be only about 1.030, you will find that such urine is sometimes sweet, sometimes saline. These differences depend upon the sugar and the urea alternating with each other. When the urine is strongly saline or bitter, the urea will be found abundant, and the sugar proportionally deficient, and *vice versa*. In such cases there is mostly distinct diuresis; but as I have already shewn diuresis is not an essential of this condition. Such are the principal inferences from the sensible and mechanical properties of the urine.

Application of reagents.—By these means we determine the relative proportion of the soluble, or principles held in solution,

to the solvent; and from the reagent itself and its mode of action, we can often determine the nature or variety of the principle. If urine be of high specific gravity, and presents certain appearances, as already stated, we may suspect an excess of urea, which we must determine by means of the test. We have already shewn this sufficiently; but here I must give you a caution. In some peculiar conditions of the urine, the urea, though very abundant, will not crystallize with the nitric acid. The cause of this I have not been able satisfactorily to determine; still the fact is certain. Here is urine, the specific gravity of which is 1.022, and it contains an excess of urea. Here is a portion in the capsule to which nitric acid has been added, and, although this is the fourth day, yet no crystallization has taken place. But here is another portion of the same, which has been standing for about ten days, and you see there is a most abundant crop of crystals, far exceeding the proportion which ten times the whole contents of the capsule of healthy urine ought to furnish; but there you see it crystallizes at last upon the slow and spontaneous evaporation of the watery portion. Thus when you have a specimen of urine of high specific gravity, and for which you cannot otherwise account, you may discover an excess of urea* by the action of nitric acid aided by the urine being placed in circumstances favourable to its slow and spontaneous evaporation. In some instances I have found oxalic acid crystallize the urea speedily when the nitric would not—anomalies for which I cannot account.

Sometimes on adding nitric acid to the urine it becomes turbid, though previously clear and transparent: this arises from the presence of chyle or albumen, which are coagulated by the acid. Perfectly transparent urine also may be sometimes rendered turbid by a very small proportion of nitric acid; this turbidity depends upon a different cause. If the urine be loaded with lithic acid held in solution by an alkali, as ammonia or potass, the addition of nitric acid, not in excess, will, by combining with the alkali, liberate the lithic acid as a cloudy mass, which, as it slowly and gradually subsides to the bottom, assumes a crystalline appearance. Any of the acids will have the same effect; examples of which you see in the present instances.

Urine which is cloudy at first, but be-

comes transparent on the addition of the nitric, hydrochloric, or acetic acid, owes this appearance to the mechanical suspension of the phosphates. Such urine is generally pale coloured. This urine may be rendered almost transparent by filtering. If the precipitate collected on the filter be heated before the blowpipe its nature may be determined. If it fuses it is either the triple or fusible phosphate. If it merely blackens, then becomes white, without any alkaline properties, it may be looked upon as phosphate of lime. If it becomes alkaline it is probably carbonate of lime, which may be readily determined by adding a few drops of acetic or hydrochloric acid to the pulverulent matter collected on the filter: effervescence will follow the addition of the acid.

There is also a semi-opalescent appearance in pale-coloured urine, which may be mistaken, or at least its cause, by casual observers. It frequently deposits a light flocculent cloud, which may be mistaken for the insoluble earthy salts, but more readily for mucus. The acids do not render this urine transparent by dissolving the suspended matter; but, on the contrary, by increasing the specific gravity of the urine, render its suspension more permanent and complete. The alkalis, by precipitating the earthy salts, causes perfect transparency, for the subsiding salines carry down this suspended matter. In general, however, the urine becomes transparent on standing for twenty-four hours; and a light, bulky, flocculent cloud, occupying a considerable portion of the length of the jar, is seen occupying the lower portion, while the supernatant urine is above perfectly clear and transparent, unless it be very prone to decomposition, when the separation of the earthy phosphates renews the turbidity. Here you have examples of urine of this sort under each of the circumstances above mentioned. The spontaneous precipitate consists chiefly of *epithelium*, described in a former lecture, and the properties of which you may now again observe in the field of the microscope.

Lastly, there is another form of amorphous sediment mechanically suspended in pale-coloured, cloudy urine, and which might be confounded with the earthy salts—pale-coloured lithate of ammonia. Sometimes it constitutes the entire sediment; sometimes it is intermixed with the phosphates or other insoluble earthy salts. If hydrochloric acid does not dissolve any or the whole, the residue may be considered as lithate of ammonia; or, if the hydrochloric acid has been in too great excess, as lithic acid deprived of its ammonia. But it will be dissolved by pure potass or by its carbonate, which the

* If the nitric acid be in excess, that portion which has not been neutralized by the alkali will react upon the lithic acid the moment it has been disengaged, and will redissolve it. But this occurs only with the nitric acid; with all the others the lithic precipitates, and becomes crystalline.

earthy salts would resist—examples of which you may now observe. Carbonate of lime sometimes appears as an amorphous sediment: it can be easily recognized. Such are the principal facts which I wished to bring before you in reference to the examination of the urine, which, though in part a recapitulation, yet I thought of sufficient moment to attract your attention.

I have now, gentlemen, performed the task which I had proposed to myself at the commencement of these lectures. I may, perhaps, appear to have dwelt upon the subject at greater length than was necessary; but I think those who have favoured me with their attendance will acquit me of this charge. You must have witnessed enough to convince you of the extreme utility of attention to this class of diseases; and, if I have in any way contributed to heighten your zeal, to direct your operations, or in any manner to diminish the difficulties of such inquiries, I shall consider myself as amply compensated. I now beg, in taking my leave, to wish you every success—both in your present occupations, and in the future exercise of your profession.

VELPEAU'S CLINICAL LECTURES ON OPHTHALMIA.

By J. HENRY BENNET, B.L. & B.S.

Sorbón.

SEQUELÆ AND COMPLICATIONS OF KERATITIS.

Softening of the Cornea.—Gangrene.—Vegetations.—Abscesses.—Ulcers; the nephelion; the lymphatic or plastic ulcer; the bothrion; the epicauma or burning ulcer; the incised ulcer.

WHENEVER a tissue becomes inflamed, the cohesion that exists between the elements of which it is formed, is always more or less diminished, according to the nature of the tissue. It is not, however, to this phenomenon, which is too general and too well known to require comment, but to a peculiar form of softening of the cornea—a form which has not yet been sufficiently studied by authors, that I wish to draw your attention.

After inflammation of the cornea, the tissue of that organ softens in some instances to such an extent, that its form may be entirely altered. Thus, M. Mirault mentions a case in which the pressure of the eyelids caused the cornea to lose its convex form, and to become perfectly flat. It may be pressed forwards, and become elongated, so as to hang between the eye-

lids, as in a case of M. Stæbers. It may also project, and assume a conical figure, when the softening occupies the centre, or form a half transparent yellowish brown tumor. When the softening is only partial, and exists in different parts of the membrane, you will sometimes see on its surface several tumors, which appear, by their brownish colour, as if formed by the iris. Some cases have even been observed in which the softening of the cornea was so great, that its form changed under the influence of muscular contraction.

I have occasionally met with a species of softening of the cornea, which is but imperfectly known; indeed, I do not know whether it has ever been properly described. The cornea, the tissue of which has become extremely rarefied, forms between the free margins of the eyelids, a black, brown, or reddish tumor, projecting like a large staphyloma of the iris. This tumor is soft, insensible, and radiated. I first observed it in two women, nurses at the Hôpital de la Maternité, who were both affected with a chronic vaginal discharge. They were both of a lymphatic constitution, deteriorated by poverty and bad living, and had been attacked without any appreciable cause, with violent purulent ophthalmia. The flaccidity of the muscles, the copper-coloured appearance of the face, and the vaginal affection, led me to suppose that they were affected with syphilis, although they positively denied this to be the case.

These various forms of softening of the cornea are nearly always attended with serious consequences to the functions of the eye. The cornea being generally more or less deformed, even in the most favourable cases, vision is necessarily disordered.

When the disease does not depend on a specific cause, astringent collyria constitute the best medication. If, on the contrary, the affection appears to be of a specific nature, the treatment must be modified accordingly. Thus, in the cases I have just mentioned, emollient and astringent applications having failed, I had recourse to antisymphilitics. This treatment very soon arrested the progress of the disease, and, by then cauterizing with the nitrate of silver, the cure was completed.

Gangrene of the cornea, considered merely as the consequence of inflammation of that membrane, is of extremely rare occurrence, so much so, indeed, that I have never yet met with a case. Saunders, it is true, says that he has often seen keratitis followed by gangrene; but the cases he brings forward, as also the facts mentioned by Mr. Lawrence, appear to me to apply more to suppuration and softening of the cornea than to gangrene of that organ. Beclard and M. Mirault in France have, however, each published a case in which

the gangrene certainly appears to have been the consequence of inflammation. If we are to look upon all these cases as being really instances of gangrene, we may conclude, that, existing as a termination of keratitis, gangrene does not always give rise to the perforation of the cornea, as the superficial lamellæ only may be disorganized. An albugo, or leucoma, is, however, the necessary consequence of such a lesion.

After keratitis, *vegetations* are occasionally seen on the cornea. The situation, and aspect of these vegetations are exceedingly variable: sometimes they occupy the circumference of the cornea; sometimes they are only met with on the centre of that membrane. When they are situated near the circumference of the organ, they may either entirely surround it, or merely shew themselves on a segment of its margin. They advance more or less on the cornea, are of a greyish or reddish colour, of variable size, and have the flattened, granular appearance of the papillæ of the tongue. When they appear in the centre, their size is smaller and their colour less vivid. They may either be separate or clustered together.

The only rational mode of treatment that can be resorted to consists in excision and cauterization. If the vegetations are small, cauterization with the nitrate of silver is generally all that is required; if they are large and hard, they should be excised with a lancet or a cataract needle, and the exposed surface then cauterized.

Under the name of aphthoid papulæ I have sometimes described to you a species of vegetation which I have often observed, and which I think constitutes the *poros* or *porosis* of surgical writers. These papulæ, which are generally found at the union of the sclerótica with the cornea, occupying the extremities of the transverse diameter of the eye, have the appearance of a variolous pustule. M. Sichel, who looks upon them as indicating scrofulous ophthalmia, says, that they are never seen beyond the limits of the sclerótica. This assertion, however, is not correct, for I have seen them on the surface of the cornea, as far as two lines from its circumference. When they appear near the edge of the cornea they are hard, adherent, of variable size, of a pale red colour, and seem formed by the conjunctiva and the cellular layers immediately underneath. The summit of the papula soon becomes flattened, depressed, and assumes a yellowish tinge, having exactly the same appearance as the aphthæ of the mouth. Those which are met with on the cornea are generally narrow, and form the summit of a vascular triangle or pyramid. These papulæ

have been described by some authors as ulcers, although, in reality, they are but simple aphthæ; the excavation which they present not depending on loss of substance, but on thickening of their parietes. Mr. Wardrop says that they are most frequently met with in winter, and in cold wet weather; I have myself seen them in every season of the year.

The presence of these papulæ, which generally disappear with the inflammation which has given rise to them, is not attended with any danger. The astringent collyria, dry or liquid, nearly always prove sufficient to effect a cure; but cauterization with the nitrate of silver is decidedly the most efficacious remedy.

Abscesses.—When the cornea is inflamed, of a white, semiliquid, puriform matter occasionally takes place between the lamellæ of that membrane, as most of you, no doubt, have frequently had an opportunity of observing. There has been much discussion to ascertain whether this matter, which Scarpa calls *concrescible lymph*, is of a purulent nature or not; or whether, indeed, the cornea is susceptible of suppuration. In my opinion the dispute is merely one of words. Each tissue may be said to have its own mode of suppurating. The suppuration of a mucous or of a serous membrane does not, as you are well aware, furnish a pus exactly similar to that which is produced by the suppuration of cellular tissue or of the skin. Is it not, therefore, perfectly rational to allow that suppuration of the cornea may present peculiar characters—characters which are not met with in the suppuration of other tissues? In short, it is of but little importance whether the matter be called pus or coagulable lymph, provided the characters which it presents, when effused between the lamellæ of the cornea, be carefully noted.

These abscesses nearly always exist as sequelæ of interstitial keratitis. Their characters differ, according as they are situated near the sclerótica, or in other parts of the cornea. When they do not occupy the circumference of the organ, their form, size, and position, may vary considerably. Sometimes they are globular, sometimes they are flattened; their size is generally about that of a millet-seed: In some instances, however, they appear under the form of yellowish patches, of variable size, surrounded by an opaline areola. They may occur in any part of the cornea, but are more frequently met with in its lateral and inferior regions, than above the pupil. If the abscess is superficial it soon opens externally; if, on the contrary, it is deep-seated, several weeks may elapse before such an event takes place; nor does

always thus terminate. The posterior lamellæ of the cornea may be perforated, and the abscess empty itself into the anterior chamber; this is, however, seldom the case. It is generally considered advisable not to open these abscesses, but to allow them to open spontaneously. Such is certainly the most rational plan, but I am inclined to think, from several experiments which I have made, that the incision of an abscess of the cornea is scarcely ever attended with serious consequences; that it is not dangerous, as has been asserted, but merely useless. That the operation should be useless is easily accounted for, when we consider that the matter which forms the abscess, being half concrete, and extremely adherent to the tissue of the cornea, does not escape through the opening which has been made; but, when the abscess is of a certain size—when it is situated opposite the pupil—and does not seem likely to open alone, it is necessary to use the lancet, as its desiccation might give rise to a permanent opacity of the cornea.

When abscesses of the cornea appear near the sclerotica, they assume a semi-lunar shape, and have received the name of *onyx*, from the resemblance which has been found between them and the lunula which is seen at the attached extremity of the nails. Some authors have asserted that they are only met with on the inferior segment of the cornea, but this is not correct, as I have seen them on every portion of its circumference. These abscesses frequently terminate by resolution, but sometimes they extend, on the contrary, in such a manner as to give rise to purulent infiltration of the entire organ. They may open externally, in which case they are followed by a deep incised ulcer, or internally into the anterior chamber, thus giving rise to hypopyum. The treatment of this class of abscesses is the same as that of the preceding, with the exception that the use of the lancet seems really to retard the cure. Every thing must be done that is calculated to promote the resolution of the effused matter. The remedies which are likely to produce this effect are those which are employed in the treatment of acute keratitis.

Ulcers of the cornea constitute an important complication of keratitis, and have ever attracted great attention from ophthalmologists. They are generally the consequence, but may also be the cause, of acute inflammation of the cornea, and as a thorough knowledge of their various modifications may throw some light on the treatment, I intend to study them with care. On examining attentively the various ulcers which are observed, and on taking into consideration their

seat, and their mode of development we may, I think, establish five species, the characters of which are sufficiently striking to distinguish them easily from one another. In the last century, many more were described by surgical writers, but those which I am about to enumerate comprise all the forms of ulceration which are really met with in practice. They are as follows:—

The *nephelion*.

The lymphatic or plastic ulcer.

The *bothriou*.

The *epicauma* or burning ulcer.

The incised ulcer (*en coup d'ongle*.)

Were the depression occupying the summit of the papulæ, which I described when speaking of vegetations of the cornea, to be considered as an ulcer, we should have to admit a sixth species; but you are well aware that the papulæ in question are merely *aphthæ*, the product of diphtherical inflammation.

The *nephelion* is an extremely superficial ulcer, and generally appears on the centre of the cornea. It is seldom single, several ulcers of the same species being nearly always clustered together. There is also nearly always a slight effusion of lymph between the lamellæ of the cornea around the ulcer, which renders it extremely difficult to distinguish it from a nebula. If, however, you examine the cornea attentively with a lens, or even with the naked eye, you will find in the centre of the slight opacity one or more small excavations in the form of a cupola. This kind of ulcer, called by the ancients *achlys* or *caligo*, is principally met with in children and young people. It is rare in persons above thirty, and is never seen in those who are above forty.

When an abscess, or a collection of coagulable lymph formed between the lamellæ of the cornea, opens externally, the small wound to which it gives rise constitutes what has been called the plastic ulcer. This species of ulcer is more frequently met with in practice than any other. The size varies from that of a pin's head to that of a millet-seed. The edges are jagged, irregular, festooned, and the bottom is uneven. It is slow in cleansing, and the tissue of the cornea being consequently protected from the contact of the air, there is less photophobia or epiphora than in the other forms of ulceration. It is worthy of remark, that the opacity to which the plastic ulcer gives rise, is generally more extensive and deeper seated than that which follows other ulcers. When it is situated near the circumference of the cornea, it generally rests on the summit of a vascular patch of a triangular or

pyramidal form, the basis of which is on the conjunctiva. The vascular patch, which at first might be taken for pterygium, is sometimes thick and moveable; sometimes, on the contrary, it is thin, or seems to belong entirely to the cornea. The plastic ulcer is considered to be one of the characters of scrofulous ophthalmia. It is more especially observed, it is true, among young people and persons of a scrofulous constitution, but this is by no means a general rule. The numerous cases of the plastic ulcer which we have had lately, or have yet, in our wards, must have proved to you that it may occur in all ages and in all constitutions.

The *Bathrion* ulcer commences by a phlyctena, which, being nearly transparent, often passes unperceived. In the course of a day or two this phlyctena breaks, and is succeeded by an excavation. The ulcer which is thus formed may be either superficial or deep-seated. When it is superficial, it is generally of a circular shape; when it is deep-seated, it often assumes the form of a tear, with the point turned outwards. The bottom is transparent, and differs so little from the tissue of the cornea, that when the ulcer is superficial, it is often only by looking at the eye sideways that you can discover its presence. The small vessels which are distributed to the neighbourhood of the ulcerated surface, arise from the deep-seated vascular layer. These vessels are often larger and more numerous around the ulcer than on the sclerotic, and sometimes appear all to arise from a common trunk, which is plainly seen on the margin of the ulcer. The dread of light, and the shedding of tears, are carried to a greater extent in this form of ulceration than in any other.

The progress of these ulcers is rather singular; the vascular injection of the cornea and other tissues of the eye gradually diminishes, and at last disappears, as likewise the photophobia and epiphora. The ulcer, however, still retains the same excavated appearance, and often remains in this state for a considerable length of time; the slight cavity it forms may even become indelible, in which case the patient is continually exposed to a renewal of the inflammation.

In this, and in the preceding form of ulceration, the tissue of the cornea is sometimes entirely destroyed. When this is the case you will see a small bulla arise gradually from the bottom of the ulcer, until it slightly protrudes on the free surface of the cornea. The small tumor or myocephalon, which is thus formed, is owing to the hernia of the membrane of the aqueous humor, and must not be confounded with hernia of the iris, or the true myocephalon.

The *Epicauma*, or serpigineous ulcer, thus denominated by the ancients, and described by Ware under the name of abrasion of the cornea, at first certainly bears much resemblance to an excoriation of the superficial lamellæ of that membrane than to a real ulcer. It is often met with in acute keratitis, when it appears under the form of a slight abrasion of the cornea, sometimes several lines in width, which is generally situated near the circumference of the organ, and which gradually advances towards the centre, without, however, ceasing to be superficial. In some instances, I have known it occupy the entire circumference of the cornea, the central portion only remaining intact. Were I to be guided by my own experience, I should say that the superior half of the membrane is more especially the seat of this kind of ulcer. If the epicauma in this, its first period, be left to itself, it gradually sinks deeper into the tissue of the cornea, and at last assumes the appearance of a real ulcer. When there are several of these ulcers present at the same time, the aspect of the cornea is peculiar; it appears as if it were covered with facets. There is little or no vascularity of the subjacent tissue of the cornea, or of that which surrounds the ulcerated surface; the conjunctiva on the contrary is, generally speaking, considerably vascularized. There is, nearly always, considerable photophobia and epiphora; but the intensity of these symptoms varies with the depth and extent of the lesion. The pain, which is often severe, is superficial, and does not irradiate to the orbit. When the ulcer is healed, there remains a slight opacity of that part of the cornea on which it was situated, and vision is consequently more or less disordered; but this opacity diminishes with time, and sometimes disappears entirely.

The *incised* ulcer, although not separated from the other species of ulcers by the ancients, is well worthy of a separate description. It has been described with care by Mr. Lawrence, in his work on Venereal Diseases of the Eye, as a symptom of venereal ophthalmia; I have, however, often met with it, when I could not possibly attribute it to a venereal affection. This ulcer is nearly always found at the circumference of the cornea, near the sclerotic, in the same situation as the senile zone, under the form of an arc of a circle, from one to four lines in length, but scarcely ever more than a line in width. It has two lips or edges, which do not offer the same characters. The outer or sclerotic lip appears as if it had been cut perpendicularly, and is red and vascular, owing to its being formed in a great measure by the conjunctiva, which is thickened and injected. The

inner lip, on the contrary, is slightly bevelled, and remains at first perfectly transparent, unless there be suffusion of that portion of the cornea. In a short time, however, vascular filaments appear in the tissue of the cornea underneath and around the ulcer; you will even sometimes see vessels perfectly isolated in the ulcerated cavity. This kind of ulcer never advances towards the centre of the membrane; its depth, however, gradually increases, and the are which it forms extends progressively along its circumference. When there are several, they may unite so as to circumscribe and isolate the cornea entirely. The incised ulcer is always accompanied by photophobia and epiphora; these symptoms are, indeed, often very intense. It gives rise to vegetations of the cornea more frequently than any of the other species of ulcer.

The various species of ulcer, which we have thus briefly examined, are nearly always the result of keratitis. They may, however, in some instances, be the cause of the inflammation of the cornea; as, for instance, when a metallic particle, flying into the eye, becomes implanted into the cornea, and, on falling, leaves behind it a bathron ulcer.

The characters which I have given you, if borne in mind, will always enable you to distinguish these ulcers from one another—a point of great practical importance in the treatment of ulcerated keratitis, for you must not suppose that the distinctions I have established are merely theoretical.

OBSERVATIONS

ON

COMPLICATED SURGICAL INJURIES,

INCLUDING GUN-SHOT AND OTHER WOUNDS.

By RUTHERFORD ALCOCK, K.T.S. &c.

Late Deputy Inspector-General of Hospitals with the Auxiliaries Forces in Portugal and Spain.

(As delivered in his Lectures at Sydenham College School of Medicine.)

[Continued from page 918.]

IV.—INJURIES OF ABDOMEN, PELVIS, AND GENITAL ORGANS.

Injuries of the abdomen—Consequences of superficial wounds—Case of fatal result—Sympathetic action of stomach—General symptoms and effects of all abdominal injuries—Absence of diagnostic signs to injury of particular organs—Lesion of stomach—Case of recovery—Wounds of intestines—Principles of treatment—On the use of sutures—Cases

of ruptured liver, spleen, pancreas, kidneys—Mere penetrating wounds—Sacculated ball in omentum—Knife wounds—Extraordinary case of recovery—Occasional consequence—Observations on treatment—Wounds of the pelvis and genital organs—Lesion of bladder—Urine not necessarily extravasated—Case of great injuries to bony walls of pelvis—Indisposition to extend inwards to cavity by inflammatory action—Two parallel cases—Dissimilar results—Principle illustrated by them—Simplicity of progress in injuries of genital organs—Cases of wounded testicles and urethra—Conclusion.

THE peritoneum is exceedingly prone to take on a high inflammatory action; hence all injuries from the parietes to the contents are of great importance. The same classification of these injuries will hold good as in those of the thorax; and, indeed, it not seldom happens that a mere superficial wound induces all the worst effects of the gravest injury. Take the following case as an example:—

Corporal Jones, October 1, 1836, was struck by a musket-ball, about an inch above Poupart's ligament, a little internal to its centre, making a horizontal slit of the integument, two-thirds of an inch in length. It appeared to have penetrated the fascia and muscles, and proceeded a little downwards and inwards. The finger was introduced the whole apparent length of the wound, and the iliac vessels distinctly felt; but no ball could be detected. The peritoneum seemed uninjured; no tendency to protrusion of the intestines, nor could they be felt by the finger.

Shortly after his admission, considerable reaction came on. A large bleeding was practised; an antimonial mixture, with a slight opiate, ordered, followed by a dose of castor oil, which, in a few hours, operated twice: after which he passed an easy night, and, on the succeeding morning, he felt no pain, tension, or tenderness of abdomen; pulse about 90; tongue slightly furred.

It is unnecessary to detail to you day by day the progress of the case; it is enough to say that, up to the fourteenth day, no one unfavourable symptom presented; wound suppurated, and was closing kindly; health good. On that day, however, he had a foul tongue; pulse was 66; skin dry and hot; bowels confined. Small doses of sulphate of magnesia were ordered; and, on the succeeding day, he was reported to have passed a very restless night; purging

and vomiting had supervened, and for the first time pain of the lower belly increased by coughing or pressure. An emollient cataplasm was applied to the wound; the patient was freely bled; and calomel and opium ordered every second hour.

17th.—The aspect a little improved, diarrhœa less frequent, and states that he felt a marked relief after the bleeding; pulse fuller, softer, 110; tongue loaded with brown fur; still pain on pressing the abdomen, but slighter than on the previous day; much thirst; no appetite; the pain referred to the umbilicus, and increased by the patient's turning from side to side.

V.S. ad 3xij. Contin. pilulæ.

18th.—Great inclination to vomit.

Acet. Morphiæ, gr. ½.

19th.—Pulse 104; the diarrhœa has ceased, and there is diminution of pain in the abdomen when pressed; sleepless; tongue foul; some tension of belly; countenance and lips of a slightly leaden hue; breathing hurried; and countenance anxious. Towards evening he became much worse.

20th.—The irritation and symptoms of peritonitis have disappeared in a great measure; some slight tension of the abdomen, but no pain on pressure or vomiting. The pulsations of the heart are quick, violent, and extending over a greater space than natural. Pulse small and quick; lips slightly livid; breathing more hurried; anxiety; and pain of chest near the region of the heart, to which he refers all his sufferings. In the morning, a quantity of green thin fluid was discharged without an effort from the stomach. He sunk and died on the 22d day.

On examination after death, great swelling and tension of abdomen was observed. The wound was unclosed. A similar fluid to that discharged several times before death, with little effort of vomiting, flowed from mouth and nostrils whenever the head was moved.

Cavity of abdomen.—Acute inflammation of the peritoneum generally might be traced; lymph had been effused in great quantity, and caused adhesion between the convolutions of the intestines. The adhesions were recent, and easily separated. Opposite to the wound there was a black circumscribed spot on the peritoneum, indicating approaching gangrene. Similar appear-

ances were visible on the peritoneal coat of the intestines, and in the intestines themselves. A large quantity of serum was also found effused in the cavity. The ball was searched for in vain, and the presumption was that it had not lodged nor penetrated farther than described by the examination with the finger.

The mucous membrane of the stomach, towards the pylorus, was more vascular than natural; that of the smaller intestines presented slight traces of inflammation. Serous effusion had taken place in the pericardium.

I prefer dwelling on this case to enumerating others; I shall, therefore, particularly direct attention to it, the more fully to impress on your minds the true principles of treatment to be adopted in wounds of the abdominal parietes.

There was here no opening into the cavity: it seems more than probable the ball had not even lodged; still it was in the close neighbourhood of the peritoneum, and it would not have seemed extraordinary, from the proximity of the wound and the serous membrane, if peritoneal inflammation had immediately set in; but, with the exception of a short period of reaction and general disturbance, immediately checked by the treatment, not even the remotest evidence of danger was afforded until the fourteenth day. Let this fact, then, impress you with a conviction of the necessity of a guarded diagnosis on the one hand, and the vigorous adoption, from the first hour, of all measures calculated to arrest or prevent the development of inflammatory action; and always remember, that abstinence, perfect repose, and a due action of the skin, bowels, and kidneys, are among the chief and best of preventive measures.

Passing on to the period comprising the fatal and inflammatory stage (from the 14th to the 22d day, a space of 9 days), you can scarcely fail to remark the sudden supervention of all the unfavourable symptoms, and how distinctly they marked the nature and intensity of the action. The first day gave simple pyrexia, a febrile action, hot dry skin, foul tongue, restlessness, confined bowels, &c.; the second pointed to the development of inflammation in the peritoneum in the lower portion of the abdomen, and in the mucous membranes generally of the alimentary canal. Thus, there was pain on pressure or coughing, re-

ferring to the serous membrane, while purging and vomiting pointed to the mucous tissue. The wound, which hitherto had been suppurating kindly, and gradually closing, immediately sympathized; the healing process stopped, and made not the least progress up to the date of his death. This also shows that, however much the wound might be the cause of all the mischief, it was remotely, not immediately; not by the extension of a bad action to the neighbouring serous membrane, but by some more subtle influence. This is the most remarkable feature of the case, and which I am most anxious you should not overlook, and thus pronounce your patient out of danger, because no peritoneal inflammation supervening for the first few days, and the wound gradually healing with a healthy action, the danger seems passed of any immediate and direct unfavourable action being communicated from the site of injury to the neighbouring cavity.

The serous effusion in the pericardium, and the corresponding effect on the heart's action towards the close of the case, I should attribute to that sympathy of action between all similar tissues throughout the body. Thus the peritoneum taking on the action of morbid effusion, the pericardium, possibly by the sympathy described, took on the same.

The treatment adopted in this case, slightly as it is indicated, is the one I would recommend. To correct inflammation of serous membranes, and to stimulate the absorbents, thus preventing accumulations of fluid, no medicine is so effective as calomel and opium combined, and employed in such doses as in ordinary cases in a few days will induce a gentle ptyalism. Bleeding was also resorted to at once, and subsequently guided by the states of the pulse; an occasional opiate of morphine to control irritability; emollient and tepid applications to the wound, with the use of gentle purgatives. These are the chief means, judiciously applied, on which I would have you rely for the relief of your patient under such circumstances.

One of the effects observed in this case is not unusual in all lesions of the abdominal cavity or parietes—viz. a sharp inflammatory action sympathetically developed in the stomach.

In all serious injuries of abdomen the stomach is generally implicated—

not always inflamed, but displaying by the constant ejection of the contents a morbid irritability developed to a great degree.

Penetrating wound of abdomen, producing sympathetic action of stomach.

Michael Dennany, æt. 34. Sanguineo-bilious temperament. Wounded Oct. 1, 1836, by a musket-ball, which struck him immediately below the sero-biculus cordis, and entered the cavity of the abdomen, near the edge of the diaphragm. Immediately succeeded by great distress and painful breathing. On admission a few hours after, the pulse was soft, rather quick, but not full; considerable tumefaction about the wound. Cold lotion was applied, and small doses of sulphate of magnesia prescribed. Spoon diet.

2d day.—Vomited, during nearly the whole of the previous night, a fluid of an intensely bitter taste, having all the appearance of bile. Distress of breathing great, and he was suffering much pain; pulse small and quick; skin cool; bowels confined; swelling about the epigastric region considerable; protrusion of the omentum.

R Magn. Sulph. ζ iv.; Pot. Carb. \mathfrak{d} j.;
Aque, ζ ij. M. ft. haust. cum cochl.
succ. limonis 3tiis hor. sumend. Barley-water.

3d.—Passed a restless night, and felt very ill. Breathing painful; tongue moist; tension of bowels less; not much pain on pressure; bowels open; no return of sickness.

4th.—He improved.

5th.—Better; not much pain; bowels soft; pulse small and not quick; tongue clean; respiration easy.

7th.—Had a better night than any since wounded; breathing free, and no pain during respiration; pain on the right side below the mamma; bowels open; pulse soft and tranquil; countenance improved; granulations were going on, and wound filling up; no protrusion.

From this period may be dated his permanent improvement and gradual recovery. Once or twice for twenty-four hours pain and uneasiness in stomach returned, all his other symptoms indicating injury or disease of lungs and liver. He was invalided in December of the same year, three months after receipt of injury, with the following note of his state:—

"Dec. 31st.—The wound, which is at the outer edge of the umbilicus, is soundly healed up, and no protrusion. He complains that he cannot and never has been able since wounded to lie upon his right side, from pain under the false ribs. He has always pain when he stoops, in the same place and in the loins. He has also night sweats, and a troublesome cough, which pains him from the site of his wound round to the spine; his expectoration is reported to contain some pus. From his account, and the symptoms, the ball would seem to have lodged in the right lobe of the liver, possibly having also injured the lungs. Pulse rather weak, but regular; appetite good."

This, as a complicated case, the exact nature or extent of the injury unascertained, and situated in the epigastric region, probably less distinctly illustrates the point under consideration than a more distant injury. This sympathy of the stomach is, however, rarely absent in any severe injury of the intestines, or even of the parietes; it is observed in strangulated hernia, and in all cases where there is a wound of intestine. It seems a wise provision of nature to prevent the stomach receiving matters, the passage of which through the wounded parts, or their effusion into the cavity, would be productive of mischief; nay, when the stomach itself is wounded, this rejection of all food, &c. conveyed to it ceases often at an earlier period than when an opening is made into a fold of intestine. Nature soon agglutinates the wounded part of stomach to the parietes, so that any fluids, instead of passing through the wound into the cavity, escape by the orifice from the body altogether.

As the abdomen incloses many and very various viscera, so are the injuries complicated in nature, not in their effects or symptoms, the varieties in these being less numerous and prominent than those resulting from injuries either of the head or chest.

Whatever the injury, general peritoneal inflammation; irritability of stomach; pain and tenderness on pressure over the abdomen; a small thready or wiry pulse, often of intermitting character, and generally exceedingly rapid—these, whatever be the viscera wounded, form the usual group of symptoms.

And I have not been able to satisfy myself of the certain lesion of any one

viscus, by the nature, order, or intensity of the symptoms of the case. If lesion of the stomach or of the intestines, the contents ejected by the wound often furnish an index to the nature of the wound. If the kidneys be injured, generally some indication is afforded by the urine, but not always; and the liver, spleen, pancreas, and even bladder, afford no certain diagnostic signs; such, as I have observed, on the contrary, have either been obscure in their indications, or variable in their character, and not seldom fail altogether in their appearance.

I have met with but one case of recovery from injured stomach, with rupture of its coats, but many are on record; the great proportion, however, are fatal, and more particularly when the wound is gun-shot; the parts do not so readily adhere and agglutinate; a sloughing action is more likely to result, and the contents of the stomach escape into the cavity, giving rise to fatal and uncontrollable inflammation. The gentleman I allude to, however, has perfectly recovered, after long treatment. I observed for a considerable time fluids escape from the stomach, but apparently prevented from finding their way into the cavity of the abdomen. The wound gradually contracted by granulations, and finally closed.

I have not met with a single case of recovery where a gun-shot has passed through a fold of intestine. The inflammation set up by the discharge of the contents has been so extensive and intense, that death has rapidly followed. Occasionally there is an attempt at agglutination of the edges of the wounds in the intestines, but much more frequently none. Here is a specimen of the kind of wound made, and you see not the least effort at agglutination has taken place. In the following case, on the contrary, where there were four openings into the intestines, one was in a great measure agglutinated, and the other three open and gaping. Nature is not always uniform in her proceedings, or rather, let us say, in the fine and complicated machinery of the human system imbued with life, injuries, however similar in appearance, may be rendered so different by some of the hidden and multiplied actions of the frame—by the relations and sympathies which bind the parts into a whole—as to require and produce different modes

for their cure in some cases, while in others their modes are so interfered with, as to be rendered entirely nugatory.

Robert Byford, wounded in the abdomen by a musket-ball, and died the same day. Pain of abdomen not constant; sickness and vomiting supervening immediately after the receipt of the injury.

Post-mortem.—The ball was found to have passed through two folds of the large intestines. Three of the wounds presented everted edges and open mouths; the fourth was flat, somewhat agglutinated, and closed. On the surface of the intestines there was an appearance of bile; the gall-bladder was uninjured. The whole peritoneal coat presented marks of active inflammation, having been developed in the few hours between the injury and his death.

Patients do occasionally recover even from very extensive and complicated rupture of the intestines, of which, perhaps, the most singular cases on record are furnished by Larrey: one where a fold of intestine, divided in its whole circumference, was stitched together, and the patient ultimately did well. In others, again, where an artificial anus has been formed, the wounded intestine is retained opposite the wound in the parietes—a state of existence to which I, were it my own case, should think death infinitely preferable. Fortunately a surgeon's duty is so clear and defined, to save life, or even prolong it, under any circumstances, and to any extent possible, that no question can arise in your minds. I must also add, that even in these cases of artificial anus, there is fair ground for hope in past experience, that many may ultimately be entirely restored to a state of health and comfort, by the re-establishment of the continuity of the divided intestine, and final closure of the external wound. In all such injuries, when the wound of the parietes and the wound of the intestine directly correspond, no interference of the surgeon is required to keep the parts *in situ*; and therefore all stitching and dragging of the wounded intestine by sutures to the external orifice, is mischievous, and, without a prospect of doing good, is well calculated to inflict injury.

Union of both wounds is the result

to be desired; and to this all your remedial measures should tend. The treatment of such injuries, when most judicious, is often of nugatory character; it rather consists in preventing the development of inflammatory action—in not allowing or doing any thing that can possibly disturb the quiescence of the parts—interrupt or alter the adhesive process. On these the patient's present safety and ultimate recovery essentially depends. It has often been recommended to use sutures to draw together the open and everted edges of a ruptured intestine: upon the whole, the facts published in support of this practice are not satisfactory. I am led, from the whole of my observations on these wounds, to believe, that if a tendency to adhesive inflammation exist, or can be created—the flattening of the everted edges—their approximation and agglutination—will take place without our interference; and if not, that no artificial approximation of the edges by suture would lead to adhesion. In this, as in all other general rules in surgery, exceptions may occur: if, for instance, a fold of intestine be completely divided, the best practice would be by one or two fine ligatures—the smallest number possible—to approximate the divided tube; or in a large and gaping longitudinal wound, sutures would not only be applicable, but afford probably the only chance of recovery for the patient. Entire abstinence of food for the first twenty-four hours, and only the most bland fluids for several days, are essential points of practice. Purgatives cannot be otherwise but injurious while there is a gaping wound in the intestine. If surrounding adhesions are to close the exit thus artificially made, or the edges of the wound agglutinate, this will take place within the first forty-eight hours—often within twelve. After the first-mentioned period, therefore, the patient may be treated upon the same general principles as those indicated for the treatment of severe injuries of the parietes, implicating directly or otherwise the cavity.

Many cases of ruptured liver, pancreas, spleen, and kidneys, have fallen under my observation; but with reference to the three first, I have not succeeded in tracing in their symptoms any distinctive signs, or rather any invariably so.

Penetrating wound of thorax and abdomen, with lesion of lung and liver.

James Cutting, æt. 24, wounded on the 16th March, 1837, by a musket-ball, which entered at the cartilage of the seventh rib, carrying a piece of an inch and a half in extent through the diaphragm, wounding the inferior lobe of left lung, and finally imbedding itself in the substance of the right lobe of the liver. The ball was, after death, found lying loose upon the intestines, and in contact with the under surface of the liver.

Progress of the case.—Second day expectoration of blood, great thirst, and pain in the chest; tongue dry, and bowels confined.

V.S. ad deliquium; sharp purgative;

and the following mixture, which was one frequently used in the injuries of the thorax and abdomen with good effect:—

R. Magn. Sulph. ℥ss.; Liq. Ammon. Acet. ℥j.; Liq. Antimon. Tart. ℥ij.; Tinct. Digitalis, ℥j.; Aquæ, ℥ivss. M. cap. ℥iss. 4ta quaque horâ.

3d day. — Relieved; tongue clean; thirst less; no hæmoptysis, but considerable pain in the chest on deep inspiration.

5th day. — *Great discharge of ichorous fluid from the wound* during the night, from which the patient expressed relief; bleeding from the nose; cough continues short and troublesome, without expectoration; the skin is hot; pulse full and bounding, about 90.

V.S. ad ℥xx. Contin. Mist.

He was bled twice on the 6th day to relieve symptoms and subdue the inflammatory action. The bowels also acted freely.

On the 7th day he died, his chief distress having always been referred to the chest and diaphragm.

On examination after death, the liver was found of a bright yellow colour in the immediate neighbourhood of the foreign body, but in its general appearance not otherwise altered. The gall-bladder natural; the mesentery of a deep red colour, from the injection of its vessels; the pleura of the left lung extensively inflamed.

The slight alteration of structure in the liver, after having been traversed, torn and bruised by the passage of the

ball, and the lodgment in its substance of another foreign body—the cartilage—is remarkable. But for the ichorous discharge, which would not have been a sign but for the external wound, we see the symptoms in no way denoted injury to the liver; and, indeed, in a somewhat parallel case, where the wound was from above, there was a total absence of all diagnostic sign as regards this organ. If we may judge from the contents of the gall-bladder, and the action of the bowels, its function was not even seriously affected. Many years ago I had a little boy under my care, who had been run over by a wagon. There was great tension of the abdomen, indicating extensive extravasation of blood. He died in about twenty-four hours; and here, as you may observe in this fac-simile wax model I made very carefully immediately after the post-mortem, the liver is ruptured in its whole diameter. The abdomen was filled with blood from the ruptured vessels. No symptom, however, indicated the liver to be the particular viscus injured.

In the following case, where both the pancreas and kidneys were extensively lacerated, there were no distinctive symptoms:—

Josefa Lorins, wounded October 1, 1836, by a musket-ball, which entered between the last true and first false rib, passing for some distance down under the integuments; it entered through the cartilage of one of the false ribs, perforated the rim of the diaphragm near its attachment to the rib, and, continuing its course downwards and backwards, traversed the pancreas and left kidney, finally lodging in the abdomen.

1st day.—Face pale; lips bloodless; tongue cold; pulse small, quick, and hurried; respiration accelerated; pain of umbilical region; vomiting; cold and clammy skin; towards evening in more severe pain, with sinking pulse and cold extremities.

2d.—Has passed a restless night; great pain, not referred to site of wound, but to umbilical region. Respiration short and difficult; anxious countenance; pulse irregular, scarcely perceptible. He died the succeeding day.

Post-mortem.—From three to four pints of coagulated blood found under the mesentery and omentum magnum. Abdomen and chest full of a fluid blood

of the consistence of treacle and water ; intestines inflamed ; lungs natural.

It is necessary to observe, however, that here the injury was of the most destructive character, not only to the organs wounded, but to life ; and as diseases of the kidneys, if not of the pancreas, give rise to distinctive symptoms of disease, it may fairly be inferred that a lesser injury than the one here related, might give signs wanting in the case quoted.

In another case of ruptured spleen there was no special indication to direct the surgeon's attention to the viscus injured ; many other parts were implicated ; the pain was constantly referred to the lower part of abdomen. The patient, on two occasions, was relieved by copious hæmorrhage from the wound. The spleen was torn into fragments. He died on the 5th day. Blood mixed with fecal matter effused, had implicated the whole cavity in disease.

It is useless following out these complicated cases further, where there is such violent injury, extensive, and implicating more than one cavity and several organs. I merely wish to show you that it is vain to look for any precise information in the symptoms ; neither is it of much importance ; no peculiar treatment could be adopted. The same general principles now employed would still be the only ones applicable, whether it was the spleen, pancreas, or liver, that was ruptured or otherwise injured.

We have passed, however, somewhat rapidly from superficial wounds or injuries and their consequences to lesion of the viscera. There is an intervening class of great importance, respecting which there is much to be said, and fortunately much to be done in treatment, with a fair prospect of success.

Even a gun-shot wound penetrating the abdomen, fatal as the majority of such cases prove, may often be brought to a successful termination. A ball may even be lodged, and yet so sacculated and enveloped as to do no farther mischief by its presence. Here is a preparation, I believe, to be unique, demonstrating the fact. It shows a musket-ball completely enveloped by the omentum, and which lay so immediately in contact with the abdominal parietes, that it was distinctly felt, and the propriety of cutting it out discussed under

the impression that it was lodged externally to the peritoneum.

The case has not otherwise any feature of unusual interest. It was a complicated injury, from which the patient died in a short period.

Knife wounds are not generally either so complicated or so fatal as gun-shot ; in civil life they are also of much more frequent occurrence. Unfortunately for England they have been increasing of late, and are not confined to accidents, or inflicted by those whose lives are devoted to murder and theft.

In other countries many such cases have been under my care, and, as they are less fatal, so do they possess more interest than the class we have just considered. It is a heart-sickening labour to watch the progress of a certainly fatal case, where all art is vain.

The worst of these cases I have observed, followed by recovery, occurred in Portugal many years ago. I was suddenly called upon to proceed without delay to a case in which the surgeon had endeavoured in vain by dilatation and other means to reduce the protruding gut. A lady had stabbed herself in a fit of jealousy—an odd feeling it seems, which sometimes produces very different effects ; for it leads some to stab their lovers, and others themselves, to inflict some injury appearing in all cases the *sine quâ non* ; and in this instance the lady was herself the sufferer. On entering the room I found the patient lying on her back, with a large wet cloth over her person. On removing this I was somewhat startled by seeing the whole of the abdomen covered by the protruded intestines, of a dark red colour, against which the coarse cloth had been some half hour in contact ; the patient almost continually vomiting, and at each effort fresh portions of viscera protruding. Our friend, in enlarging the opening, had increased, in a ten fold degree, the mischief ; and finding that the woman's convulsive efforts protruded fresh portions upon him, had left her at last, frightened at the quantity exposed to view and his ill success in diminishing it. It appeared that an hour and a half had elapsed since the injury was inflicted. Several feet of intestine were exposed, many parts of a dark and purplish hue. A Portuguese surgeon had been called in during the absence of the first, who declared she was a dead woman, and sent for the priest to ad-

minister to her soul. The intestines, with some difficulty and careful manipulation, were returned in a few minutes, and chiefly by taking care that, while the forefinger of one hand restored a small portion, the point of the finger was not removed, until by the right hand another portion was pressed down upon it in a similar manner. When all was returned I passed a strong suture through the muscular parietes, closed the wound, and subsequently a rigorous antiphlogistic treatment was adopted. The woman not only perfectly recovered, but that which is more extraordinary, in five months she was safely delivered, having been four months advanced in pregnancy at the time she wounded herself.

This is one instance among many which may serve to prove to you that a case, however desperate it may seem to you, should never be given up, and I need scarcely remark that nothing could be more reprehensible than the retreating tactics of the first operator. An operation once begun should always be concluded *secundum artem*—according to the circumstances of the case, however untoward may be the supervening results, or the accidents that may seem to render the operation unavailing. The surgeon will best consult the welfare of his patient, to say nothing of his own reputation, by seeing that the patient, even if death seem inevitable, die, at all events as regards the operation, surgically, if I may so express it. Sometimes he will find, in spite of all prognosis, the patient recovers. I have had a patient lie apparently dead under my own scalpel, and under that appalling circumstance I concluded the operation, and my doing so was the means of saving his life, when all around me had conceived it impossible, and he perfectly recovered.

I cannot agree with some modern authors in their censure of sutures, and their recommendation in the generality of cases to dispense with them; even if the wound of the integuments and peritoneum be only an inch in extent, yet in nine cases out of ten a less suture will be required. It must be remembered that the patient is generally extremely restless; in the first instance most frequently convulsed with vomiting, the abdominal muscles in violent action or writhing with pain; and under these circumstances how are folds of intestine just returned to be prevented from pro-

truding, if not by a suture? No bandage or pressure can be endured, not even for a few minutes; how then is hernia to be prevented? By strips of sticking plaster? Assuredly not. After again and again performing the same operation to the manifest injury of the patient—of handling and returning the gut, the surgeon will at last be obliged to resort to the only secure means, which he ought to have adopted at first, and passing a strong ligature through the integuments and part of the muscular parietes, close the wound and effectually confine the elastic contents of the abdomen.

A knife thrust into the abdomen may either wound some viscera or induce disease in any organ in the neighbourhood of the wound, particularly if such organ be predisposed: the following is a case of this kind:—

Wm. Keating, aged 25, stout and muscular; subject to pain in the region of the liver; weakness and pain in the small of the back. He, in a drunken brawl, was stabbed with a knife, which penetrated between the cartilages of the tenth and eleventh ribs on the right side, and was supposed to have passed outward and downwards into the abdomen. When I saw him on the third day he complained of severe pain extending six or seven inches round and affecting both the chest and abdomen. Pulse 102, regular, full, and bounding; skin dry; bowels much constipated; he had been bled to sixteen ounces on the succeeding day, which relieved him; before the bleeding his respiration had been extremely difficult; a pint of blood was again abstracted, and a mixture with the vin. antimonialis and tinct. digitalis was ordered, as also pulv. jalapæ ʒj; pulv. ipecac. gr. iij.

In the succeeding days signs both of inflammation of the pleura and of the liver set in, accompanied by a yellow coated tongue and a yellowishness of the whole skin; these symptoms were subdued by active treatment. On the ninth day I found him better, with hardly any cough, and the febrile excitement gone. Pain in the region of the liver only on pressure; tongue dry and furred. He was ordered doses of calomel, opium, and ipecacuanha, which, although in very small doses, in a few days affected his mouth, and seemed to act very beneficially. He remained subject from slight causes to return of

pain in the liver, and at the end of the second month, three weeks after the wound had entirely healed, he still complained of a nearly constant pain, much aggravated by any exertion, with obstinate costiveness. The wound was six inches above the umbilicus, in a direct line drawn in the centre between the umbilicus and anterior superior spinous process of the ilium. Permanent disease of a more active form than any previously existing in the liver seemed to be a permanent consequence of this wound, and yet there were scarcely any grounds for believing that organ to have been injured in the first instance.

Wounds of the Pelvis and Genital Organs.

Lesion of bladder by a musket-shot generally leads to a paralysis of its muscular fibre and retention of urine. I have before me the notes of a very interesting case, in which, notwithstanding the ball had made two apertures in the bladder, it retained four pints of urine. There was vast mischief in the serous membranes from the extravasation of fecal matter, the intestines being also wounded, but scarcely any in the mucous tissue. These injuries are not necessarily or always fatal; the first and chief indication is to relieve the bladder of its contents, and by a catheter to keep it so. Some patients cannot bear the continued presence of a catheter, in which case it must be used very frequently. If, however, its presence can be borne without much irritation, it is better to leave one in the point, merely passing about half an inch beyond the neck, and so secured. In the case alluded to, one of the apertures was in the posterior and *inferior* aspect of the bladder, showing how effectually nature had instantly closed the wound. The mucous membrane of the bladder also was *pale and healthy*, further proving the absence of a proneness to take on inflammatory action.

I remember a French soldier who had a wound that seemed to leave little hope of his recovery. A musket-ball had passed through the os innominatum, traversed the cavity of the pelvis, and was cut out under the integuments of the abdomen. He had scarcely any bad symptoms, and recovered partly.

Here are two beautiful specimens of the most extensive fracture by musket

shot and subsequent caries of the whole of the innominatum, yet with all this little or no mischief supervened in the pelvis; disease rather extended externally among the muscles and into the joint.

Fig. 1 is difficult of description, not only from the extensive injury to the bone over a variety of surfaces, and from a portion of these appearances being the direct result of the contact of the ball in its passage and others from subsequent disease. The three bones of the os innominatum and the head of the femur are all implicated: the ilium most, the ischium second, the pubis least—only in that portion which enters into the formation of the acetabulum. Judging from the appearance of the bone, the ball would seem to have struck the dorsum of the ilium, crushed between its plates, passing obliquely out near the sacro-ischiatic notch, injuring the superior portion of the acetabulum. There is an irregular opening at the dorsum of the ilium and obliquely through it. The opening through the inner plate seems rather to be a consequence of absorption than the passage of a ball. Into the acetabulum there are two openings—one long irregular slit proceeding from the ilium to the superior internal edge of the acetabulum; and this I think was probably caused at first by the direct action of the ball fissuring the bone in that direction, another larger opening running parallel but swelling at the bottom and proceeding to the centre of the acetabulum, and this seems to have been wrought by absorption. The dorsum and venter of ilium both present appearances of absorption, and some feeble efforts at throwing out of callus around the broken edges. The whole of the lower portion of the ilium, from the anterior to the posterior inferior spinous process, is broken down, and more or less absorbed and diseased. The whole of these portions of the ischium and pubis which enter into the acetabulum, are in precisely the same state. The head of the femur is rough, irregular, and denuded of its smooth bony covering, save in one spot, where the smooth covering both of the head and corresponding portion of the acetabulum still adhere, although partially detached. There is in the venter of the ilium an appearance resembling earthy concretion sealing off. The process forming the ischiatic notch is also

- c. Small portion of the smooth bony covering of the head of the femur still remaining, although partially detached. There is a corresponding surface in the acetabulum.

diseased, and partially absorbed. The rest of the bones which enter into this preparation are natural. It is worthy

of remark, that the disease affecting the head of the femur seems to describe the line formed by the attachment of the capsular ligament, as if it had been confined within its limits.

A very short outline of the progress of the case will put you in possession of the chief features resulting from such a severe and extensive injury in the bony walls of the pelvis. The ball entered at the outside of the thigh, within three inches of the anterior superior spinous process, and, passing upwards, lodged, producing a fracture extending into the hip-joint. The symptoms scarcely began to develop until the 18th day; there was then great restlessness; pain in the groin; and on the 20th much irritation from the hip-joint. On the 27th day there was difficulty in voiding the urine; and, gradually on to the 40th day, granulations springing from the wounds assumed unhealthy characters, with great constitutional irritation. At this time great debility, anxiety, and dejection, were perceptible, accompanied by diarrhœa; pulse 90; patient restless and slightly delirious; stomach irritable; and so he gradually sunk; a capacious appetite, and intervals when more collected intervened until the 56th day. There was then a slough over the sacrum; he seemed more idiotic; there was headache; foul tongue; irritable sore; great prostration; and to the last a state of aberration rather than marked delirium. He died on the 72d day.

Post-mortem.—The soft parts formed the walls of a great abscess extending into the glutæus maximus, studded in an extraordinary manner with innumerable little rough bits of bone, some adherent and others loose. The probe passed across the back in a sinus, grating against pieces of bone. Another large abscess was found in the opposite side nearly in the same situation. The trochanter major rough from absorption. *Internally the cavity of the pelvis and abdomen natural.*

This last circumstance is well worthy of remark, the more so that in this second case, fig. 2, where, as you perceive, the injury to the bone is much less—confined, indeed, to an irregularly circular space of about two inches immediately below, and adjoining the junction of the sacrum with the ilium—a contrary event resulted: by comparing the post-mortem examinations of the two we shall find that, although the patient lived until the

process and vain endeavours at restoration, but by a general and severe inflammation of the whole of the abdominal and pelvic cavity. It is unnecessary to enter into the progress of the case further than to observe, that the serous cavity did not seem implicated in the first instance, nor indeed until a late period.

On examination after death the soft parts were found much disorganized in the neighbourhood of the wound, and occupied by collections of purulent matter. The abdomen contained a quantity of seropurulent fluid; the peritoneum of the cavity and intestines inflamed; and both these were effects equally observable in the pelvis.

15 1st day, he was at last carried off, not by the mere exhaustion of a fruitless

These two cases may serve to show you that even from the most complicated injuries of bone and external coverings of the pelvis, the greatest danger is not to be anticipated from the extension of diseased action to the cavity of the pelvis; certainly not in the first stages, but from the irritative fever which results from the laborious and ineffective nature of the reparative process set up.

To remove all loose portions of bone, prevent sinuses and accumulations of matter, bed sores, and sloughing of depending portions, with a careful support of the patient's powers, is nearly all a surgeon can do to avert a fatal termination.

Wounds, however, in which the soft parts beneath the perineum are lacerated, almost invariably lead to a fatal degree of inflammation, not even confined to that serous membrane, but extending to others. As the first case, fig. 1, demonstrates how little mere contiguity of structure has to do with the extension of disease, so will the case I am about relate to you prove another fact not less general in its application; viz. that similarity of structure very frequently induces an extension of disease, even to distant parts, and from one cavity to another.

Case of flesh wound through the perineum, inducing fatal inflammation of pelvic, abdominal, and thoracic cavities, with effusion in the latter.

Alexander Wilson, wounded by a musket-ball, June 6th, 1836, which entered about the centre of the glutei muscles of the left side, traversed in the course of the perineum, slanting off from the ischium, passing by the neck of the bladder (not injuring the peritoneum), and, turning over the pubes lodged on the outer part of the upper third of the right thigh. The parts connected with the course of the ball are thus described, from examination after death: they were found in a gangrenous state, and a very large quantity of dark coagulated blood was found near the symphysis pubis. No peculiar symptoms marked the progress of the case; they were chiefly those of irritative fever, with the supervention of peritoneal inflammation. Accordingly, not only the serous coat of the intestines, in nearly their whole extent, bore marks of inflammation, but also the omentum.

On opening the cavity of the chest a

large collection of bloody serum was found in both sides, with adhesions between the pleura pulmonalis and costalis; the left lung gorged with dark grumous blood.

In the genital organs some very awkward wounds occasionally are met with; and really it not seldom happens that the simplicity of their course is the most remarkable feature. I am afraid these said organs have been somewhat traduced by the labours of the learned to do them all justice. How many thousand works are there on the diseases and injuries of the genital organs! To read but a list of them would scarcely allow any one to think that these very parts will submit in the most kindly way to the most complicated injuries—*sans rancune*, as the French have it—and without reminding their owners that at one time they really had been very grievously maltreated.

I must confine myself to a very few observations on these injuries; nor will time at this period of the course allow me to proceed further at present in this series of lectures.

A short outline of two cases will show you how wonderfully these parts recover themselves; I say themselves, for it is hardly fair, where so little of treatment is often required, to give the surgeons more credit than that of being quiet.

Case of a wounded testicle, cured in eighty days.

Pat. Farley, struck on the scrotum by a musket-ball, which passed through, laying open the tunica vaginalis, and injuring the testicle. Leeches were freely applied, followed by warm and emollient poultices, and by the 11th day the swelling had much abated, and laudable pus began to be discharged. Part of the testicle at this time protruded through the upper wound.

14th day.—Doing remarkably well; swelling of scrotum nearly subsided; wounds granulating healthily.

15th.—A small collection of matter had taken place in the tunica vaginalis of the injured side, and was evacuated by the bistoury.

Towards the end of the second month wounds nearly healed; general health was good; complained of some pain and uneasiness in the wounded testicle when walking. Ordered to wear constantly a suspensory bandage.

56th day.—Wounds healed; slight pain continuing in wounded testicle, which in a short period disappeared.

In another case which fell under my observation, at Oporto, in 1832, a ball entered at the upper and outer side of the thigh, and having passed through the limb wounded both testicles. Both local and general inflammation supervened with severity, and lasted for many days; so much so, that great portions of the scrotum sloughed away, leaving the testicles bare and exposed. They were speedily covered in, however, with granulations, little pain attending the process, and in less than two months the patient was discharged quite well.

A more complicated injury resulted from the same action with an equally favourable result. The ball here, too, entered at the outside of the thigh, and, passing through the limb, wounded not only the scrotum, but traversed the penis. The urethra was laid open at the junction of the penis and scrotum, through which the urine freely passed. Although the penis remained twisted and swelled for a considerable time, the parts took on no bad action: one or two abscesses formed about the scrotum, and one month after the date of injury, on carefully examining the urethra, I found some contraction a short distance below the wound; yet before the end of the 3d month he was perfectly recovered, the wounds healed, and his water passed freely by the natural channel.

This case proved the value of a vigorously enforced antiphlogistic treatment; and secondly, that the disposition to contraction is by no means ungovernable. Indeed, I had occasion more than once to enforce the propriety of regularly passing the bougie, from having observed some carelessness on this point; neither was it passed as early as I had desired.

These, gentlemen, are the views I have formed from the observation of a very large number of complicated injuries; many forms I have described, it is true, you will but rarely—perhaps never—be called upon to treat. In civil life, however, injuries not less fearful and complicated occur from machinery, and even from falls, to which precisely the same principles detailed in reference to those injuries produced by gun-shot, are applicable; whereas there are some features and peculiarities of this latter class

which are not to be learnt by reference merely to the former. From these considerations I was led to devote a certain number of lectures to the nature and treatment of all the more complicated injuries, in which ought necessarily to be included those occasioned by gun-shot. The subject is large as it is important, and upon some other occasion I must render the series complete by some observations (which time will not permit me to lay before you now) on complicated injuries of the extremities in reference to the question of amputation, and the different modes and periods for its performance.

POST-MORTEM EXAMINATION

IN A

CASE OF OVARIAN TUMOR.

With Observations.

By HENRY DAVIES, M.D.

Physician to the British Lying-in Hospital, &c.

[For the *London Medical Gazette*.]

Mrs. PARBERRY, aged 43, and the mother of five children, first came under my care in July, 1828. The details of the case until July 30th, 1833, were published in the first volume of the *Medical Quarterly Review*; and it will be sufficient to observe that she was suffering from a tumor in the lower part of the abdomen, which was not much benefited by medical treatment; but in January 1830 the integuments gave way at the umbilicus, and a thick red discharge issued from the orifice, which gave her great relief. The last report, dated July 30th, 1833, says, "Mrs. Parberry has generally enjoyed tolerable health since the last report. She occasionally suffers from violent pain and tension of the abdomen, but this is eventually relieved by a discharge from the umbilical orifice, which admits a probe easily. She was this day found actively engaged in her avocations as a laundress."

I heard nothing of Mrs. Parberry till I attended her for an attack of enteritis in 1837. I was informed that the tumid abdomen was very troublesome, and that the orifice had closed, from which previously the discharge had occasionally issued, and which afforded her so much relief. In November 1838 she had pneumonia—after her recovery she complained much of her suffering from distension of the abdomen, and it became a question how far occasional relief might be afforded,

by imitating the operation which nature had formerly performed, and making a perforation with a grooved needle at the umbilicus, thus letting out a portion of the contents of the cyst. Upon making an examination with this view, something like a large hernia was found at the umbilicus. The whole tumor had become more consistent and solid, and there was no fluctuation.

Mrs. Parberry continued in average health till 27th April, 1839, when she was suddenly seized with an attack of apoplexy, accompanied by paralysis of the right side. She died on Monday, the 29th, and a post-mortem examination was made on Wednesday, with Mr. Woolridge, of Jermyn Street, her usual medical attendant, and Mr. Lane of Grosvenor Place, who has favoured me with the annexed report.

Post-mortem examination of the body of Mrs. Parberry.

On opening the abdominal cavity an immense fleshy tumor presented itself, invested by the peritoneum, and weighing 17 lbs. The abdominal parietes had given way opposite to the umbilicus, and a portion of the tumor formed a sort of irreducible hernia in this situation. On examining carefully the protruded parts it was found to be composed of a portion of the fleshy tumor, surrounded by an extensive cyst now empty, and closely applied, but not adherent to it. This cyst was not confined to the protruded part of the tumor, but covered a considerable portion of that contained within the abdominal wall. Opposite the umbilicus, the cyst and the hernial sac, and skin, were all adherent, and together not more than a line in thickness.

The left ovary was in close contact with the tumor; the right could not be distinguished. The vagina as well as the uterine cavity were much enlarged and elongated, but the lining membrane apparently free from disease. The wall of the uterus was implicated in the tumor, and on making sections into it the peculiar texture of the uterus was occasionally apparent. The colour of the tumor was of a yellowish or pinkish white—its consistence between that of scirrhus and fungoid disease, its texture fibrous*.

The other viscera of the abdominal

* One of the membranous divisions with which the tumor was intersected was continuous to the point of the umbilicus, forming a pouch, from the extremity of which the fluid had formerly been discharged.—H. D.

cavity (which alone was examined) were healthy.

My impression was that the tumor offered a good specimen of the advanced stage of fleshy tubercles, which had developed themselves between the fibres of the uterus, and that the cyst, which had occasionally emptied itself at the umbilicus during life, was probably connected with the right ovary.

S. LANE.

Aug. 28, 1839.

The gradual alteration in the consistence of this tumor may be remarked as disabling her from having the relief which she formerly had received, by a discharge of a portion of its contents, when it became painful from distension.

This is the third patient with an ovarian tumor whom I have seen die of congestion of the brain. One is that of S. Larman, reported in the *Medical Quarterly Review*, immediately after Parberry. Mrs. Larman had been cured for four years.

The third was that of a lady, aged about 30, who had been operated on by the late Mr. Vance, and was in average health for two or three years subsequently. She died of congestion in the brain. After death the remains of the cyst were found the size of an orange flattened, with calcareous granulations issuing from its internal surface.

How far the pressure made by these large tumors on the great blood-vessels or descending aorta, by obstructing the free circulation towards the lower extremities, may have caused some degree of fulness or dilatation of the vessels of the superior extremities and brain, so as to predispose them to a congestive state, on any adequate exciting cause being applied, is, of course, a matter of speculation. To me it seems sufficiently probable.

18, Saville Row,
Sept. 14, 1839.

MR. ESTLIN ON THE NEW VACCINE VIRUS.

[For the *London Medical Gazette*.]

THE following is an abstract of a paper which was read at the Medical Section of the British Association, during its late meeting in Birmingham.

On the *New Vaccine Virus* of 1838. By J. B. ESTLIN, F.R.S.

The author stated, that as the history

of this new supply had been given to the public in various communications in the *MEDICAL GAZETTE*, he should not enter into details respecting it, but merely describe the changes that had taken place in the effects produced by the lymph, during the twelve months that he had watched its course.

He was induced to bring the subject forward, as in consequence of the dissatisfaction felt with the lymph furnished by the National Vaccine Establishment, he had been applied to for supplies of the new virus by practitioners in every part of England; and its employment in the charitable institutions of Liverpool, Manchester, Birmingham, and Bristol, was a sufficient proof of the extent to which it was used, and gave an importance to its past and present history.

The result of the author's observations was, that at first (during the three or four months following its inoculation from the cow) severe local and constitutional symptoms very frequently arose: so serious, indeed, did they appear to some medical practitioners, that they discontinued the use of the new lymph, and others were reproached by a few of the less intelligent class of their patients with having used spurious virus for inoculation.

The particular appearance of the vesicle at different periods was described, and it seems that a gradual change took place in the intensity of the lymph, though one that was hardly observable from week to week: at the present time the lymph being forty-eight removes from the cow, the author stated that it had lost much of the activity it possessed when removed only fifteen degrees from its original source, while at the same time it retained all those appearances which Jenner describes as characteristic of a perfect specimen of the disease.

The author observed that he was not aware that the course of one particular stock of vaccine virus, kept quite distinct from every other, had been often carefully watched in its progress from the cow during a considerable number of successive vaccinations, and he therefore thought the subject might not be uninteresting to the section. He adverted to the statement made by the National Vaccine Establishment, in their last report, that the lymph supplied by them was of the stock originally introduced by Dr. Jenner, while in the same docu-

ment it was declared that they had occasionally "recruited their stores" from the original source, and in a recent letter in the *Lancet* from Mr. Leese, a vaccinator at one of their stations, it is affirmed that the source of his supply was from cows which had the disease in 1836, from which he had furnished the parent institution with 27,183 changes!

The fact was noticed of the liability of the vaccine vesicle to become deteriorated in particular constitutions. A perfect vesicle, it was stated, will in some children produce a pock deficient in the characteristics of the genuine vaccine vesicle; matter taken from such a pock will reproduce other defective ones, and thus lymph of the best quality in two or three transmissions may become totally degenerated, and unfit for use. With this obvious fact in view, it was needless to theorize about the effects which frequent transmissions of virus have in "humanizing it:" the practical suggestion is of more consequence, the careful selection of the best vesicles only for future inoculations, and a return to the original source when satisfactory lymph cannot be procured.

At the conclusion of his memoir, the author adverted with high encomium to a series of experiments made by Mr. Ceely, of Aylesbury, and brought forward at the late meeting of the Provincial Medical Association at Liverpool, in which cows inoculated with small-pox had vesicles produced where the matter was inserted, with all the characters of the natural vaccine pock; lymph taken from these pocks, produced in children, through twenty-five successive inoculations, a most satisfactory and regular vaccine vesicle. The pathologist, it was stated, would feel great interest in this confirmation of Jenner's hypothesis of the identity of small-pox and cow-pox; and society at large could not too highly appreciate a discovery which furnishes an easy method of producing the vaccine disease at any time, so particularly important in countries where the ordinary supply of cow-pox could not be obtained when most required, on the breaking out of small-pox. The author congratulated the profession at large, that under the want, so long felt in this country, of a National Institution with power and energy either to add to the stock of knowledge on the subject of vaccination itself, or to encourage the pursuit of it in others, a vaccination

section had been established in the Provincial Medical Association, which in so short a time had promulgated results of such importance.

The President (Dr. Yelloly) remarked that having received from Dr. Bright some of Mr. Estlin's lymph during the earlier period of its use, he employed it in his own family, and could testify to its activity.

Dr. Inglis stated he had lately received from a physician in Berlin an account of the progress of vaccine virus, confirming Mr. Estlin's observations upon its diminished intensity when removed to a little distance from its original source.

DR. WILLIAMS'S REPLY TO DR. HOPE.

To the Editor of the Medical Gazette.

SIR,

THE letter of Dr. Hope contained in your last number scarcely requires a reply, as it entirely evades the subject of my former communication; saying, as his sole defence, that I first acceded to, then refused, a *second* arbitration. I think it only necessary to explain that this second arbitration was proposed to me by the Rev. Mr. Niven, during the late contest for St. George's, with a view to *reconciliation* between Dr. Hope and myself. I acceded to this proposal, not being then aware of his attack on me published a little before; but as soon as I had seen this, I felt that it would be hypocrisy on my part to promote any arbitration with reconciliation as its object. To arbitration for justice sake I was and am still most ready to appeal; and it was because I felt sure that the good sense of your readers would do me justice on comparing Dr. Hope's statement with Sir B. Brodie's letter, that I asked and obtained permission to publish that letter. To it I again confidently appeal, in support of my title to the experiments in question; and if any one wishes to examine further the grounds of this title, I will show him conclusive "documentary evidence," not from my own *notes* only, but from the letters and statements of *others*, and from *published* works.

The "final agreement by Dr. Macleod," referred to by Dr. Hope, amounted to

this: after the arbitration, Dr. Macleod made proposals from Dr. Hope that both he and I should publish the experiments, as if they had been conjoint; I at once refused to concede any part of my title to the experiments, now confirmed by Sir B. Brodie's arbitration; but I consented to allow Dr. Hope to publish them, and accordingly lent him the original notes.—I am, sir,

Your obedient servant,

CHAS. J. B. WILLIAMS.

Half Moon Street,
Sept. 18, 1839.

MEDICAL GAZETTE.

Saturday, September 21, 1839.

"Licet omnibus, licet etiam nihil, dignitatem
Artis Medicæ tueri; potestas modo veniendi in
publicum sit, dicendi periculum non recusor."

CICERO.

MEDICAL PROCEEDINGS OF THE BRITISH ASSOCIATION.

EACH succeeding year seems to render the benefit afforded to medicine, by the existence of this society, more problematical and indistinct. There is either some defect in the constitution of the British Association, or some fault in British climate or customs, which is decidedly unfavourable to the success of migratory science. Perhaps it is, that the communication of men of science is too easy to render their meeting at any fixed time or place an event anxiously to be looked for; all of them are almost sure to meet either in the great focus of the metropolis, or in their annual tours of relaxation, and the benefit of a general assembly is thus materially lessened, if not entirely superseded. The Association also have erred, we think, in holding their meetings so frequently; if a bull is permissible, twelve months is too short a time to elapse between the anniversaries, for in all these cases the general effect of an event, and the anxiety with which it is anticipated, are in direct proportion to its rarity; and after it is passed, as time only serves to magnify its plea-

tures, and to obliterate the remembrance of its defects, the more time that elapses before the next succeeds, the better appetite have its patrons for a repetition.

But, whatever be the causes, the British Association this year is *medically* a complete failure. The assembly of members of our profession was scanty and unimportant—the papers that were read for the most part hackneyed and uninteresting—the valuable results arrived at, null—the suggestions and encouragement for future inquiries few and insignificant. We were so little struck with admiration at last year's proceedings, that we felt no inclination for a special report of these of this meeting. The short account that we think it may be interesting to give we extract from the *Athenæum*, the only journal, we believe, which has given a detailed account of all the proceedings, and certainly the only one that can be relied on for the accuracy of its reports.

The first paper read was by Sir David Dickson, containing abstracts of some remarkable cases, of which the only one that possesses the merit of great rarity is a rupture of the duodenum in four places, the result of external violence, an ill effect to which the intestine was predisposed by morbid softening and thickening. The next was by Mr. Middlemore, for the purpose of introducing to the section the instrument (of which he favoured us with an account, which was published in our number for the 7th April), for the removal of the opaque capsular cataract through the sclerótica. He has not yet had occasion to employ it in the human subject. These were the only two papers read on the first day of the meeting of the medical section.

On the next day (Tuesday) Mr. Goodsir read, in the Zoological section, a paper on the Follicular Stage of Dentition in the Ruminants, in which he further developed the opinion which he published in the *Edinburgh Medical and*

Surgical Journal for July. Mr. Middlemore, in the medical section, detailed a case of successful formation of artificial pupil; and Dr. Foville read a paper on the arrangement of the fibres of the brain. Dr. Macartney undertook a subject which in Birmingham may be regarded as somewhat daring—"the means of repressing hæmorrhage from the arteries,"—in which he advocated his now well-known views of the non-inflammatory process of healing (in which we confess there still appears to us to be a distinction without a difference between his ideas and those of most people); and then recommended the use of *metallic ligatures*, which he was led to adopt by observing that such substances frequently remained in the body without exciting any uneasiness. He had experimented with ligatures of leaden wire on the arteries of dogs, and the jugular veins of rabbits, and with success, but had not yet employed them in the human subject. Dr. Gibson, of Philadelphia, said, that Dr. Physic had once introduced similar ligatures; and Mr. Hodgson rendered the communication more valuable by giving, as the result of his own experience, that, of all ligatures, he deemed "hemp, as in common twine, the best." The inconvenience of using metallic ligatures, indeed must be evident; and as for the little irritation they occasion when left in the body, we much doubt whether they produce less than fine silk would. In Mr. Lawrence's experiments, the most annoyance that followed cutting both ends of the ligatures (of strong silk) close to the artery, was the formation of little abscesses, through which, after having separated from the vessel, they were discharged, and in many cases even that did not occur, but they remained quietly in the little sacs that formed around them.

Dr. Blakiston read a paper on the sounds produced in respiration and on

the voice, in which he contended that the sound of vesicular respiration is not produced in or around the vesicles, nor by the rubbing of the pleura, but (if we understand it rightly) at the larynx, from which it is propagated along the trachea and bronchi, becoming constantly softer and weaker by the divergence which it undergoes at each subdivision of these tubes, and by the solid obstacles which their walls, and the heterogeneous tissues around them, place in the way of its transmission. The abstract given of this paper is unfortunately short.

On the Wednesday, Mr. Evans presented a case of spina bifida in a strong, active, and apparently healthy boy, 12 years of age. The tumor was in the lumbar region, and as large as a child's head. Dr. Golding Bird read some "Observations on Poisoning by the Vapours of Burning Charcoal," with which our readers are doubtless already well acquainted, from our reports of the Proceedings of the Westminster Medical and the Guy's Hospital Societies. Dr. Macartney read a paper "on the Rules for finding with exactness the Position of the Principal Arteries and Nerves, from their relations to the external forms of the body," in which he endeavoured to prove the existence of certain laws of proportion, according to which the vessels and nerves occupy lines dividing the external form into halves (as in the sciatic nerve), or into thirds (as the brachial, the radial, and ulnar, &c.) This paper may afford a useful aid for the memory in retaining these fugitive points of relative anatomy, and certainly demonstrates a singular series of partial coincidences, but it is illustrative of no fixed principle of construction.

Dr. Inglis communicated observations on the Cause of the Increase of Smallpox; and Mr. Estlin, on the New Vaccine Virus. The former we need not

notice, as Dr. Baron promises to include the whole subject in a report which he is about to publish on Variola, and which will of course merit a particular consideration. An abstract of the latter will be found in our present number.

On the last day a paper was read on Alkaline Indigestion, by Dr. R. D. Thompson; and another, by Mr. Hodgson, on Redness of the Internal Coat of Arteries, in which he proved that of which there can now be no reasonable doubt, that in a large majority of cases it is in no degree connected with inflammation. Mr. Coathupe detailed the results of his experiments on the production of carbon by animal respiration, possessing some interest, and Dr. Costello reported ten cases of lithotrity, in some of which he "exemplified the progress of surgery and steam travelling;" he operated on three patients residing in three counties, and travelled upwards of 200 miles in 18 hours; "*sat cito*" at least.

Mr. Nasmyth communicated some of his observations on the microscopic structure of the teeth, in which the chief novelty was the statement that the inter-fibrous substance is not, as usually supposed, structureless, but distinctly cellular. He also read a paper on the structure of the epithelium; but (except a very accurate description of the epithelium of the mouth, and especially of that covering the alveolar arches, which is so remarkable for its thickness that it has been classed as cartilage) this paper contains little more than the abstract which we published a few weeks since from Dr. Henle's writings. Dr. Güterbock exhibited some of his gelatine bougies, made by abstracting the earthy matter from ivory, with which also our readers are probably familiar.

These are positively all the medical communications of this year's meeting; they are in number 18, and in novelty

yet less remarkable, for nearly half of them had already appeared in public. In importance, too, they must confess themselves but poor, considering the occasion. The council seem to have entertained no higher opinion of their value, or of their future prospects, for only £125 was voted for the furtherance of medical investigations.

In short, the Medical Section of the Association must, unless some powerful exertion is made for it, soon cease to exist. The next meeting, to be held at Glasgow, offers a good opportunity for emulation between the nations of Britain—an emulation which is at all times deficient, and too often has its place occupied by animosity. It is for this, we believe, that in some measure scientific *reunions* succeed less in Britain than in Germany. Here every *confrère* is a competitor in the trade of his profession, and would be profited by the intellectual extinction of his rival, and a generous emulation can never, under such circumstances, exist. There, on the other hand, though the professors of different universities are rivals, they are not pecuniary opponents: they war for reputation only, not for fame with the appendage of money; and their wars are comparatively friendly, for the only weapons that they call for are those of the intellect, sharpened, not for satire and spleen, but for cautious and accurate disputation. The meetings, therefore, of this kind that are held in Germany seldom pass by without important results for the service of medicine; while, in those of England, we should have some difficulty in finding any thing in which real benefit has resulted.

We published last week a letter announcing a scientific meeting at Pymont. We may add, from a notice which is advertized in Müller's Archiv, that a similar meeting, on the plan of those of Germany, will be held at Pisa,

from the 1st to the 15th of October, in this year, under the presidency of Prince Charles Buonaparte.

DEATH OF DR. SWEATMAN.

OUR readers will learn with regret the death of this estimable practitioner, which took place at his house in Berners' Street, on Wednesday the 18th. Dr. Sweatman was deservedly respected for his abilities, and beloved for his moral worth. His early decease, for he was only thirty-nine years of age, has left a blank in the circle of his friends which will not easily be filled up.

MEDICAL RELIEF UNDER THE NEW POOR LAW.

THE Council of the Provincial Medical and Surgical Association beg leave to call the attention of the Members, and of the profession in general, to the following letter received by the Secretary of the Poor Law Committee from Mr. Serjeant Talfourd.

It will be seen that the propositions for legislative enactment have undergone considerable modification since the Report of the Poor Law Committee in 1837.

The results of last year's Parliamentary inquiry, the proceedings of the Poor Law Commissioners since that inquiry, the transactions of the British Medical Association, and, chiefly, Mr. Talfourd's valuable advice and important suggestions in the frequent communications with which he has favoured the Poor Law Committee, have each and all proved of essential service in maturing the plan contained in this letter.

It is obvious that the success of the learned Serjeant in prosecuting this measure during the next session must depend greatly on the extent to which he is supported by the profession; and therefore it is earnestly hoped that the Members of the Provincial Association will, before Parliament meets again, call the attention of their representatives to the subject, and, if possible, obtain their support to the proposed clauses; and that the profession generally will agree in their respective localities to

petition Parliament in favour of the measure, on the opening of the next Session.

CHARLES HASTINGS, M.D.,
J. P. SHEPPARD, Surgeon.
Secretaries to the Association.

Mr. Sergeant Talfourd's Letter.

My dear Sir,

As circumstances have rendered necessary the postponement of our endeavour to engraft on the system of Poor Law administration, enactments for the protection of the Medical Profession, and of the sufferers committed to their charge, I am anxious to state to you, and through you to the Provincial Medical Association, the objects for which it is proposed to contend, and the course by which we hope to achieve them. If the Bill for continuing the powers of the Commissioners had been introduced at a convenient period of the session, I should have felt it to be my duty, in fulfilment of the trust with which I was honoured by your Committee, to present the amendments then contemplated to the notice of the House of Commons, and to seek their addition to the measure which the Government promoted. But the large consumption of time occasioned by the fierce conflicts and singular vicissitudes of party, deferred the introduction of the Bill to a period when my professional engagements rendered it impossible for me to await the season when the amendments could be regularly presented; and when, if presented, I think they could not have secured, even in far more influential hands than mine, that calm attention which they require and deserve. I would fain hope that no personal disability on my own part has really produced a delay, which might otherwise have been averted, and that if the delay has caused regret to others as it has to me, it will bring with it the compensation not only of a more matured scheme, but of a more lasting destiny than could have awaited our hopes, if they had been embarked with a temporary measure like that which has been at length submitted to Parliament by Ministers. At all events, it will afford opportunity for the consideration, by medical gentlemen, of the propositions to be submitted to Parliament, which I will now state, not as suggestions of my own mind, but as the results which repeated conferences with yourself and other members of the Committee have matured and sanctioned.

The first, and perhaps the most important object we propose to contend for, is the appointment of an additional Commissioner of the Medical Profession, who shall act in co-urrence with the other Commissioners

in the decision of all questions connected with the medical relief of the poor, but who shall not vote, though he may attend, on other discussions. We neither propose to invest him with a share in the general powers of the Commissioners, nor with exclusive power in medical cases, but we are contented to leave to the discretion of the Board the degree of influence which he shall exert within his peculiar province; chiefly desiring that the feelings and the knowledge of the Medical Profession should have an appropriate organ to express them, and satisfied with the result which may thus be produced. The Medical Commissioner, who will be a physician or surgeon of five years' standing, will, however, have the especial duty of considering the medical returns from the various Unions, and of framing an annual report, to be appended to that of the general Commissioners, approved by them, and issued under their sanction. In order to enable him to present in that report a comprehensive view of the medical relations of the poor and their guardians, it will be proposed to compel every medical officer to transmit a report to him on or before Lady day in every year, so as to allow him three months at least to digest the materials, before he will be required to report upon them.

Besides the security of a general supervision of medical relief resulting from the appointment of the additional Commissioner, there are *three specific objects* which it is proposed to submit to Parliament:—

1. The limitation of the extent of Medical Districts.
2. The ascertainment of certain limits of Medical Remuneration.
3. The Qualification of Medical Officers.

With respect to the extent of medical districts,—a matter of great importance to the interests of the poor, though comparatively indifferent to the medical profession,—it is proposed to enact that no district committed to the charge of a single officer shall embrace an area of more than sixteen square miles, or a population of more than five thousand persons; except in towns where the space allotted for a district being smaller, the population may be more numerous. In those cases, it is proposed that a district not more than four square miles may include six thousand inhabitants, and if not more than one square mile in area, a population of ten thousand. As the changes which will be necessary in established Unions to carry this provision into effect, will require time, we propose that a period of three years should be allowed for completing them, and that the districts shall be regulated on the principle

thus ascertained, by orders made under the common seal of the Commissioners.

On the subject of remuneration, while we yet think that certain limits should be set, beyond which it should not vary, we feel that it is desirable to leave considerable discretion in the hands of the Guardians. The extent of the district, the nature of the population, and the habits and even caprice of the neighbourhood, very naturally influence the feelings of Guardians, and expand or moderate the wishes of resident practitioners; and therefore the establishment by law of a *maximum* and *minimum* rate, seems the course best adapted to secure proper attendance for the sick without destroying the control of the local authorities. On this subject it should, however, be observed, that the minute of the Poor Law Commissioners of the 6th of June last, proposing a course whereby, at the commencement of each parochial year, a sum should be fixed as payment for attendance on the paupers then sick, while every case subsequently arising should be for at an ascertained charge, develops an improvement on existing practices so decided, that is possible, if it be efficiently carried out, that it may prevent the necessity of legislative inference on this point. The same minute contains a recommendation, which at all events it will be desirable to adopt—that the sum to be paid by each Union to its medical officer, shall be apportioned among the parishes according to the number of sick which each shall contain.

With respect to the qualification of medical officers, it is proposed to provide that no one shall be eligible to a future appointment unless he shall have practised for three years; that if he shall dispense medicines, he shall be a Licentiate of the Apothecaries' Company, and that whether he be a physician or an apothecary, he shall also be a member of the College of Surgeons. It is also proposed, that if the district shall contain a medical practitioner duly qualified, who has resided for six months within it, desirous of undertaking the trust, he shall be preferred to a stranger.

These provisions, I believe, comprise the final results of the communications with which I have been honoured by the Committee of your Association, as requisite to secure the objects in which the welfare and the honour of the Medical Profession are inseparably connected with the health and comfort of the poor. I once proposed to embody them for circulation in the form of clauses, but I have been induced to abstain from thus prosecuting them, by the uncertainty which exists whether the Government will next

year propose a renewal of the powers of the Commissioners, or will make a new and permanent provision for the working of the system of relief; and, in the latter case, and while the spirit of the propositions to be submitted to the legislature would continue, their shape would undergo an entire change. It may also be hoped from that gratifying alteration in the tone of the Commissioners, which experience alone was required to produce, that some of the proposed alterations may be forestalled by Government, or that such a spirit of accommodation may be evinced, as shall render it expedient to consider how our objects may be attained with the least alloy of opportunities or struggle.

As it continues to be the wish of your Association that I should present their views to the House of Commons, I shall place a notice forthwith in the book of my purpose,* on the introduction of the bill of next year, to call the attention of the House to the subject of medical relief, with a view to introduce clauses amending the law respecting it; and shall, if necessary, follow up that notice by moving an instruction to the committee at the proper season. Most happy, however, shall I be, when the time for renewing the discussion shall arrive, to find the duties of your advocates in the legislature assume the humbler form of suggesting and aiding the awakened wishes of Government to do justice to your profession and to the afflicted poor, rather than compelling a hostile presentment of their own plan, which, if won by contest, would lose all its grace, and much of its value.

I remain, my dear Sir,

Your obedient and faithful servant,

T. N. TALFOURD.

To H. W. RUMSEY, ESQ.,

Secretary to the Poor Law Committee.

GENERAL DISPENSARY, ALDERSGATE STREET.

To the Editor of the Medical Gazette.

SIR,

A LETTER having appeared in the MEDICAL GAZETTE of the 14th inst., signed "John H. Houghton," and annexing the copy of a note from me, as the Collector to the above institution, I feel called upon, in consequence of the unfounded insinuation contained in Mr. Houghton's letter, to state the circumstances under which my note was written.

* The notice was accordingly given to the House by Mr. Serjeant Talfourd in his place on August 17th.

There were seven candidates for the vacant office of Apothecary to the institution, and all of them, with the exception of Mr. Houghton and another, having inquired of me the latest hour up to which I could receive subscriptions from their friends, so as to entitle them to vote at the then ensuing election, I named nine o'clock in the evening of the 28th August; and in order that no misunderstanding might arise, I wrote the note above referred to, to each of the candidates.

I beg to add, that my note was written solely in answer to the inquiry made of me by several of the candidates, and not for any such purpose as is insinuated in Mr. Houghton's letter, and that I wrote without the sanction or even knowledge of any member of the committee, or any officer of the Institution.

I shall feel obliged by your insertion of this in your next publication, and remain

Your obedient servant,

H. PIPER.

85, Aldersgate Street,
17 Sept. 1839.

[It appears, therefore, that the Aldersgate Street Dispensary is not so black as it is painted; the candidates are not asked to buy themselves in, but if they wish to do so, they are just informed of the latest hour when they may empty their purses. We fully exposed this system, at the same place, six years ago. Dispensaries are certainly among the worst managed institutions in London, and that of Aldersgate Street will not raise the reputation of the genus.—*Ed. Gaz.*]

MUSCULAR COATS OF THE EXCRETORY DUCTS.

G. H. MEYER has published an examination of the muscular layer of the excretory ducts of glands. He used for this purpose a galvanic column of 50 pairs of plates. The gall bladder contracted between the wires to a fourth of its previous diameter; the ureters also evidently contracted, and the vasa deferentia and vesiculæ seminales, both with galvanic and mechanical stimuli.

In the gall bladder of the sheep and the ureters of the horse, there are different layers of reddish-yellow fibres, which in microscopic characters agree exactly with the organic muscular fibres. Their course appears more evidently after they have been boiled. After 24 hours' boiling some gelatine is obtained, probably from the cellular tissue and the remains of the mucous membrane.

The ureters consist of three muscular layers—an external and an internal, of longitudinal fibres, and a layer between them of circular fibres; the external layer

arises from the urinary bladder with strong fasciculi, which become finer towards the kidneys. In the middle circular layer, the fibres lie closer together, and have a resemblance to the middle arterial coat, though they are not of an elastic nature. The fasciculi of the inner layer are more connected, and project somewhat internally.

The gall-bladder receives two fasciculi of long intestinal fibres from the intestine, which pass into its outer layer; below these there is a second series of stronger circular fibres, which again covers an obliquely placed layer. Lastly, there is the undermost layer, which consists of longitudinal fibres. It is the same in the shark; two muscular fasciculi, ascending from the intestine to the ductus choledochus, divide on the gall-bladder, and part ascend even up the hepatic duct.—*Müller's Archiv. Jahresbericht*, p. xviii.

POISONOUS WINE.

It was recently reported that the crew of the *Asie*, merchantman of Cherbourg, had suffered under the effects of poison during a voyage to South America. This vessel is now at Marseilles, and it appears that the statement was only partially true. Several of the officers were poisoned, and the captain, after a long illness, has just died in that city. The two mates are still very ill, but hopes are entertained of saving them. This misfortune is attributable to the use of some hermitage, several cases of which had been purchased at Monte Video, in 1838, for the Captain's table, and into which it appears there had been put, according to the culpable practice adopted by some of the dealers in that wine, a quantity of litharge or oxide of lead to correct its acidity. The chemists of Gibraltar, where the *Asie* had stopped, have given this opinion, and in order to ascertain the truth, a chemical analysis of the wine, and a post-mortem examination of the captain's body, have been ordered to take place at Marseilles. *Times* of Sept. 18th, from *Calignani's Messenger*.

VOLUNTARY MUTILATION.

Private in—regt. to which the author belonged, was one morning dividing the meat for the different messes of a company, when he cut off the thumb of the left hand. The mutilation was stated to be the result of accident, but when the amputated portion of the thumb was examined, a deep incision was found in it, obviously shewing that the amputation must have been voluntary, and that it had not been accomplished by the first stroke of the cleaver.—*Marshall on Enlisting, &c. Soldiers.*

ORIGIN OF WHEAT.

At the sitting of the Academy of Sciences on the 12th of August, M. A. de St. Hilaire read a note on the genera *Egilops* and *triticum*. Some botanists have supposed, from the extreme resemblance of the fruit of the *egilops* to the grains of cultivated wheat, that the latter is only an *egilops* modified by cultivation. M. Esprit Fabre, whose excellent observations on the fructification of the marsilea are known to every botanist, having found some plants of the *egilops triticoïdes* in the neighbourhood of Agde, last year, has sown the fruit in his garden, and has obtained a plant in which the characters of the *egilops* have almost entirely disappeared and made room for those of the *triticum*. M. Fabre proposes next year to sow the grains collected this one, and to continue the observations which he has begun.—*Gazette Médicale*, Aug. 17th 1839.

CURE OF APHONIA BY AMMONIACAL VAPOURS.

A YOUNG lady was affected, in consequence of a cold, with complete loss of voice, which had already existed three months, notwithstanding all the remedies which were tried. Dr. Gerner, supposing the cause of the affection to be a relaxed state of the mucous membrane of the trachea, at last cured the patient completely in three days by the inhalation of ammoniacal vapours, disengaged from a mixture of a solution of muriate of ammonia and carbonate of potass.—*Zeitschrift für die ges. Med. and Br. & For. Med. Rev.* July, 1839.

CLOT BEY.

CLOT BEY, first physician to Mehemet Ali, has lately been created, by the Pope, Commander of the Order of Gregory the Great.

BOOKS RECEIVED FOR REVIEW.

Illustrations of the Comparative Anatomy of the Nervous System. By Joseph Swan. Part V.

Illustrations of Cutaneous Disease.—A Series of Delineations of the Affections of the Skin in their more interesting and frequent forms; with a Practical Summary of their Symptoms, Diagnosis, and Treatment, including appropriate Formulae. By Robert Willis, M.D. &c. Parts 4, 5, 7, 8, and 9.

Air-press, observations on the, as an acoustic instrument, by Mr. H. Savage, 619.

Alcock's, Mr. Rutherford, observations on complicated surgical injuries, including gun-shot and other wounds (as delivered in his lectures at Sydenham College School of Medicine) with engravings—see surgical injuries, &c. 138; on military surgery, and the general characters of gun-shot wounds, *ib.*; gun-shot wounds, 139; on the various characters of gun-shot wounds generally, and their indications for treatment, also on some complications by fracture, 196; on complicated injuries

of the extremities, 236; injuries of the extremities complicated by lesion of blood-vessels and nerves, 298; injuries complicated by lesion of blood-vessels, 325; fracture of femur through popliteal space, the artery escaping injury, 326; compound fracture of the bones of the face—loss of power of mastication and impaired articulation, 328; general return of surgical cases treated, and capital operations performed, in the General Military Hospital of St. Elmo, San Sebastian, from 5th May, 1836, to June 10th, 1837, 329; injuries of the head, considered first merely in relation to injuries of scalp and fractures of bone, 364; on injuries of the head, 411; on the elementary forms of injury, and the classification of their effects, 413; skeleton frame for observations and inquiries, 414; on the elementary forms of injury, and the classification of their effects, continued, 444; concussion, compression, lesion, and ramollissement—their effects examined and compared, 486; on the influences regulating, and the indications afforded by, the iris, the pulse, and respiration, 513; general conclusions on their symptoms, effects, and treatment, 550; injuries of the spine, 583; on the nature of various lesions, *ib.*; the symptoms and effects referable to each, *ib.*; injuries of the chest, 848; case of complicated superficial wound, subsequently implicating the lungs and heart, 849; case of wound, barely opening the cavity, followed by disease in the lungs, &c. 850; on blood-streaked sputa, &c. 883; want of vitality, 884; case of permanent tendency to engorgement and inflammation of lung, 885; possibility of great pleuritic mischief, affording but little indication of its existence—cases, 885-6; occasional inefficiency of bleeding—case, 887; pain a devious indication of site or nature of

- injury—cases in illustration, 910; varieties in the suppurative action.—Much purulent expectoration not always a sign of extensive pulmonary disease: neither is its absence to be taken as a proof to the contrary.—Occasional sudden evacuation of contents of an abscess of the lungs by the mouth, 914; hæmorrhage on receipt of wound—how occasionally arrested.—Internal hæmorrhage ushered in by rigors, 916; intermission of chest symptoms, 917.—Foreign bodies not always giving rise to disease when lodged in the lungs.—Treatment of severe injuries of chest, *ib.*; wound of heart, 918.
- Alcock's, Rutherford, lectures on injuries of the abdomen, pelvis, and genital organs, 954.
- Aldis, Dr. C. J. B. case of fits and paralysis, 389.
- Albatt's, Dr. R. H. observations on the functions of the great sympathetic nerve, in answer to Mr. Wells, 724; Mr. Wells' reply, 383; Dr. Albatt's reply, 389.
- America, Medical Students in, 763.
- Aldersgate Dispensary, Mr. Houghton's note respecting the office of Apothecary at the, 913.
- Amussat's, M. case of formation of an artificial anus, by opening the descending colon without penetrating the peritoneal cavity, 574.
- Anæmia, case of, cured by proto-carbonate of iron, by Mr. Jay, 140.
- Anæsthesia, cases of, in the domain of the fifth pair of nerves, by Dr. Romberg, 428.
- Anatomical subjects, on the supply of, in Glasgow, by Mr. J. Douglas, 221.
- Antony Bill, editorial observations on the, 51.
- Anatomy and physiology of the human body, as understood by the Chinese, by Mr. G. T. Lay, 378.
- Anderson, Mr. A. on the intestinal glands, (4 engravings) 144.
- Animal economy, on the action of various saline substances on the, when injected into the circulatory system, by Mr. J. Blake, 510.
- Animals, editorial observations respecting experiments on living, 160, 212.
- Anus, case of formation of an artificial, by opening the descending colon without penetrating the peritoneal cavity, by M. Amussat, 574.
- Aorta, obliteration of the abdominal, the left iliac, and femoral arteries, 31.
- Apparatus, description of an immovable, for the more efficient treatment of compound fractures of the leg, of simple fractures without splints, and of injuries to the ankle joint, by Mr. F. A. Bulley, 301.
- Apothecaries' Company, the, versus Greenhow—see editorial paper, 353.
- Apothecaries' Hall, list of gentlemen who have received certificates, 96, 123, 176, 221, 238, 320, 352, 400, 452, 480, 544, 624, 656, 736, 781, 816, 896, 944, 976.
- Arnott's, Mr. clinical lectures on surgery, delivered at the Middlesex Hospital, 20; foreign bodies under the upper eyelid, *ib.*; deep-seated yellow opacity in the eye, not dependent on medullary fungus, 21; penetrating ulcer of the cornea, hernia corneæ, 22; blepharospasmus, 23; symblepharon, the effect of mortar, 39; iritis, use of turpentine, 90; chronic cornecitis, use of iodide of potassium, 91; deafness, from disease of the lining membrane of the tympanum, use of the acetate of lead, 92; note on varicose capillaries, 861.
- Arsenic, Orfila's discoveries on poisoning by, 939.
- Aspland's, Mr. A. notes on diagnosis of adherent pericardium, 159.
- Asthma, two cases of, by Mr. Melbourne R. Galloway, 765; third case, 796; general remarks, 798.
- Atmosphere, on the comparative influence of heat and gravitation in regulating the density of the, by Mr. Brayley—see Royal Institution, 93.

B.

- Badham's, Dr. David, suggestions on the "Physiological problem" of Dr. Griffin, 337.
- Badham's, Professor Dr. C., letter concerning the recent appointments at Glasgow, 881.
- Barrett, J. Esq. on the regulations of the College of Surgeons, 764.
- Barry's, Dr. Martin, observations in reply to T. Wharton Jones' strictures, 771; Mr. Jones' note in answer, 804; Dr. Barry's reply, 317; Mr. Jones' rejoinder, 887; Dr. Barry's second reply, 938.
- Barry's, Dr. M. reply to Mr. T. W. Jones' rejoinder, 938.
- Belly, fatal cases of obstruction and enormous distension of the, arising from a peculiar formation of the colon, by Dr. Buchanan, 639; concluded, 674.
- Bird, Dr., on the *modus operandi* of the carbonic acid gas in cases of poisoning—see Westminster Medical Society, 25.
- Birt's, Mr. H. case of carcinoma mammae, 17; removal of a thorn which had been five years in the eye, 654.
- Black and White, grades between, constituting the names of Mulatto, Sambo, Quadroon, Mustee, and Mustefino, 735.
- Bladder, inflammation of the—see Dr. Venables' lectures, cystitis, 737; causes, diagnosis, 738; prognosis and treatment, 739;

- cystirrhœa or catarrhus vesicæ, 739; treatment, 741; ulceration in the, 785; irritable, diagnosis, *ib.*; causes, 786; treatment, 787; spasm, paralysis, treatment, 738; retention of urine, causes, treatment, 317; suppression of urine, 818; causes, diagnosis, treatment, 819; incontinence of urine, 820; treatment, pains in the loins, 821; hæmaturia, 865; diagnosis, *ib.*; treatment, 866; mucous and purulent urine, 867; treatment, 868.
- Blake, J. Esq. on the action of various saline substances on the animal economy when injected into the circulatory system, 510.
- Blepharitis—see Velpeau's clinical lectures on ophthalmia, 631, 663.
- Blood globules of the camel and alpacha, 128.
- vessels of tendinous tissues, observations on the, by Mr. J. Paget, 562.
- Books, analyses and notices of:—Dr. Roupell's short treatise on typhus fever, reviewed, 32; Dr. Bull's hints to mothers, &c. reviewed, 83; Mr. Mead's manual for students who are preparing for examination at Apothecaries' Hall, &c. remarks on, *ib.*; Mr. Morgan's lectures on diseases of the eye, reviewed, 157; Dr. Richter on Wiesbaden as a residence for invalids, &c. reviewed, 159; the principles and practice of medicine, founded on the most extensive experience in public hospitals and private practice, and developed in a course of lectures delivered at University College, London, by J. Elliotson, M.D. F.R.S., edited by Dr. Rogers, reviewed, 309; the surgical anatomy of the perinæum, by Thomas Morton, formerly one of the house surgeons of the University College Hospital, 310; essays on the most important diseases of women, by Robert Ferguson, M.D. &c. part 1, puerperal fever, reviewed, 390; researches on the development, structure, and diseases of the teeth, by Alexander Nasmyth, F.L.S. F.G.S. member of the Royal College of Surgeons, London, fellow of the Royal Medical and Chirurgical Society, reviewed, 492; a treatise on the nature of club-foot and analogous distortions, by W. J. Little, M.D. &c. reviewed, 468; medical notes and reflections, by Henry Holland, M.D. F.R.S. &c. reviewed, with extracts, 529; the discovery of the vital principle; or physiology of man, ironical observations on, 566; an inquiry into the morbid effects of deficiency of food, chiefly with reference to their occurrence amongst the destitute poor; also, practical observations on the treatment of such cases, by Richard Baron Howard, M.D. &c. editorial observations on, 566; ten, its effects, medicinal and moral, by G. G. Sigmond, M.D. &c. reviewed, 645; on the enlisting, discharging, and pensioning of soldiers, with the official documents on these branches of military duty, by Henry Marshall, F.R.S.E. deputy inspector-general of army hospitals, reviewed, 646; retrospect of the progress of surgical literature for the year 1838-9, by Messrs. Newnham, W. Wickham, and Salter, analysed, 726; the surgical anatomy of the groin, the femoral and popliteal regions, by Thomas Morton, formerly one of the house surgeons of University College Hospital, commended, 723; a treatise on varicose capillaries, as constituting the structure of carcinoma of the hepatic ducts, and developing the law and treatment of morbid growths, with a new form of the pus globule, by T. G. Hake, M.D. &c. reviewed, 353; cure of club foot, bent knee, wry neck, spinal, and other deformities, by Gustav. Krauss, M.D. &c. observations on, 389; sparks from the wheel of a man wot grinds, reviewed, 890.
- Books reviewed for review, 64, 400, 433, 480, 624, 756, 784, 816, 864, 896, 944.
- Boussangault, M. on the source of nitrogen in plants, 479.
- Brain—see head, Mr. Alcock's lecture on injuries of the, 411.
- Brayley, Mr. on the comparative influence of heat and gravitation in regulating the density of the atmosphere—see Royal Institution, 93.
- British Association, medical proceedings of the, 969.
- Bronze, analysis of, by G. Turner, Esq. 210.
- Brooke, Mr. on fracture of the neck of the femur—see Westminster Medical Society, 60.
- Buchanan's, Andr. M.D. fatal cases of obstruction and enormous distension of the belly, arising from a peculiar conformation of the colon, 639; concluded, 674.
- Budd's, Dr. W. contributions to the pathology of the spinal cord—see Royal Medical and Chirurgical Society, 23.
- Bull's, Dr. hints to mothers, reviewed, 83.
- Bulley's, Mr. F.A. description of an immoveable apparatus for the more efficient treatment of compound fractures of the leg, of simple fractures without splints, and of injuries to the ankle joint, 304.
- Bullock's, Mr. case of idiopathic tetanus, 927.
- Burials, weekly account of, from bills of mortality, 52, 64, 96, 128, 176, 224, 256, 228, 320, 352, 400, 432, 480, 511, 542, 576, 624, 656, 704, 736, 784, 816, 864, 896, 944, 976.
- Burials, disgusting method of conducting, at Naples—see gleanings from the note book of a physician, 637.
- Burne's, Dr. J. clinical lecture on elephantiasis of the abdomen, ecthyma purpura urticans, with lithic acid diathesis; alkaline treatment—see Westminster Hospital, 55.

C.

- Calculus complaints, letter from R. Smith, Esq. on the influence of the sea in, 43.
- Calculus, lectures on the chemical history, pathology, and medical treatment of calculus, and the various disorders of the urinary system, by Dr. Venables, 1; diuresis urcosa, *ib.*; diuresis saccharina, 33, 35; tabular view of the qualities of urine, 66; morbid anatomy, 67; pathology, 69; immediate cause, 99; prognosis, 130; tubes diuretica, 131; of urinary gravel and calculi, 225; amorphous sediments, *ib.*; crystallized sediments, usually named gravel, *ib.*; solid concretions, or urinary calculi, 226; lithic acid calculus, 227; lithate of ammonia calculus, *ib.*; oxalate of lime, or mulberry calculus, 228; carbonate of lime calculus, *ib.*; phosphate of lime, or bone-earth calculus, 229; the ammonio-phosphate of magnesia, or triple calculus, 257; calculus composed of a mixture of the phosphate of lime and ammonio-phosphate of magnesia, or fusible calculus, 258; alternating calculus, or compound calculus in distinct layers, 259; mixed calculi, or calculi with their ingredients intimately intermixed, *ib.*; cystic oxide calculus, 260; of urinary gravel and calculi, 289; xanthic oxide calculus, *ib.*; fibrinous calculus, 290; prostatic calculus, *ib.*; silicious gravel, 291; symptoms of stone, 292; stone in the kidneys, *ib.*; stone in the ureters, *ib.*; stone in the bladder, 353, 355; stone in the kidney, 354; stone in the urethra, 357; stone in the prostate, *ib.*; calculi in women, 401; causes and pathology of calculi, *ib.*; table of the composition of calculi, 402; lithic acid diathesis, 433; causes and pathology, 434; treatment, 436; amorphous sediments, *ib.*; red or lateritious sediments, *ib.*; pink sediments, 437; crystallized sediments, or gravel, 431; continued change in the system at the age of forty, arising from an increased secretion of lithic acid, 513; oxalate of lime or mulberry diathesis, 516; diagnosis, 517; pathology, *ib.*; treatment, 546; cystic oxide diathesis, 543; diagnosis, *ib.*; continued, 577; treatment, 579; phosphatic or earthy diathesis, *ib.*; change from the lithic to the phosphatic diathesis, *ib.*; change from the oxalate of lime to the phosphatic diathesis, 580; change from cystic oxide to the phosphates, *ib.*; of the crystallized phosphatic sediments, *ib.*; of the amorphous phosphatic sediments, 581; phosphatic diathesis, (continued) *ib.*; pathology, *ib.*; treatment, *ib.*; stone in the kidney and ureter, 629; stone in the bladder, 630; constituents, 657; lithic acid, *ib.*; oxalate of lime, *ib.*; cystic oxide, *ib.*; phosphatic calculi, 658; treatment of stone in the bladder, *ib.*; lithic acid, 639; lithate of ammonia, 660; oxalate of lime, *ib.*; cystic oxide, *ib.*; phosphatic calculi, *ib.*; are there any solvents for stone in the bladder? 661; use of phosphoric acid as a solvent for stone in the bladder, 705; nephritis, 706; diagnosis, 707; causes, *ib.*; treatment, *ib.*; suppuration, 768; induration, 709; gangrene, *ib.*; hæmaturia, 865; diagnosis, *ib.*; treatment, 866; mucous and purulent urine, 867; treatment, 868; gonorrhœa virulenta, 897; treatment of gonorrhœa, continued, 945.
- Cape's, Dr. lecture on inoculation, vaccination, and revaccination, delivered at St. Thomas's Hospital, 234.
- Carbonic acid, discussion on the poisonous effects of—see Westminster Medical Society, 60.
- Chapman, Mr. on spinal curvatures—see Guy's Hospital Physical Society, 27; Charing Cross Hospital, Mr. Hancock elected assistant surgeon, 652.
- Chatto's, Mr. J. objections to medical coroners, in reply to Dr. Fife, 81; on ergot of rye in protracted labour, 575; two cases of adherent placenta, followed by phlegmasia dolens, 922.
- Chest, injuries of the—see Mr. R. Alcock's lectures, 843; case of a complicated superficial wound, implicating the lungs and heart, disturbing their functions, 849; case of wound, barely opening the, followed by fatal disease in lungs and cavity, and effusion of lymph and serum in the pelvis, 850.
- Children, on artificial respiration, in cases of suspended animation in still-born, by H. Terry, Esq. 644.
- Chinese, human anatomy and physiology as understood by the, by Mr. G. Tradescant Lay, 378.
- Chowne's, Dr. case of poisoning by gin, Westminster Medical Society, 255; farther particulars of the case, and post-mortem examination, 377.
- Clavicle, a simple method of treating dislocation of the, by Jos. Thomas, Esq. 735.
- Club-Foot, remarks upon an instrument for the cure of, with description of a case of congenital varus, representing one of the highest degrees of that deformity, cured at the age of 23 years, by dividing the tendo achillis, the tendon of the musculus abductor, pollicio pedis, and the plantar fascia, by Dr. G. Krauss—see Royal Medical and Chirurgical Society, 210; the paper in full, with six cases, 342—see Dr. Krauss on Parisian practice, 844.
- Colchicum, on the external use of, in removing pain from rheumatism, gout, &c. by Mr. Laycock, 383; case of over-dose of, by T. A. Henderson, Esq. 763.

- Colon, fatal cases of obstruction, and enormous distension of the belly, arising from a peculiar conformation of the, by Dr. Buchanan, 639; concluded, 674.
- College of Surgeons, complaint respecting the early closing of the library, 944.
- Conjunctiva—see ophthalmia, Velpeau's lectures on, 709, 742.
- Cooper's, Samuel, Esq. clinical lectures at University College Hospital; lecture i. on the non-mercurial treatment of syphilis, 119; primary sore and bubo, 120; sloughing chancre, with profuse hæmorrhage and phimosi, *ib.*; secondary syphilis, ulcers, and rupia, 121; secondary syphilis, tubercular eruption, rupia, and ulcers, *ib.*; lecture ii. on oblique inguinal hernia of fifty years' duration, and very large size, strangulated, 252; penetration of the skull and membrane of the brain by a nail, 254; dislocation of the head of the femur, from disease of hip-joint, 255.
- Cooper, Mr. S. letter to Mr. Liston, relative to a presumed misrepresentation in the *Lancet*, 224; farther correspondence, 256, 255.*
- Copaiba, syrup of, recommended by Mouchon, 364.
- Cornea, destruction of the, in small pox, by Mr. Marson, Secretary Westminster Medical Society, 255—see Velpeau's lectures: inflammatory affections of the, 789; keratitis, *ib.*; vascularity of the sclerotic—non-existence of scleritis, 791; coloration of the, 822; suffusion of the, *ib.*; photophobia and epiphora, 823; disorder of the visual functions—keratitis, acute and superficial, 824; interstitial and deep-seated, 825; termination and prognosis, 827; general treatment, 869; blood-letting, *ib.*; blisters, setons, moxas, &c. 871.
- softening of the—see ophthalmia, Velpeau's clinical lectures, 950.
- Coroner, remarks on the office of, in reply to Mr. Chatto, by Dr. Fife, 12; objections to a medical, by Mr. Chatto, in reply to Dr. Fife, 81; farther remarks by Dr. Fife, 218; on the coronership and inquests, by a constant reader, 219.
- Corpus luteum, on the structure of the, by Dr. R. Lee, Secretary Royal Medical and Chirurgical Society, 504.
- Corrigan's, Dr. clinical lectures, delivered in Jervis-street Hospital, Dublin, 1838-9, 6; paralysis of the first and second branches of the sensitive root of the fifth pair of nerves—case of Goulding, *ib.*; anatomy of the fifth pair of nerves, 7; application of it to diagnosis of the case, *ib.*; paralysis of the portio dura, *ib.*; third branch of fifth, *ib.*; fifth and seventh combined, 8; classification of paralytic affections of the face, *ib.*; treatment and recovery of Goulding, 9; phthisis, 71; division of the disease into two stages, *ib.*; treatment of the case by the iodine diffuser, 72; consideration of the first stage of phthisis, 73; its treatment by blood-letting, mercury, &c. 74; principles of this treatment, *ib.*; on the exhibition of remedies in the form of vapour, with engraving, 49; appointed physician to his excellency Lord Ebrington, 256.
- Cranium, extensive fracture of the, in consequence of a fall during an epileptic paroxysm—see Dublin Pathological Society, 543.
- Curling's, Mr. J. B. case of congenital absence of the pericardium—see Royal Medical and Chirurgical Society, 210; case of a girl who voided from the urethra a number of entozootic worms, not hitherto described—with an account of the animals—see Royal Medical and Chirurgical Society, 505.
- Cuticle, pus, and mucus, discovery of Dr. Henle of Berlin, upon, 313; concluded, 359.
- D.
- Davidson, Dr. W. on the decomposition of iodic acid by uric acid and by albumen, and on the value of it as a test for morphia in cases of poisoning by opiate preparations, 761.
- Davies's, Mr. case of fibro-albuminous tumour of enormous size—see Westminster Medical Society, 26.
- Davies, Dr. Thomas, assistant physician to the London Hospital, &c. death of, 396.
- Davies' Henry, M.D. post-mortem examination in a case of ovarian tumor, with observations, 966.
- Death, case of, from pumping air into the eustachian tube for the relief of deafness, 538; note on ditto, *ib.*; notes from Mr. Lyon and Dr. Turnbull, 576; post-mortem examination, with observations by Mr. S. Savage, 616.
- Deaths, sudden, researches relative to the causes of, by M. Duvergie, 179.
- Dicken, Mr. on diagnosis in adherent pericardium, 247.
- Discovery of the vital principle, or physiology of man, reviewed, 555.
- Diuresis uriosa—see Dr. Venables' lectures, 1; causes, 2; diagnosis, *ib.*; treatment, 4; saccharina, 33; causes, 31; cases, *ib.*; diagnosis, 35; tabular qualities of urine, 66; morbid anatomy, 67; pathology, 69; immediate cause, 99; prognosis, 130; tabes diuretica or urinary emaciation of children, 181.
- Domeier, Dr. on the effects of coloured and pure emetine. 929.

Douglas, Mr. James, on the supply of subjects in Glasgow, 221.
 Drugs, monthly list of, with their prices and duties, 63, 223, 319, 512, 655, 863.
 Dublin Pathological Society, proceedings of the, 542; perforating ulcer of the stomach, *ib.*; ileo-cæcal abscess, with perforation of the intestine and groin, 543; incipient cirrhosis of the liver, with chronic gastritis and congestion of the mucous membrane of the intestines, *ib.*; extensive fracture of the cranium, in consequence of a fall during an epileptic paroxysm, *ib.*; formation of numerous cysts in the kidneys, with extensive depositions of phosphate of lime, 543.
 — regulations for medical graduation in the University of, 812.
 Duffin's E. W. Esq. particulars of the illness and death of the late Mr. Mori, the violinist, 524.
 Dunn, John, Esq. case of dislocation of the left femur on the pubes, 275.
 Duvergie's, M. researches relative to the causes of sudden death, 479.
 Dysentery, on balsam of copaiba in, 31.

E.

Ear, observations on the, in answer to Dr. Deleau's work on the catheterism of the eustachian tube, &c. by Mr. W. Wright, 13, 45; on the use of acetate of lead in a case of deafness from disease of the lining membrane of the tympanum—see Mr. Arnot's lecture, 89; Mr. W. Shand on the stethoscope 496—see eustachian tube, case of death from pumping air into the, 476, 616; on the agency of sound on the, by W. Shand, Esq. 607; observations on the air-press, as an acoustic instrument, by Mr. H. Savage, 619; clinical observations on the use of the air-douche in the diagnosis and treatment of diseases of the, by Mr. T. W. Jones, 670; case, accumulation of wax in external auditory passages—obstruction of eustachian tubes—cavity of the tympanum free, 572; case *ii.* some affection of the auditory passages—opacity of the left membrana tympani—clogged state of the tympanic cavities from accumulated mucus—eustachian tubes pervious, 717; case *iii.* chronic inflammation of the lining membrane of the tympanic cavities, with accumulation of mucus—no obstruction of the eustachian tubes—auditory passages natural, 754; remarks, 757; case *iv.* *ib.*; case *v.* exploration of the ears by the air-douche, shewing obstruction of the eustachian tubes—complete on one side, but incomplete on the other—hearing not improved by removal

of the obstruction, 793; case *vi.* exploratory treatment, by which obstruction of both tubes was ascertained, but the removal effected no change in hearing, 794; case *vii.* showing perviousness of the tube, examined, *ib.*; remarks on cases *i.* *vi.* and *vii.* 795; exploratory treatment, followed by improvement in hearing, with remarks, *ib.*; description of an apparatus for injecting ethereal vapours, 833; case *ii.* continued renewal of deafness—eustachian tubes pervious and the tympanic cavities free from any accumulation of mucus—treatment by ethereal vapours sent into the tympanic cavities, assisted by general remedies, 134; case *ix.* experimental treatment by ethereal vapours sent into the tympanic cavity, 877; case *x.* recent inflammation and tumefaction of the mucous lining of the eustachian tube and cavity of the tympanum of left side, 878.
 Ecthyma, case of, by Dr. Burne, 56.
 Editorial Papers:—Quack medicines, 17; the anatomy bill, 51; treatment of poisoning, 86; use and abuse of purgative medicines, 117; experiments on living animals defended, 160, 212; medical charities, 249, 280; of what may patients judge? 311; medical servants, 348; lying-in hospitals, 349; practitioners at home and abroad, 393; Medical Congress at Dublin, 426, 470, 501; observations on the trial for libel, Field versus Austen, 503; the late medical elections, sixteen places and ninety-four candidates, 535; successful physicians, chiefly in answer to a work entitled *Physic and Physicians*, 567; French and English schemes of hospital government contrasted, 612; successful physicians and surgeons in continuation from p. 571-649; the new Edinburgh pharmacopœia, 694; medical examinations, 728; observations on the new Edinburgh pharmacopœia continued, 774; on the treatment of English practitioners at Wiesbaden, 776; observations on the new Edinburgh pharmacopœia continued, 810; the rivals in discovery, 855; the Apothecaries' Company versus Greenhough, 858; curious medical lawsuit, 890; state of the poor in Glasgow, 892, 931; medical proceedings of the British Association, 969.
 Edinburgh Pharmacopœia, the new, farther observations upon—see editorial paper, 931; Mr. R. Phillips's remarks on, 686; editorial paper on, 694; Mr. Phillips's remarks continued, 758; editorial observations continued, 774, 810.
 Egypt, on the climate and diseases of, extracts from Dr. Morpurgo and Dr. Cumming's notes of a wanderer, 690.
 Elliotson's, Dr. J. principles and practice of medicine founded on the most extensive

- experience in public hospitals and private practice, and developed in a course of lectures delivered at University College, London, edited by Dr. Rogers, reviewed, 309.
- Embryo, case of congenital absence of the liver in a human, 543.
- Embryology, observations on the ova of the mammifera before and after impregnation, in reference to Dr. Martin Barry's researches in, by T. W. Jones, Esq. 592; Dr. M. Barry's observations in answer to Mr. T. W. Jones' stricture, 771; Mr. Jones's answer, 805; Dr. Barry's reply, 847; Mr. Jones's rejoinder, 887; Dr. M. Barry's reply to Mr. Jones's rejoinder, 938.
- Emetine, on the effects of coloured and pure, by Dr. Domeier, 929.
- Empyema, cases of, with observations by Dr. Hughes, 369.
- Endermic medicine, extracts on, from Dr. Ahrensen's *dissertatio de methodo endermatica*, 699.
- Epidemic in London, observations on the symptoms of the prevailing, 16.
- Ergot of rye, on the use of, in protracted labour, by Mr. J. Chatto, 575.
- Estlin's, Mr. J. B. third and fourth letters on the new vaccine virus, 151; fifth letter, containing a report of the committee appointed by the Glasgow Faculty of Medicine to superintend the employment of it, 208; the letter entitled third inserted by mistake, 222; further remarks, 967.
- Eustachian tube, death from pumping air into the, for the relief of deafness, 538; note on ditto, ib.; notes from Mr. Lyon and Dr. Turnbull, 576; post-mortem examination, with observations by Mr. H. Savage, 616;—see Mr. T. W. Jones's clinical observations, 673; continued, 717, 793.
- Eye, deep-seated yellow opacity in the, eye not dependent on medullary fungus, 21; penetrating ulcer of the cornea—hernia corneæ, 22; blephorasmus, 23; case of symblepharon, the effect of mortar—see Mr. Arnott's lecture, 89; use of turpentine in a case of iritis, ib. 91; use of iodide of potassium in chronic cornetitis, ib.; characters of various discharges from the—fistula lacrymalis—cataract—&c.—see notes on professor Jungkens' clinical remarks, 125; cases of ophthalmia, by Mr. J. Walker, 146; Mr. J. Morgan's lectures on the diseases of the, reviewed, 157; Mr. Middlemore on the employment of mercury in iritis, 496; living worms under conjunctiva of the negro, 624—see Velpeau's clinical lectures on ophthalmia, 620; removal of a thorn which had been five years in the, by Mr. Birt, 651; inflammatory diseases in the globe of the—see Velpeau's lecture, 709; conjunctivitis, 710; simple conjunctivitis—conjunctivitis with chemosis, 711; partial—papular and granular conjunctivitis, 712; treatment of inflammation of the conjunctiva, 742; conjunctivitis, simple, ib.; with chemosis, 743; partial, papular, and granular, 744; purulent and gonorrhœal described, 745; their treatment, 747; Egyptian purulent, 748; inflammatory affections of the cornea—keratitis, 789; causes, 790; symptoms, 791; vascularity of the sclerótica, 791; non-existence of scerotitis, 792; inflammatory affections of the cornea: coloration—the water green, brown, yellow, and dark red tints, 822; suffusion of the cornea, ib.; photophobia and epiphora, 823; disorder of the visual functions, keratitis acute and superficial, 824; interstitial keratitis—deep-seated keratitis, 825; termination—prognosis, 827; general and local treatment, 870; blood-letting, ib.; blisters, setons, moxas, &c. 871.
- Eyelids, on foreign bodies under the upper—see Mr. Arnott's lecture, 20.
- peculiar ulceration of the, extending to the bones of the nose and orbit, 31; inflammatory diseases of the—see Velpeau's clinical lectures on ophthalmia, 631; mucous blepharitis—glandular blepharitis, ib.; granular blepharitis—ciliary blepharitis, 652; purulent blepharitis of new-born children; on the treatment of blepharitis, 662; mucous—glandular, 663; granular, 664; purulent, in new-born children—ciliary, 665.
- Eyes, luminous appearance in the, 702.
- F.
- Femur, on fracture of the neck of the, by Mr. Brooke—see Westminster Medical Society, 60; case of dislocation of the head of the, from disease of the hip-joint—see Mr. Cooper's clinical lecture, 255; case of dislocation of the left, on the pubes, by Mr. John Dunn, 275; clinical lecture on osteitis of the upper third of, simulating hip-joint disease, by Mr. J. M. Ferrall, 313; anatomical characters, Walther's case, 506; causes—scrofula, lues, scurvy, local injury, 507; treatment, local depletion, cautions, 508; mercury, hydriodate of potass, 509; Sir B. Brodie's opinions, 510; chronic or mild form of osteitis—diagnosis, 539; other diseases—osteo-sarcoma, cancer and encephaloid disease, 540; analogous changes in lower third of femur—osteitis and periostitis confined to trochanter, treatment, general and local, 541; case of dislocation of the, into the ischiatic

- notch, with fracture—the dislocation reduced, after the lapse of six weeks, by Mr. C. Thornhill, 609; case of ununited fracture of the, treated by excision of the ends of the bones, by Mr. T. B. Peacock, 846.
- Fenner, Mr. J. L. on the advantages of a speculum cushion, with an engraving, 307.
- Ferguson's, Dr. Robert, essays on the most important diseases of women, part 2, puerperal fever, reviewed, 390.
- W. Esq. observations on the susceptibility of infection in yellow fever, 938.
- Ferrall's, Mr. J. M. clinical lecture on osteitis of the upper third of the femur simulating hip-joint disease, delivered in St. Vincent's Hospital, Dublin, 313; continued, 306, 359.
- Fever, clinical observations on, by C. Lendrick, M.D. 9; Dr. Roupell's treatise on typhus, reviewed, 82; Dr. Lendrick's observations on continued—natural tendency to recovery in fever, 104; extent to which the bowels ought to be acted upon, *ib.*; cooling applications to the head, 102; use of James's powder and mercury, *ib.*; abstraction of blood, 103; leeching the temples, *ib.*; opening the temporal artery, cold douche, *ib.*; blisters, *ib.*; rules for treating inflammation combined with typhus, 103; on the use of stimulants, *ib.*; various kinds of wines and malt liquors, 106; conclusion, necessity for cleanliness, means of insuring this—prevention of excoriations—methods of treating this where it occurs—different kinds of poultice—hydrostatic bed—retention of urine—necessity for catheterism and mode of effecting it—management of convalescence, 183; petechial, at St. Petersburg, 816; observations on the susceptibility of the infection of the yellow, by W. Ferguson, Esq. 838.
- Fife's, Dr. G. remarks on the office of coroner, in reply to Mr. Chatto, 12; further remarks, in reply to Mr. Chatto, 219.
- Fits and paralysis of the right side, case of, by Dr. Aldis, 389.
- Fluids, on the effects of warm, received into the stomach in cases of debility from loss of blood, &c. by Mr. N. Rumsey, 215.
- Fœtus, tumor connecting the, with the womb, by Mr. J. Hall, 462.
- France, Mr. two cases of gangrene, with remarks by—see Guy's Hospital Physical Society, 95.
- Frørier's, Dr. R. account of a case of absence of the mammary gland, 861.
- Gallwey's, Mr. Melbourne B. two cases of asthenia, 765; third case, 796; general remarks, 798; presumed to be a case of chlorosis in the male, 799.
- Gangrene, two cases of, with remarks by Mr. France—see Guy's Hospital Physical Society, 95; remarkable case of dry, occurring in a child of three years and seven months old, by Mr. S. Solly, 397.
- Generation, equivocal, Messrs. Schultze and Schwann's experiments upon, 895.
- Gillkrest, Dr. extraordinary case of melanosis of the skin in a woman in whom the greater part of the surface became of a dark colour, 721.
- Gonorrhœa, Dr. Venables on the causes and treatment of, 899, 945.
- Glasgow, University of, establishment of a Professorship of the Institutes of Medicine in the, 603; letter from the professor of medicine concerning the recent appointments at, 881; regulations regarding degrees in medicine and surgery, agreed upon 29th April, 1839, 894.
- , state of the poor of—see editorial paper, 892.
- Gonorrhœa—see venereal disease, Mr. F. C. Skoy's lecture, 437.
- Grant, Professor, on the motor powers of reptiles—see Royal Institution, 58.
- Grantham, Mr. John, on the vaccine lymph, 575.
- Graves, Professor, clinical lectures on medicine, lecture xiii, 38; treatment of syphilis (continued) 38; use and abuse of mercury, with cases, *ib.*; on the causes which impede its beneficial action, *ib.*; corrosive sublimate to be preferred in some cases, 42; observations on authors, &c. *ib.*
- Greenhow, Mr. E. observations on the nature and properties of sea air, 340.
- , the Apothecaries' Company v.—see editorial paper, 858.
- Griffin's, Dr. W. physiological problem, does suffering necessarily imply consciousness? are sentient beings necessarily percipient? No. i, 74; No. ii, 108; No. iii, 133; No. iv, 183; suggestions on Dr. Griffin's physiological problem, by Dr. D. Badham, 337.
- Guerin, M. Jules, on the division of certain muscles in the treatment of lateral curvatures of the spine, 734.
- Gulliver, Geo. Esq. on the composition and elementary structure of the pus globule—see Royal Medical and Chirurgical Society, 282.
- Gun-shot wounds, &c.—see surgical injuries, Mr. R. Alcock's lectures on, 139, 196, 236, 298, 325, 364, 411, 444, 486, 513, 550, 583, 848, 883.
- Guy's Hospital Physical Society, Mr. Chapman on spinal curvatures, 27; Mr. France on gangrene, 95; Mr. Menzies on the treatment of syphilitic iritis, 216.

G.

Germany, scientific meeting in, 936.

Guy's, Professor W. A. observations on the diurnal variations of the pulse, 453.

H.

Hæmorrhage (case of spontaneous) into the peritoneum, following suppression of menstruation, 734.

Hall's, Dr. M. memoir on the condition of the muscular irritability in paralytic limbs—see Royal Medical and Chirurgical Society, 93.

Hall's, Mr. J. case of tumor connecting the fœtus with the womb, 462.

Hamilton's, Dr. Reply to Dr. Murphy's article in the Dublin Journal, entitled, "An examination of Dr. Hamilton's letters in defence of his opinions, especially in reference to the management of the first stage of labour," 21*; Dr. Murphy's letter in reply—see *extra limites*, 273* to 287*.

Harbord, Mr. H. G. on Mr. McLellan's case of strangulated hernia, 15.

Harnier's, Dr. notice of the annual scientific meeting in Germany, 936.

Hawkins, C. Esq. on a peculiar form of tumor of the neck—see Royal Medical and Chirurgical Society, 396.

Head, on injuries of the, in relation to the scalp, and fractures of bone—see Mr. Alcock's lecture, 364; on the elementary forms of injury, and the classification of their effects: various kinds of injury, cause of the complicated nature of their signs, 411; true mode of studying the pathology of the brain, necessity of avoiding the deduction of general laws from inadequate data, 412; classification of injuries of the brain—1. concussion, 2. compression, 3. lesion, 4. ramollissement, necessity of determining their symptoms singly, and then in various combinations, 413; system of investigation, *ib.*; form or skeleton frame for observations and inquiries, 414; analysis of the causes of stertorous breathing—not a sign of any particular form of injury or compression, *ib.*; progress of the case, 415; points for observation in a post-mortem examination, 416; difficulty of establishing general diagnostic laws, *ib.*; observations on the various kinds of morbid impression on the brain, 417; arrangement of cerebral organs and structure, 418; remark on effects of cerebral injuries, two cases, 419; concussion and its subsequent effects: the different nervous centres affected, varying actions of the iris, 444; lesion by concussion not common, indications of stertor, classification of Mr. Abernethy only different stages of same degree, how to estimate the different degrees, 445;

effects of concussion, coma occurring sometime after not a sign of extravasation or effusion frequently, general error on this head, case in proof, 446; the degree or order of consequences cannot be predicated from knowledge of the injury, 447; cases of dispersed or distant effects of injuries, 448; permanent irritability of fibre, most common consequences of concussion, cases, 451; case of concussion, inducing inflammatory effects, without any intervening coma from the blow, 452; inflammation during coma, complicated case, 486; post-mortem examination, 487; disorganization partial or general of brain, 488; case of death by lesion of function, without perceptible alteration of structure, 489; confirmed by effects of concussion in the eye, *ib.*; cases, partial loss of sensation and motion from lesion of cerebral nerves, effects do not cease with comatose symptoms, 490; disguising and paralyzing power of concussion compared with compression, 491; cases of extravasation and ramollissement compared, *ib.*; indications afforded by pupils and pulse, how to be understood in practice, 492; exemplified in cases shewing three degrees of concussion, gradually subsiding lethargy, and absence of all re-action, 493; cases of concussion, 518; mode of distinguishing concussion from compression, 520; an intermitting pulse not indicative of either, 521; cases, 522; causes of compression classed, 521; general conclusions on their symptoms, results, and treatment, 550.

Hake's, Dr. T. G. alleged discovery of varicose capillaries, disputed—see communication from Mr. Kiernan, 725; letters from Dr. Hake, Mr. Kiernan, &c. 721; Dr. Hake's statement, 806; treatise on varicose capillaries, as constituting the structure of carcinoma of the hepatic ducts, and developing the law and treatment of morbid growths; with an account of a new form of the pus globule—reviewed, 853; the controversy between Dr. Hake and Mr. Kiernan analysed—see editorial paper, "rivals in discovery," 855.

Ham-string tendons, case of section of the, for the cure of contracted knee-joint, by Mr. B. Phillips, 601.

Hancock, Mr. elected assistant-surgeon at Charing Cross Hospital, 652.

Heart, cysts in the parietes of the, 31; see pericardium, 216, 247, 459; Dr. Hope's claim to certain experiments on the sounds of the, disputed by Dr. C. J. B. Williams, 837; Sir B. Brodie's letter of arbitration, *ib.*; Dr. Hope's letter, 930; Dr. Williams' reply, 969.

Helie's, M. Th. three cases of abortion, with symptoms of poisoning, produced by the use of rue, 171.

- Henderson's, Mr. T. A. case of overdose of colchicum, 763.
- Henle's, Dr. of Berlin, discoveries on cuticle, pus, and mucus, 313; continued and concluded, 359.
- Hernia, remarks on Mr. McLellan's case of strangulated, by Mr. H. G. Harbord, 15; case of oblique inguinal, of fifty years' duration, and very large size, strangulated, operation, hernial sac divided into separate compartments, with remarks—see Mr. Cooper's clinical lecture, 252.
- Hip joint—see femur, Mr. J. M. Ferrall's lecture on osteitis of the, 313, 366.
- Holland's, Dr. Henry, medical notes and reflections—reviewed, with extracts, 529.
- Hope, Dr. succeeded Dr. Chambers as physician at St. George's Hospital, 652.
- Hope's, Dr. claim to certain experiments on the sounds of the heart disputed by Dr. C. J. B. Williams, 837; Sir B. Brodie's letter of arbitration, *ib.*; Dr. Hope's explanation, 930; Dr. Williams' reply, 969.
- Hospital government, French and English schemes of, contrasted—see editorial paper, 612.
- Hospitals, changes at the Metropolitan, 652.
- Hospitals at Paris, rebuilding of the Hotel Dieu,
- Howard's (Dr. R. B.) inquiry into the morbid effects of deficiency of food, chiefly with reference to their occurrence amongst the destitute poor; also practical observations on the treatment of such cases, 566.
- Hughes's, Dr. cases, with observations: empyema, 369.
- Hull (Dr. R.) on nervous excitement being often mistaken for hydrophobia, 466.
- Humerus, dislocated, reduced—see professor Langenbeck's surgical practice, 302.
- Hunter's, Dr. R. notes of a case of dissection of a hunchback, 919.
- Hydrocele—see professor Langenbeck's surgical practice, 302.
- Hydrophobia, nervous excitement often mistaken for, by Dr. R. Hull, 466.
- I.
- Impostors in Italy—see gleanings from the note book of a young physician, 632.
- Infusoria, on the structure of the, by M. Mayen, 173.
- Intestinal glands, four engravings representing the appearance of the, with remarks, by Mr. A. Anderson, 111.
- Intestine, sloughing and discharge of about twenty-five inches of large, 222.
- Iodic acid, on the decomposition of, by uric acid and by albumen; and on the value of it as a test for morphia, in cases of poisoning by opiate preparations, by William Davidson, M.D. 761.
- Iritis, Mr. Middlemore on the employment of mercury in, 496.
- Ischiatic notch, case of dislocation of the femur into the, the dislocation reduced after the lapse of six weeks, by Mr. C. Thornhill, 609.
- Italy, gleanings from the note book of a young physician in, 635.
- J.
- Jay's, Mr. E. case of anæmia cured by proto-carbonate of iron, 150.
- Jeffery, J. D. Esq. case of puerperal mania, with remarks, 114.
- Jefferys' dropping tube for conveying fluids into the teeth, 467.
- Jenks, G. S. Esq. case of tic douloureux, 279.
- Jones's, T. Wharton, Esq. clinical observations on the use of the air-douche in the diagnosis and treatment of diseases of the ear, No. i, 670; case i, accumulation of wax in external auditory passages—obstruction of eustachian tubes—cavity of the tympanum free, 672; case ii, some affection of the auditory passages—opacity of the left membrana tympani—clogged state of the tympanic cavities from accumulated mucus—eustachian tubes previous, 717; case iii, chronic inflammation of the lining membrane of the tympanic cavities, with accumulation of mucus—no obstruction of the eustachian tubes—auditory passages natural, 754; case iv, 757; case v, exploration of the ears by the air-douche, showing obstruction of the eustachian tubes—complete on one side, incomplete on the other. Hearing not improved by the removal of the obstruction, 793; case vi, exploratory treatment, by which obstructions of both eustachian tubes was ascertained, but the removal of which effected no change in the hearing, 794; case vii, exploration by the air-douche, showing perviousness of the eustachian tube in the ear examined, *ib.*; case viii, exploratory treatment followed by some improvement of hearing, 795; description of an apparatus for injecting ethereal vapours, 833; case ii. continued; renewal of deafness, eustachian tubes pervious, and the tympanic cavities free of any accumulation of mucus—treatment by ethereal vapours sent into the tympanic cavities, assisted by general remedies, 834; case ix, experimental treatment by ethereal vapours sent into the tympanic cavity, 877; case x, recent inflammation and tu-

mefaction of the mucous lining of the eustachian tube and cavity of the tympanum of left side, 878.

—observations on the ova of the mammifera, before and after impregnation, in reference to Dr. Martin Barry's "researches in embryology," 592; Dr. M. Barry's observations in answer to Mr. Jones' strictures, 771; Mr. Jones' further answer, 805; Dr. Barry's reply, 847; Mr. Jones' rejoinder, 887.

Jüngken's, Professor, clinical remarks, notes of, 125; characters of various discharges from the eye—fistula lacrymalis, cataract: cod's liver oil, 125.

K.

Kidneys, formation of numerous cysts in the, with extensive depositions of phosphate of lime—see Dublin Pathological Society, 543; case of scrofulous abscess of both, in a boy ætat. 12 years, by Mr. S. G. Lawrence, 563.

Kiernan, F. Esq. communication from, refuting Dr. T. G. Hake's alleged discovery of varicose capillaries, &c. 725; letters from Dr. Hake, Mr. Kiernan, &c. 781; Dr. Hake's statement, 806; the controversy between Mr. Kiernan and Dr. Hake analyzed—see editorial paper, 855; note from Mr. J. M. Arnott, 864.

Knee-joint, case of wound in the, by Mr. J. B. Samuel, 397; case of section of the ham-string tendons for the cure of contracted, by Mr. B. Phillips, 601; case of amputation below the—see Professor Langenbeck's surgical practice, 802.

Krauss's, Dr. Gustavus, remarks upon an instrument for the cure of club-foot, with description of a case of congenital varus, representing one of the highest degree of that deformity cured at the age of 23 years, by dividing the tendo-achillis, the tendon of the musculus abductor pollicis pedis, and the plantar fascia—see Royal Medical and Chirurgical Society, 210; the paper in full, with six cases, 342; on Parisian hospitals and practice, 843; on the cure of club-foot, bent-knee, wry-neck, spinal and other deformities, &c. &c. reviewed, 889.

L.

Labour, case of induction of premature, with remarks by Dr. James Patterson, 332; cases in which the membranes were punctured, and cases in which ergot induced labour without any other means

being used, compared, by Dr. F. H. Ramsbotham, in reply to Dr. Patterson, 420.

Langenbeck's, Professor, surgical practice at Göttingen, 800; extirpation of part of the tongue, ib.; chronic abscess treated by a seton, ib.; fungus hæmatodes of the os humeri—amputation at the shoulder-joint, 301; extirpation of the uterus, ib.; an odd case, 802; compound fracture of the skull—has the brain sensation? ib.; suspected stricture of the rectum, ib.; hydrocele, ib.; cancerous (?) mamma, ib.; dislocated humerus into axilla, ib.; amputation below the knee, ib.; tumor on the throat, ib.

Lawrance's, Mr. G. S. case of scrofulous abscess of both kidneys, in a boy ætat. 12 years, 563.

Lay, Mr. G. Tradescant, on human anatomy and physiology as understood by the Chinese, 378.

Laycock, Mr. T. on the external use of colchicum, in removing pains from rheumatism, gout, &c. 388.

Lee's, Dr. R. clinical report of twenty-three cases of uterine hæmorrhage, from attachment of the placenta to the neck of the uterus, 554; second report—nine cases of accidental uterine hæmorrhage, 667; continued, fifteen cases, 713; third report—twenty cases of retained placenta, seven fatal, and thirteen more or less dangerous, 749; fourth report—comparative view of the present state of obstetrical surgery in Great Britain, France, and Germany, 827; histories of cases of difficult labour in which the forceps was employed, 872, 908.

Lee, Dr. R. on the structure of the corpus luteum—see Royal Medical and Chirurgical Society, 504.

Leg, description of an immoveable apparatus for the more efficient treatment of compound fractures of the, of simple fractures without splints, and of injuries to the ankle-joint, by Mr. F. A. Bulley, 304.

Lendrick's, Dr. C. clinical observations on fever, 9; continued, see fever, 101 to 106; concluded, 185.

Levers, Mr. J. C. W. statistical account of 120 cases of carcinoma uteri—see Royal Medical and Chirurgical Society, 505.

Liegard's, Dr. of Caen, anti-neuralgic mixture, 399.

Liston's, R. Esq. remarks on the removal of vascular tumors by deligation—see Royal Medical and Chirurgical Society, 283; remarks on the acute form of anasarcaous tumor of the scrotum—see Royal Medical and Chirurgical Society, 506.

Lithophagus, particulars of the disease and post-mortem examination of a, by Dr. Nèret, physician to the hospital St. Charles, at Nancy, 782.

- Lithotripsy, clinical remarks on, with a case by H. Mayo, Esq. 43; performed on a surgeon, 862.
- Little's, Dr. W. J. treatise on the nature of club-foot and analogous distortions, reviewed, 438; elected assistant physician at London Hospital in place of Dr. Davies, deceased, 652.
- Liver, incipient cirrhosis of the, with chronic gastritis and congestion of the mucous membranes of the intestines—see Dublin Pathological Society, 543; congenital absence of the, in a human embryo, 543.
- Liverpool Northern Hospital—dislocation of the lower end of the fibula, 703; dislocation of the head of the radius backward, *ib.*
- London Hospital, Dr. Little elected assistant physician in place of Dr. Davies, deceased, 652.
- Lying-in cases, report of the parochial, during the year 1838, by Dr. J. Reid, medical superintendent of the parochial infirmary of St. Giles', and St. George's, Bloomsbury, 268.
- Lying-in hospitals, editorial observations on the increase of mortality attendant upon, 319.
- Lyon, Mr. J. note from, respecting the cause of the death of Joseph Hall, 576; second note, 738.
- M.
- Magnetism, a prize of 3000 francs offered to any magnetiser who will produce a magnetised person that can read through a piece of cloth, calico, or sheet of paper, 735.
- Mammæ, case of carcinoma of the, by Mr. H. Birt, 47.
- Mammary gland, account of a case of absence of the, by Dr. R. Frasier, 861.
- Mania, case of puerperal, with remarks by J. D. Jeffery, Esq. 114.
- Marchand, Dr. R. on pathological secretions in general, 177.
- Marshall, Henry, Esq. on the enlisting, discharging, and pensioning of soldiers; with the official documents on these branches of military duty, reviewed, 646.
- Marson, J. F. Esq. on variolous ophthalmia, 204.
- Mayen, M. on the structure of the infusoria, 174.
- Mayo's, Herbert, Esq. clinical remarks on lithotripsy—being part of a lecture delivered at the Middlesex Hospital, March 25, 43.
- Meade's, Mr. manual for students, editorial remarks on, 84.
- Medical and Surgical Provincial Association, seventh anniversary meeting of the, at Liverpool, 732; report of the council of the, for 1838-9, 777.
- Medical charities, editorial observations on, in reference to a work entitled, an inquiry into the moral, social, and intellectual condition of the industrious classes of Sheffield, part 1; the abuses and evils of charity, especially of medical charitable institutions, 249, 280.
- Medical congress at Dublin, editorial papers upon the, 426, 470, 501.
- Medical elections, editorial observations on the late, 535; analytical representation of the poll at Charing-cross Hospital, 537.
- Medical examinations, editorial remarks on the recent improvements in, 728.
- Medical graduation, regulation for, at the University of London, 474, 571, 615, 653, 732; at the University of Dublin, 812, at the University of Glasgow, 894.
- Medical law-suits, curious—see editorial paper, 390.
- Medical libel, editorial observations on the trial, Field versus Austen, 503.
- Medical Missionary Society in China, 122; an abstract of the report of the cases that have been admitted at the Ophthalmic Hospital at Canton, under the care of Dr. Parker, 123; diseases of the eye and ear, *ib.*; cutaneous affections, *ib.*; miscellaneous, *ib.*; cartilaginous tumor, 124; sarcomatous tumor, *ib.*
- Medical patriarch, M. Asclar of Lisle a, 864.
- Medical practitioners at home and abroad, editorial observations on, 393; on the expulsion of the English from under the police regulations from Wiesbaden, 776; English practitioners allowed to prescribe for their countrymen, the restriction having been removed by the Duke of Nassau, 894.
- Medical relief of the poor, observations on the, with tabular statements of unions and districts, 383.
- Medical School, Aberdeen, proposed disunion of the two colleges, 352.
- Medical servants, editorial remarks on, elicited from an advertisement in the Times newspaper, 348.
- Medical Society, anniversary dinner at the Parisian, 29.
- Medical students in America, 783.
- Medical relief under the new poor law, Mr. Talfourd's letter on, 973.
- Medicine, on the use and abuse of—see editorial paper, 117;—see endermic, 699.
- Medullary sarcoma and melanosis in all the textures of the human body, cases of, by Mr. Thomson—see Westminster Medical Society, 26.
- Melanosis of the skin, extraordinary case of, by Dr. Gillkrest, 721.

Menzies, Mr. on the treatment of syphilitic iritis—see Guy's Hospital Physical Society, 216.

Meteorological Journal, 64, 96, 127, 224, 256, 288, 320, 352, 400, 432, 480, 544, 579, 624, 704, 736, 784, 816, 896, 944, 976.

Middlemore, Mr. R. on the employment of mercury in iritis, 496.

Midwifery, clinical reports of difficult cases in, at St. George's Hospital, by Dr. R. Lee:—clinical report of twenty-three cases, 554, 665; rupturing the membranes first practised by Mauriceau in 1682, not relied upon by Portal, Raderer, Levret, &c. introduced into England by Smellie, 656; second report, nine cases of accidental uterine hæmorrhage, 667; further cases, 713; third report, twenty cases of retained placenta, seven fatal and thirteen more or less dangerous and difficult, 719; fourth report, a comparative view of the present state of obstetrical surgery in Great Britain, France, and Germany, 827; histories of cases of difficult labour, in which the forceps were employed—cases lxxix to lxxx, 830;—cases lxxxi to xcix, 872.

Mixture, anti-neuralgic, of Dr. Liegard, 599.

Morgan's, Mr. John, lectures on the diseases of the eye, reviewed, 157.

Mori, Mr. the violinist, particulars of the illness and death of, by E. W. Duffin, Esq. 524.

Morphia, on the decomposition of iodic acid by uric acid, and by albumen—and on the value of it as a test in cases of poisoning by opiate preparations, by Dr. W. Davidson, 761.

Morton's, Mr. Thomas, surgical anatomy of the perinæum, reviewed, 310; surgical anatomy of the groin, the femoral and popliteal regions, ditto, 728.

Moure's, M. case of poisoning with opium, 573.

Murphy's, Dr. E. W. letter in reply to Dr. Hamilton—see *extra limites*, 21* and 273* to 287*.

Muscles, discovery of, which rotate the dorsal vertebræ (*rotatores dorsi*) in men and mammalia, by Professor Theil, 574.

N.

Nairne, Dr. elected assistant physician at St. George's Hospital, vacated by Dr. Hope's appointment as physician, 652.

Nasmyth's, Mr. Alexander, researches on the development, structure, and diseases of the teeth—reviewed, 422.

Nerve, disease of the sciatic, 30.

Nerves, paralysis of the first and second branches of the sensitive root of the fifth pair of—see Dr. Corrigan's clinical lectures, 6; case of Goulding, *ib.*; anatomy of the fifth pair of, 7; paralysis of the portia dura and third branch of fifth, 7; fifth and seventh combined, 8; classification of paralytic affections of the face, *ib.*; treatment and recovery of Goulding, 9; cases of anæsthesia in the domain of the fifth pair of, by Dr. Romberg, 428; on the influence of the sympathetic, in poisoning, by Mr. T. J. Wells, 656; observations on the functions of the great sympathetic, in answer to Mr. Wells, by Dr. Alnatt, 724; Mr. T. S. Wells' reply to Dr. Alnatt, 803; Dr. Alnatt's reply, 889.

Nervous ganglia, anatomy of, 61.

Nervous system, memoir on the condition of the muscular irritability in paralytic limbs, by Dr. M. Hall—see Royal Medical and Chirurgical Society, 93.

Newham, Wickham, and Salter's (Messrs.) retrospect of the progress of surgical literature for 1858-9, analysed, 726.

Nitrogen, on the source of the, in plants, by M. Boussingault, 479.

O.

Opium, case of poisoning with, by M. Moure, 573.

Ophthalmia, cases of, by Mr. J. Walker, 146; on variolous, by J. F. Marson, Esq. 204; comparison of German, English, and French writers on,—see Velpeau's lectures 620; the division of ophthalmia into scrofulous and rheumatic attempted to be established by the school of Beer, erroneous, 622; diseases of the eye may be divided into three classes; 1. the eyelids, 2. the inner canthus, 3. the eye itself, 623; inflammatory diseases of the eyelids, *ib.*; mucous blepharitis, glandular blepharitis, 631; granular blepharitis, ciliary blepharitis, 632; purulent blepharitis of new-born children, 633; on the treatment of various forms of blepharitis, 662; mucous blepharitis, glandular blepharitis, 663; granular blepharitis, 664; purulent blepharitis of new-born children, 665; ciliary blepharitis, 666; the pathology of inflammatory diseases of the eye appropriately named ophthalmology—see Velpeau's lecture, 709; conjunctivitis, 710; simple conjunctivitis, conjunctivitis with chemosis, 711; partial, papular and granular conjunctivitis, 712; granular identical with the disease described by German authors as catarrhal ophthalmia, 713; on the treatment of in-

- Inflammation of the conjunctiva, 742; conjunctivitis, simple, *ib.*; with chemosis, 743; partial, papular, and granular, 744; purulent and gonorrhoeal described, 745; their treatment, 747; Egyptian purulent, 748; inflammatory affections of the cornea, keratitis, 789; causes, 790; symptoms, 791; vascularity of the sclerótica, 791; non existence of sclerotitis, 792; inflammatory affections of the cornea, colouration—the water green, brown, yellow, and dark red tints, 822; suffusion of the cornea, *ib.*; photophobia and epiphora, 823; disorder of the visual functions, keratitis, acute and superficial, 824; interstitial keratitis, deep seated keratitis, 825; termination, prognosis, 327; general and local treatment, 869; blood letting, 870; blisters, setons, moxas, &c. 871; sequel and complications of keratitis, 959; abscesses, 951; ulcers, the nephelion, 952; the lymphatic, bothriion, epicauma or burning, and incised, 953.
- Orfila's, M. late discoveries on poisoning by arsenic, 939.
- Os humeri, fungus hæmatodes of the, amputation at the shoulder joint—see professor Langenbeck's surgical practice, 806.
- Ova of the mammifera, observations on the, before and after impregnation, in reference to Dr. Martin Barry's "Researches in Embryology," by Mr. T. Wharton Jones, (with 17 engravings) 592; Dr. M. Barry's observations in reply to Mr. Jones, 771; Mr. Jones' answer to Dr. Barry, 804.
- Ovarian tumor, post-mortem examination in a case of, with observations by Dr. H. Davies, 966.
- P.
- Paget, Mr. James, on the blood-vessels of tendinous tissues, 862.
- Paris, number of dead and wounded soldiers conveyed to the hospitals during the riots on the 12th of May at, 400.
- Parisian medical sketches, 155; Sœurs de la Charité, *ib.*; doctors, 156; No. 2. skin doctors, Alibert, 276; Monsieur Bielt, 278.
- Parisian hospitals and practice, observations on, by Dr. Gustavus Krauss, 843.
- Paterson, Dr. James, case of induction of premature labour, with remarks, 332.
- Pathological Society of Dublin, extracts from the proceedings of the 39.
- Pathological secretions in general, observations on, by Dr. R. Marchand, 477.
- Patient, how to get rid of one, 31.
- Patients, of what may they judge? as regards temperature, food, &c.—see editorial article, 312.
- Pericardium, case of congenital absence of the, by T. B. Curling, Esq.—see Royal Medical and Chirurgical Society, 216; diagnosis of adherent, by Mr. P. Dicken, 247; notes on diagnosis of adherent, by Mr. A. Aspland, 459.
- Peritoneum, case of spontaneous hæmorrhage into the, following suppression of menstruation, 734.
- Petersburgh, St. petechial fever at, 816.
- Pharmacopœia, remarks on the, of the Royal College of Physicians, Edinburgh, by R. Phillips, Esq. 686; continued, 758; editorial paper on ditto, 694; continued, 774, 810.
- Phillips, Benjamin, Esq. on a new and successful method of treating prolapsus uteri—see Royal Medical and Chirurgical Society, 283; continued, 494; case of section of the ham-string tendons for the cure of contracted knee-joint, 601.
- Phillips, Richard, Esq. remarks on the pharmacopœia of the Royal College of Physicians, Edinburgh, 1839, 686; continued, 758.
- Phosphorus, the human body rendered luminous by, 176.
- Phthisis, division of, into two stages—see Dr. Corrigan's lectures, 71; treatment of by the iodine diffuser, 72; consideration of the first stage, 73; its treatment, by blood-letting, mercury, &c. 74; treatment of with hydrocyanic acid, 62.
- Physic and physicians—see editorial papers on successful physicians and surgeons, 567, 649.
- Physicians, Royal College of, Drs. Mayo, Bright, Burrows, and Todd, elected censors; Drs. G. Gregory, F. Cobb, H. Davies, and G. M. Burrows, elected Fellows, 571.
- Physicians and Surgeons of Ireland, resolutions passed at the great meeting of the, May 29, 1839, 474.
- Physician, gleanings from the note book of a young, in Italy, 635.
- Physick, Dr. memoir of, from the American Journal of the Medical Sciences, 933.
- Pituitary gland, the origin of the, traced by M. Rathke, 127.
- Placenta, adherent, two cases of, related by Mr. Chatto, 922.
- Plants, on the source of the nitrogen in, by M. Boussangault, 479.
- Poisoning, editorial observations on treatment of cases of, 86; from gin, case of, by Dr. Chowne—see Westminster Medical Society, 255; see further particulars and post mortem examination, 377; case of with opium, by M. Moure, 573; on the influence of the sympathetic nerves in, by Mr. T. J. Wells, 656.
- Porrigio, pathology of, 176.

Powell's, Mr. answer to Dr. Hake's statement relative to the discovery of varicose capillaries,
 Powell's, Mr. H. second letter in answer to Dr. Hake's statement, 936.
 Practitioners, English, on the expulsion of, from Wiesbaden, 776.
 Professorship of the institutes of medicine, establishment of a, in the University of Glasgow, 698.
 Prize questions proposed by the Société de Pharmacie, 399.
 Provincial Medical and Surgical Association, seventh anniversary meeting of the, at Liverpool, 732; report of the council of the, for 1838-39, 777.
 Prussia, prescribing in, 704.
 Pulse, observations on the diurnal variations of the, by professor W. A. Guy, 453.
 Purpura urticans, lithic acid diathesis, case of, with alkaline treatment, by Dr. Burne, 56.
 Pus globule, on the composition and elementary structure of the, by Mr. G. Gulliver—see Royal Medical and Chirurgical Society, 282.

Q.

Quack medicines—editorial paper respecting, 17.
 Quina, citrate of, recommended by professor Berandi, in intermittents, 783.

R.

Ramsbotham, Dr. F. H. on the induction of premature labour, in reply to Dr. Patterson, 420.
 Rectum, suspected stricture of the—see professor Langenbeck's surgical practice, 802.
 Reid, James, M.D. medical superintendent of the parochial infirmary of St. Giles and St. George, Bloomsbury, report of parochial lying-in cases during the year 1838, 268.
 Remedies, large doses of active, translated from M. Forget's "*Bulletin de Therapeutique*," 126.
 Richter's, Dr. G. H. Wiesbaden considered as a residence for invalids, &c.—reviewed, 159.
 Rigsby, Dr. J. J. on the medical relief of the poor, with tabular statements of ten unions containing 41 districts, 333.
 Rivals in discovery, the—see editorial paper, 855.
 Robbs, W. Esq. a case of compound fracture of the ulnæ, with remarks, 242.

Romberg, Dr. on cases of anæsthesia in the domain of the fifth pair of nerves, 428.
 Roupell's, Dr. short treatise on typhus fever, reviewed, 83.
 Royal Institution, professor Grant on the motor powers of reptiles, 58; Mr. Brayley on the comparative influence of heat and gravitation in regulating the density of the atmosphere, 93.
 Royal Medical and Chirurgical Society—contributions to the pathology of the spinal cord, by W. Budd, M.D. 23; a case of enlargement from encephaloid and melanoid disease of the prostate gland in a child of five years old, by R. A. Stafford, Esq. surgeon to the St. Marylebone infirmary, 93; memoirs on some principles of pathology in the nervous system, by Marshall Hall, M.D. F.R.S.L. & E. &c. ib.; memoir 1, on the condition of the muscular irritability in paralytic limbs, ib.; a case of congenital absence of the pericardium, by T. Blizard Curling, Esq. assistant-surgeon to the London Hospital, &c. 216; remarks upon an instrument for the cure of club foot; with description of a case of congenital varus, representing one of the highest degrees of that deformity, cured at the age of 23 years, by dividing the tendo-achillis, the tendon of the musculus abductor pollicis pedis, and the plantar fascia, by Dr. Gustavus Krauss, ib.—see Krauss, Dr. 342; on the composition and elementary structure of the pus-globule, by Geo. Gulliver, F.R.S. assistant-surgeon to the Royal Regiment of horse guards, 282; on a new and successful method of treating prolapsus uteri, by Benjamin Phillips, F.R.S. surgeon to the St. Marylebone Infirmary, 283; on the removal of vascular tumors by deligation, by R. Liston, Esq. surgeon to the North London Hospital, 283; on a peculiar form of congenital tumor of the neck, by Cæsar Hawkins, Esq. surgeon to St. George's Hospital, 396; on a remarkable case of dry gangrene occurring in a child of three years and seven months old, by Samuel Solly, F.R.S. lecturer on anatomy at St. Thomas's Hospital, 397; on the structure of the corpus luteum, by Robert Lee, M.D. F.R.S. 504; statistical account of 120 cases of carcinoma uteri, by John C. W. Lever, Esq. communicated by Dr. Clendinning, 505; the case of a girl who voided from the urethra a number of entozoic worms not hitherto described; with an account of the animals, by T. B. Curling, Esq. assistant-surgeon to the London Hospital, ib.; on the acute form of anasarcaous tumor of the scrotum, by R. Liston, Esq. surgeon to the North London Hospital, 506.

- Rumsey, Mr. N. on the effects of warm fluids taken into the stomach in cases of debility from loss of blood, &c. 245.
- S.
- Saint George's Hospital, Dr. Hope succeeded Dr. Chambers as physician; Dr. Nairne succeeded Dr. Hope as assistant-physician, 652.
- Samuel's, Mr. J. B. case of wound of the knee-joint, 397.
- Savage's, Mr. H. post-mortem examination, with observations on a recent case of sudden death, 616; remarks on the air press, as an acoustic instrument, 619.
- Scrofulous abscess of both kidneys in a boy ætat. twelve years, case of, by Mr. S. G. Lawrance, 563.
- Scrotum, remarks on the acute form of the anasarous tumour of the, by Mr. R. Liston—see Royal Medical and Chirurgical Society, 506.
- Scientific meeting, annual, letter on the, by Dr. Hamier, 938.
- Sea air, observations on the nature and remedial properties of, by Mr. E. Greenwood, 340.
- Searle's, Mr. oxygenous aerated water, 283.
- Shand, W. Esq. on the stethoscope and ear, 493; on the agency of sound on the ear, 607.
- Sigmond's, Dr. G. G. on tea; its effects medicinal and moral, reviewed, 645.
- Skey's, F. C. Esq. lecture on the venereal disease, delivered at the Aldersgate School of Medicine, March, 1839—see venereal disease, lecture i. 229; lecture ii. 261; lecture iii. 293; lecture iv. 321; lecture v. 358; lecture vi. 406; concluded, lecture vii. 437.
- Skin, extraordinary case of melænosmosis of the, in a woman in whom the greater part of the surface became of a dark colour, by Dr. Gillkrist, 721.
- Skull, case of penetration of the, and membrane of the brain by a nail—suppuration under the bone, trephine, with remarks—see Mr. Cooper's clinical lecture, 254; compound fracture of the—has the brain sensation?—see Professor Langenbeck's surgical practice, 802.
- Small-pox at Sydney, 477; on preventing of pitting in, by M. Legrand and M. Larrey, 862.
- Smith, R. Esq. on the influence of the sea is calculous complaints, 48.
- Solly, Mr. S. a remarkable case of dry gangrene occurring in a child of three years and seven months old—see Royal Medical and Chirurgical Society, 397.
- Sound, on the agency of, on the ear, by Mr. W. Shand, 607.
- Sparks from the wheel of a man what grinds a light on the pharmacopœia, reviewed, 890.
- Speculum cushion, on the advantages of a, by J. L. Fenner, Esq. 307.
- Spinal columns, on the sensibility of the anterior, 702.
- Spine, injuries of the—on the nature of various lesions—the symptoms and effects referable to each—see surgical injuries, &c. Mr. Alcock's lecture, 583; on the division of certain muscles in the treatment of lateral curvatures of the, by Mr. J. Guerin, 734—see Dr. Krauss on Parisian practice, 344.
- Statistics of St. Petersburg, 128.
- Stethoscope, Mr. W. Shand on the, and ear, 489.
- Stomach, enormous dilation of the, 222.
- Stone in the kidney and ureter—see Dr. Venables' lectures, 629; stone in the bladder, ib. 630; constituents, lithic acid—oxalate of lime, cystic oxide, 657; phosphatic calculi, 658; treatment of stone in the bladder, ib.; treatment of lithic acid calculi, 659; lithate of ammonia—oxalate of lime—cystic oxide—phosphatic calculi, 660; are there any solvents of stone in the bladder? 661; Sir B. Brodie's experiments, 662; phosphoric acid, a healthy constituent in urine, its use as a solvent, 665; phosphatic concretions in the prostate gland, 706; nephritis, ib.; diagnosis, causes, and treatment, 707; suppuration, 708; induration and gangrene, 709.
- Surgeons, Royal College of, list of gentlemen who received diplomas in March, 526; April, 320; May, 544; June, 576; the Jacksonian prize awarded to M. E. Lee, 176; notice to candidates for the studentships in human and comparative anatomy, 320; ordinance, 351; regulations, 352; R. Keate, Esq. elected president, and J. P. Vincent, Esq. and G. J. Guthrie, Esq. elected vice-presidents, 624; letter on the regulations of the, by Mr. J. Barrett, 764.
- Surgeons, College of, letter on the early hour of closing the library at the, 944.
- Surgery, comparative view of the present state of obstetrical, in Great Britain, France, and Germany—see Dr. Lee's report, 327.
- Surgical injuries, observations on complicated, including gun-shot and other wounds in military surgery, by Mr. R. Alcock, with engravings, 138; on the various character of gun-shot wounds generally, and their indications for treatment, also on some complications by fracture, 196; on complicated injuries of the extremities, 296; injuries of the extremities complicated by lesion of blood-

vessels and nerves, 298; continued, 325; fracture of femur through popliteal space, the artery escaping injury, 326; compound fracture of the bones of the face, loss of power of mastication and impaired articulation, 328; general return of surgical cases treated, and capital operations performed in the general military hospital of St. Elmo, San Sebastian, from May 5, 1836, to June 10, 1837, 329; injuries of the head considered, first, merely in relation to injuries of the scalp and fractures of bone, 364; on injuries of the head, 411; on the elementary forms of injury, and the classification of their effects, 413; skeleton frame for observations and inquiries, 414; on the elementary forms of injury, and the classification of their effects, 444; inflammation during coma, complicated case, 486; post-mortem, 487; disorganisation, partial or general, of brain, 488; case of death by lesion of function, without perceptible alteration of structure, 489; confirmed, by concussion in the eye, *ib.*; cases, partial loss of sensation and motion from lesion of cerebral nerves—effects do not cease with comatose symptoms, 490; disguising and paralyzing power of concussion, compared with compression, 491; cases of extravasation and ramollissement compared, *ib.*; indications afforded by pupil and pulse—how to be understood in practice, 492; exemplified in cases shewing three degrees of concussion—gradually subsiding lethargy and absence of all reaction, 493; case of concussion, 518; mode of distinguishing concussion in certain cases from compression, 520; intermittent pulse not an indication of compression, neither of concussion—case of lesion of brain giving an intermittent pulse, 521; case of lesion, with cerebral inflammation, fixed and dilated pupil, 522; case of compression producing coma and dilatation of pupil, 523; causes of compression classed, 524; injuries of the head—general conclusions on their symptoms, results, and treatment, 550; résumé of the results and facts brought forward in these lectures—i. as connected with the nature of the various injuries, *ib.*; ii. in reference to their symptoms and effects, 551; iii. as regards their treatment; injuries of the spine—on the nature of various lesions—the symptoms and effects referable to each, 583; the principle controverted, that immediate death follows fracture above fourth cervical vertebra, case proving, 584; occasional absence of all urgent symptoms in fracture of spine, case, 585; fatal injury within spinal canal not occasioning paralysis, case, 586; Sir Astley Cooper's opinion on non-dislocation of

head of ribs controverted—two cases of this injury, 587; necessity of a careful and guarded diagnosis in spinal injuries, 588; analysis of causes producing three degrees or kinds of paralysis in sphincters and bladder—i. loss of voluntary muscular power; ii. loss of power in the involuntary muscular fibre; iii. impaired elasticity of structure surrounding neck of bladder, 589; cases and facts in illustration, 590; importance of these views in diagnosis—principles of treatment, 591; injuries of the chest, 848; case of complicated superficial wound, subsequently implicating the lungs and heart, disturbing their functions, 849; case of wound, barely opening the cavity of the chest, followed by fatal disease in lungs and cavity, and by effusion of lymph and serum in the pelvis, 850; on blood streaked sputa, &c. 853; want of vitality, 884; case of permanent tendency to engorgement and inflammation of lungs, 885; possibility of great pleuritic mischief, affording but little indication of its existence, cases, *ib.* 888; occasional inefficiency of bleeding, case, 887; injuries of the abdomen, pelvis, and genital organs, 951. Surgical literature, retrospect of the progress of, for 1838-9, by Messrs. Newnham, Wickham, and Salter, 726. Sweatman, Dr. notice of the death of, 973. Syphilis, on the use and abuse of mercury in—see Professor Graves' lecture, 58; causes which impede the beneficial action of mercury, *ib.*; corrosive sublimate preferable in some cases, 42; cases of, treated without mercury—see Mr. S. Cooper's clinical lecture, 119. Syphilitic iritis, on the treatment of, by Mr. Menzies—see Guy's Hospital Physical Society, 216.

T.

Talbot's, Mr. letter on medical relief under the new poor law, 973. Farleton, Mr. W. on a remarkable case of self-inflicted wounds, 276. Tendinous tissues, on the blood-vessels of, by Mr. J. Paget, 562. Tetanus, idiopathic, Mr. Bullock's case of, 927. Teeth, Mr. Nasmyth's remarks on the development, structure, and diseases of the, reviewed, 422. ——— dropping tube for conveying fluids into the, by Mr. J. D. Jeffery, 467. Terry, H. Esq. on artificial respiration in cases of suspended animation in still-born children, 611.

- Thornhill's Mr. Charles, case of dislocation of the femur into the ischiatic notch, with fracture—the dislocation reduced after the lapse of six weeks, 609.
- Tibia and fibula, fracture of the, with laceration of the anterior tibial nerve, producing neuralgia, 30.
- Tic-douloureux, case of, by G. S. Jenks, Esq., 279.
- Theil's, Professor, discovery of muscles which rotate the dorsal vertebrae (rotatores dorsi) in men and mammae, 574.
- Thomas, Mr. Jos. on a simple method of treating dislocation of the clavicle, 735.
- Thomson's, Dr. cases of medullary sarcoma and melanosis in all the textures of the human body—see Westminster Medical Society, 26.
- Todd's, Mr. R. B., letter on varicose capillaries, 396.
- Tongue, extirpation of part of the—see Professor Langenbeck's surgical practice, 300.
- Tumor, case of fibro-albuminous, of enormous size, by Mr. Davies—see Westminster Medical Society, 26; encephaloid of the abdomen, with obliteration of the vena cava, 30; remarks on the removal of vascular tumor by deligation, by Mr. R. Liston, 283; on a peculiar case of congenital tumor of the neck, by Mr. C. Hawkins, 396; an odd case of, 302; on the throat, *ib.*
- Turner, G. Esq. analysis of bronze used for imitative gilding, 210.
- U.
- Ulcer, perforating of the—see Dublin Pathological Society, 512.
- Ulnæ, case of compound fracture of the, with remarks, by W. Robbs, Esq. 212.
- University of Dublin, regulations for medical graduation in the, 312.
- University of London, examiners in the, 474; list of gentlemen who have passed their first examination for M. B. with copies of the printed paper to which answers are required, 571; examination for honours, with papers of questions in chemistry and materia medica, 615; papers for second examination, 653, 722.
- University College, Dr. C. J. B. Williams elected Professor of Medicine in, 652.
- University College Hospital, Dr. C. J. B. Williams to succeed Dr. Elliottson, 652.
- Urea, on the formation of, in animal bodies, 478; converted into carbonate of ammonia by the action of fixed alkali, 625.
- Ureosa, diuresis—see Dr. Venables' lectures, 1; causes, 2; diagnosis, *ib.*; treatment, 4.
- Urethra, practical observations on the treatment of stricture of the, by Mr. Ure, 680.
- Urinary system—see Dr. Venables' lectures, and Calculus, 1, 33, 65, 99, 130, 131, 225, 257, 269, 289, 353, 401, 433, 513, 545, 577, 625—see bladder, inflammation of the, Dr. Venables' lecture, cystitis, 737; causes—diagnosis, 756; prognosis and treatment, 739; cystorrhœa or catarrhus vesicæ, *ib.*; treatment, 741; ulceration of the bladder—irritable bladder—diagnosis, 785; causes—diagnosis—treatment, 786; spasm—paralysis—treatment, *ib.*; retention of urine—causes and treatment, 817; suppression of urine, 819; causes—diagnosis and treatment, *ib.*; incontinence of urine, 820; treatment—pains in the loins, 822; hæmaturia, 865; diagnosis, *ib.*; treatment, 866; mucous and purulent urine, 867; treatment, 868.
- Urinary system, &c. treatment of gonorrhœa, 337; continued, 945.
- Uteri, carcinoma, statistical account of, 120; case of, referred to by J. C. W. Liver, Esq. Royal Medical and Chirurgical Society, 505.
- Uteri, prolapsus, a new and successful method of treating, by Mr. B. Phillips, 283; continued, 494.
- Uterine hæmorrhage, from attachment of the placenta to the neck of the uterus, a clinical report of twenty-three cases of, by Dr. R. Lee, 554; the operation of turning first practised by Guillemeau, recommended by Petit, Giffard, Rœdezerer, Levret, Smellie, Douglas, and W. Hunter, 545; second report, nine cases of accidental uterine hæmorrhage, 665; continued, fifteen cases, 713; third report, twenty cases of retained placenta, seven fatal, and thirteen more or less difficult or dangerous, 719.
- Uterus, extirpation of the—see Professor Langenbeck's surgical practice, 301.
- Uterus, on rheumatism of the, in pregnancy and parturition, 942.
- V.
